Preface

This conference represents the 11th triennial in a series, in which the previous ten were held in Ottawa (1978), Gaithersburg (1981), Espoo (1984), Singapore (1987), Brighton (1990) Omiya (1993), Stockholm (1996), Vancouver (1999), Brisbane (2002) and Lyon (2005). The evolution of these works indicate that the notion of durability of materials and components is becoming more significant in society as public awareness of environmental issues combined with the requirement for economic sustainability is steadily rising, in part due to concerns for the future. In the context of buildings and constructed assets, with special reference to materials and components that constitute the structural system, building elements and mechanical services, such notions on sustainability inevitably have implications on life-cycle performance. Awareness that investment and design decisions affect the subsequent life-cycle phases of construction, occupancy and demolition is reflected in the increasing number of contributions touching on this aspect. Such awareness of the life cycle of buildings has brought about further advances in implementing sustainable design principles. For example, within the preliminary design phase, designers may now review the occupancy phase and the manner in which this may be extended through refurbishment to take advantage of the prescribed economic service life of building components. This has, in part, been possible through the development of tools, methods, approaches and techniques for life-cycle analysis and service life planning and prediction that have been the outcome of these many conferences over the past decades.

One of the more important prerequisites for a "satisfactory" building, one for which the maintenance and refurbishment costs are minimized whilst offering an acceptable minimum level of performance, is ensuring a durable external as well as internal fabric, for which the weakest component may perhaps dictate the overall degree of long-term performance of the building assembly or system. Hence appropriate choices in respect to the type of components selected at the component design and selection phase is a foremost consideration to avoid premature failure or the need to subsequently rectify design choices. Consideration should also me made to spatial design of the building; flexibility in design is highly useful as it may very well obviate the need for premature refurbishment of components and as well, help accommodate subsequent changes in building function. Appropriate choices of components for building projects of "sustainable design" may indeed require basic research, or the development of materials and components, prior to acquiring adequate specifications for performance-based and competitive products that also conform to the requirements for sustainable construction. But what of sustainable design practices in the context of design proposals that incorporate "durable" and "recyclable" products? Such approaches, using products perhaps requiring minimal repair and maintenance, are regarded as viable solutions that are in keeping with the basic notions of ecological waste management. However, there are still some conflicts to resolve regarding the implementation of such notions within a consumer-oriented society for which there is a tendency to use products of reduced service life. It is not well understood that products identified as having a long service life combined with a short ecological recovery life are deemed as most "sustainable". In this aspect, the current proceedings lend credence to the idea that the development of viable sustainable products and methods can only be based on knowledge of their durability, that is, their long-term performance, as is evident from the many contributions published in these proceedings.

dbmc
11th International Conference on
Durability of Building Materials and Components

The intent of this conference is to gather information on and provide a forum for review and discussion of the most recent theoretical, experimental and field research work completed in this domain. This process necessarily allows dissemination of the proceedings to, for example, public and private practitioners and institutions, but also, offers an opportunity to review the various research approaches that, in turn, helps determine the scope for further research. Hence the primary research themes on which the conference was based covered a wide range of areas including: Durability of Materials, Durability of Systems and Components in Buildings, Response of Building Elements to Environmental Loads, Service Life Prediction & Planning Methodologies, Risk Analysis Approaches, Durability and Sustainable Buildings, Building Maintenance and Pathology from materials to maintenance; significant contributions to the advancement of research in these fields are offered in the proceeding.

The proceeding will be of interest to researches, designers, civil engineers, and expert practitioners in building construction, as well as manufacturers and suppliers of construction materials, components and systems.

Development of Autoclaxed Lightweight Concrete Outer Walls and its Freeze-Thaw Resistance

Taku Sanda [1]
Toshizi Mimori [2]
Takao Tairaku [3]

T 11

ABSTRACT

In order to build a house in Japan, one must consider that there are four seasons. Durable houses are necessary to create stable living conditions.Outer wall materials are directly affected by climatic change. The motivation for this type of research is that there is a significant demand for highly durable outer wall materials. In addition, because of the compulsory 10-year guarantee on houses, it is demanded that outer wall materials are made much lighter, high strength and more durable than ever before. Furthermore, due to diverse customer needs, the demand for materials that are distinctive has increased.

The focus of this research is to develop the autoclaved lightweight concrete outer walls with long-term stability, high-strength and high-durability and investigate its freeze-thaw resistance.The outer walls have dimensional stability by generation of 1.1nm tobermorite in the materials and high-strength by reduction of water to powder ratio of the materials and autoclaved curing.Since significant scaling or cracking deterioration did not observed on these high Strength Lightweight Concrete during sustained one-side freezing testing, it is estimated that these materials were resistant to freeze-thaw action with little risk of deterioration under normal use conditions. I propose to conduct research on how to decrease changes in measurements due to heat/cold, and dryness/moisture, and age- related deterioration caused by the ultraviolet ray, the heat and snow, and to develop materials which improve the long-term durability.

KEYWORDS

Autoclave curing, High-strength lightweight concrete, Dimensional stability, High durability, Freeze-thaw resistance

1 INTRODUCTION

In constructing housing in Japan, an important item to be considered is existence of four seasons. Surrounded with a variety of climates such as spring, summer, autumn and winter, housing with durability is required for people to spend stable and peaceful lives.

As the part of building, the materials that receive the strong impact of climate are outer walls. Therefore, long-term durability is required as their functions. In addition, the enactment of the "Law for the promotion of ensuring housing quality" and the "Housing quality warranty system" has enforced 10-year guarantee for housing. As a result, building materials have come to be required to have better qualities in terms of lightweight, high strength, high durability (freeze-thaw resistance), and dimensional stability [Saito *et al.* 2005]. Let's think about these four requirements for qualities for general housing materials (outer wall materials). For instance, ALC (autoclave-cured lightweight foam concrete) is excellent in lightweight, thermal insulation, flame resistance, and dimensional stability, and it is widely used as building materials.

However, since ALC has low compressive strength and high water absorption rate, it is very vulnerable against freezing deterioration depending on usage, which requires special precautions in using in cold regions. When ordinary concrete is used as outer walls, it has similar defects as ALC. Since ordinary cement has problems of shrinkage and considerable degree of heavyweight as outer wall panels, it troubles human hands in manual work.Then, this study aimed to develop outer wall materials with improved four performances such as lightweight, high strength, high durability (freeze-thaw resistance) and dimensional stability to satisfy the performances required for long-term durability as housing outer walls.Specifically, as a high-strength building material, calcium silicate hydrate, which was formed by mixing cement and siliceous material in low water-powder ratio, followed by autoclave processing, was considered. The low water-powder ratio was realized using a high-performance AE water-reducing admixture.

2 EXPERIMENTAL SCHEME

2.1 Materials Used

The materials used were ordinary Portland cement (3000 cm^2/g), silica sand (2700-3300 cm^2/g), lightweight aggregate (fly ashhollow material) for decreasing weight, and accelerated curing admixture (calcium aluminate : anhydrite = 1:1) for quickly hardening. Other materials used were aramid fiber for reinforcing panels, high-performance AE water-reducing admixture (polycarboxilate type), and foaming agent.

2.2 Material Compositions

The chemical components of main used materials are shown in Table 1, and the mixing ratio for mortar is shown in Table 2.

Table 1. Chemical components of main used materials (%).

	SiO_2	Al_2O_3	Fe_2O_3	CaO	SO_3	f-CaO
PC	21.64	5.08	2.93	64.53	1.95	0.4
SI	95.9	1.54	0.99	-	-	-
F	56.2	26.8	5.1	3.5	0.3	-
AC	3.5	54.5	1.3	36.5	-	-

PC: Portland cement, SI: Silica sand, F: Fly ash (type IV), AC: Accelerated curing admixture

Table 2. Mixing ratio for mortar (wt%).

W/P	PC	SI	LG	AC	fiber	Admix-ture
0.36 ~ 0.4	49.0	29.5	15.0	6.0	0.25	0.25

W/P: Water-powder ratio, LG: Lightweight aggregate, Admixtures:high-performance AE water-reducing admixture, foaming agent, and hydration modifier

2.3 Manufacturing Methods

2.3.1 Kneading

Admixtures (high-performance AE water-reducing admixture, foaming agent, and hydration modifier) and water for kneading are fed into an omni-mixer and agitated for 1min in order to generate foams. Next, powders such as cement and aggregates are fed, and the mixture is agitated for 1 min. Finally, the accelerated curing admixture, in the form of slurry made by mixing with part of water for kneading, is added, followed by agitating for 30sec for preparing mortar.

2.3.2 Curing

Manufactured mortar is cast into a mold form, and after maintaining at 40°C (ambient temperature) for 60 min, the product is demolded. By demolding at early stages due to the use of the accelerated curing admixture, manufacturing time can be shortened. Then, wet-air curing for pre-curing is applied at 40°C for 10 h, and autoclave curing (high-temperature high-pressure curing) is applied at 180°C and 10 atm for 8 h. Then, in preparation for coating as outer walls, forced drying is applied to reduce water content.

2.4 Evaluation on Compositions, Physical Properties and Durability

Using manufactured specimens, measurements of basic properties such as scanning electron microscope, absolute dry density, compressive strength, bending strength, as well as testing for freeze-thaw resistance are conducted. Meanwhile, when manual work at a site such as crusting board is supposed, it is necessary to set density at 1.0 or below. On the other hand, in order to prevent chipping and cracking during transfer after manufacturing, reasonable strength is necessary. Then, considering application at a site, the absolute dry density of specimens is set at 0.9 g/cm^3 and 0.95 g/cm^3 for evaluating durability performance.

2.4.1 Scanning Electron Microscope (SEM)

The crystalline morphology of tobermorite is observed with SEM

2.4.2 Compressive Strength Test and Bending Strength Test

Using an angular specimen of 4×4×16 cm, these tests are conducted following JIS R5201.

2.4.3 RILEM CIF Method Test [RILEM 2000]

In CIF test, predetermined curing is applied to a beam-shaped specimen of 10×10×20 cm, and the sides of the specimen was sealed with aluminum tapes with butyl rubber. Then, the lower surface is immersed in a temperature-controlled chamber at 20°C and 60% RH for 7 days to absorb water. Afterwards, using a CIF freeze-thaw test apparatus shown in Fig. 7, one-side freeze-thaw test, under lower- surface water-absorbing condition, is repeated at a rate of two cycles a day up to 100 cycles. The conditions are as follows; highest temperature at 20°C (keeping for 1 h), lowest temperature at –20°C (keeping 3 h), and temperature gradient at ±10 K/h. Measurement items are weight change, relative dynamic elastic coefficient, and peel-off quantity. In the peel-off quantity test, 3-minute ultrasonic cleaning is applied to the whole test apparatus after each measurement cycle, and the solution was filtrated. The peeled pieces are dried at 105°C for 24 h, and the weight is measured. The relative dynamic elastic coefficient is measured with a flexural oscillation method.

2.4.4 Measurement of Foam Structure [Hama *et al.* 2005]
Measurement of foam structure is conducted following ASTM C457 (linear traverse method), and air volume, average foam diameter, and foam interval coefficient are calculated.

2.4.5 In-water Freezing and in-Water Thawing Test
This test is conducted following JIS A1148 Method A (freeze and thaw test of concrete). A beam-shaped specimen of 10×10×40 cm is used. Before the test, the whole body of specimen is immersed in water for 48 h for absorbing water. Using a freeze and thaw test apparatus, the specimen is subjected to midair freezing at –18°C for 2.5 h and in-water thawing at +5°C for 1.5 h, and this cycle is repeated up to 300 cycles. Measurement items are weight change and relative dynamic elastic coefficient, and the latter is measured with a flexural oscillation method.

3 RESULTS AND DISCUSSIONS

3.1 Basic Physical Properties

Within four performances lightweight, high strength, high durability freeze-thaw resistance and dimension stability that satisfy required performances for long-term durability, dimension stability has already been described. Here, in order to reduce weight, by changing the addition quantity of a foaming agent, specimens with different slurry densities of mortar were prepared, and their physical properties were measured. For comparison, ALC of pre-form type (P-ALC) was measured.

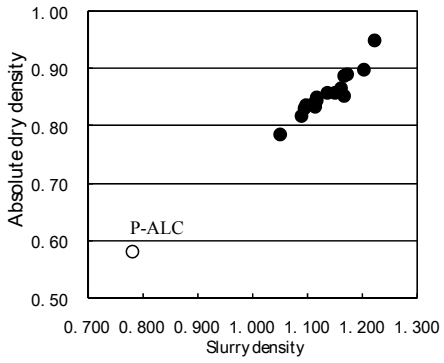

Fig. 1. Relations between mortal density and absolute dry density.

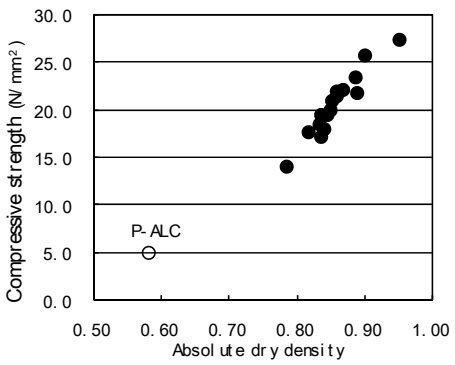

Fig. 2. Relations between absolute dry density and compressive strength.

In the relations between the mortar density after kneading and the density of a sample absolutely dried (drying at 105°C for 48 h) after autoclave curing, absolute dry density linearly increased as mortal density increased. From these relations, it is possible to estimate absolute dry density after autoclave curing from the figure when mortar is kneaded. In the relations between absolute dry density and compressive strength, compressive strength linearly increased as absolute density increased. When the absolute density of high-strength lightweight concrete was 0.9 and 0.95 g/cm^3, corresponding compressive strength was 25.7 and 27.4 N/mm^2. Due to the autoclave treatment, it was possible to obtain high-strength lightweight concrete with about threefold of relative strength compared with P-ALC.

3.2 CIF Test

Changes in relative dynamic elastic coefficient are shown in **Fig. 3**. Decrease in the relative dynamic elastic coefficient of the high-strength lightweight concretes was hardly seen, and the figure was 96% and 97%, respectively, at the end of 100 cycles. In comparison, the relative dynamic elastic coefficient of P-ALC tended to decrease immediately after the start of the freeze-thaw test, and it showed 78%

after the end of 100 cycles.Changes in peel-off quantity are shown in **Fig. 4**. The high-strength lightweight concretes showed minor scaling in the rang of 5 g, while P-ALC showed rapid scaling around after 20 cycles, recording 40 g of peel-off (ca. 10 mm as peel-off depth) when the test ended.

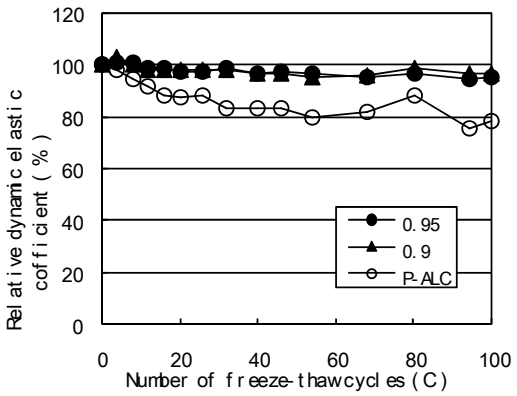

Fig. 3. Changes in relative dynamic elastic coefficient in CIF test.

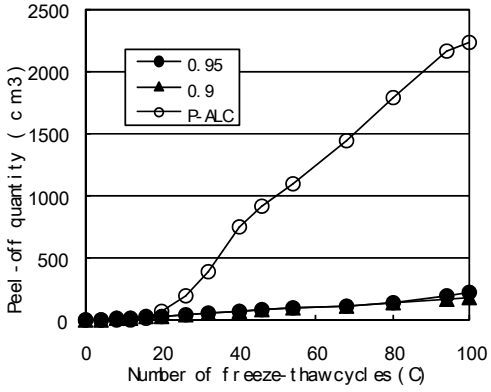

Fig. 4. Changes in peel-off quantity.

Changes in water absorption rate are shown in **Fig. 5**. The water absorption tendency of the high-strength lightweight concretes was similar to that of P-ALC. The water absorption rate after 40 cycles hardly showed an increase, keeping saturated conditions. P-ALC showed a little increase in water absorption during 7 days of lower-surface water absorption, and a remarkable increase during later freeze-thaw conditions.

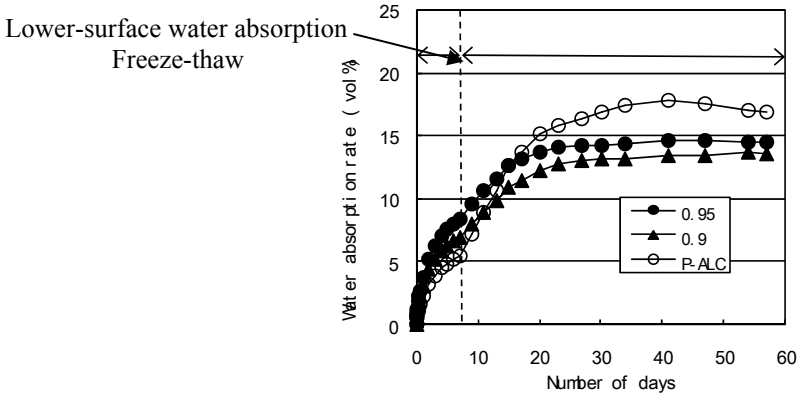

Fig. 5. Changes in water absorption rate in CIP test.

Since deterioration due to freeze-thaw has a close relation with absorption conditions, it is important to judge the possibility of reaching threshold water saturation degree (saturation degree within a limit not to cause deterioration) under supposed environment. Then, let's discuss deterioration from the viewpoints of changes in relative dynamic elastic coefficient in **Fig. 3** and changes in water absorption rate in **Fig. 5**. In P-ALC, relative dynamic elastic coefficient started to decrease immediately after freeze-thaw started. From this fact, it is suggested that deterioration started when water absorption rate reached 5.5 vol%, as the absorption rate when lower-surface water absorption ended, and successively water absorption accelerated due to damage of fine structure following the progress of deterioration. On the other hand, in the high-strength lightweight concretes, water absorption rate reached nearly saturated condition at 14 vol%, and yet deterioration was not recognized ever at this high water absorption rate. Although it is difficult to specify the threshold water saturation degree, the possibility of deterioration, such as strength decrease and collapse due to freeze-thaw action, seems be little under normal environment.

3.3 Measurement of Foam Structure

The relations between absolute dry density and air volume are shown in **Fig. 6**, the relations between absolute dry density and average foam diameter in **Fig. 7**, and the relations between absolute dry density and foam interval coefficient in **Fig. 8**. Although the air volume of the high-strength lightweight concretes varied in a wide range such as 25.0-38.3%, average foam diameter and foam interval coefficient little varied. In particular, foam interval coefficient was nearly 0.1 mm, showing very excellent foam structure against freeze-thaw damage compared with evaluation on ordinary concrete [Hama *et al.* 2005].

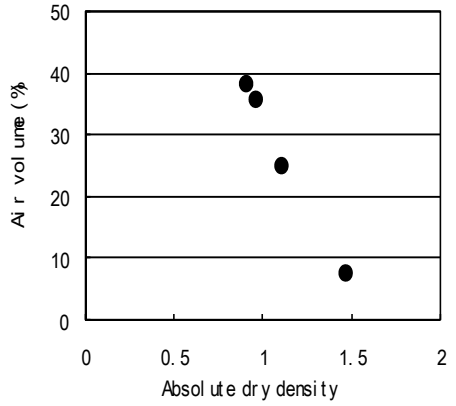

Fig. 6. Changes in absolute dry density and air volume.

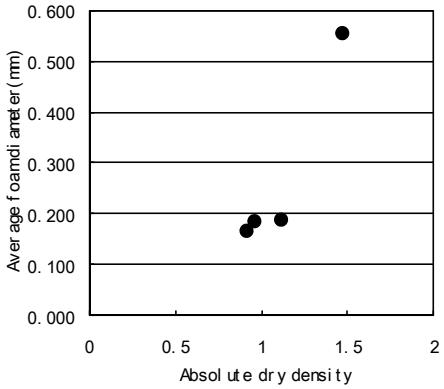

Fig. 7. Changes in absolute dry density and average foam diameter.

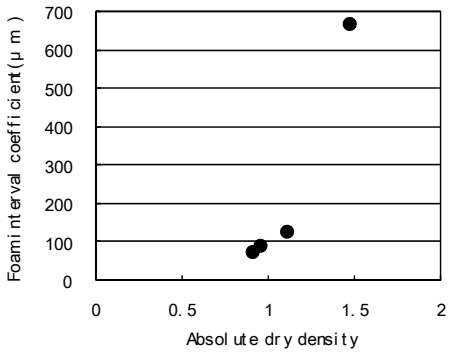

Fig. 8. Changes in absolute dry density and foam interval coefficient.

3.4 In-water Freeze and in-water thaw test

Changes in relative elastic coefficient are shown in **Fig. 9**. The high-strength lightweight concrete with a density of 0.95 g/cm^3 dropped its relative dynamic elastic coefficient to 80% or below during 90-120 cycles. With a density of 0.9 g/cm^3, decrease in relative dynamic elastic coefficient was suppressed, and it was kept over 80% even after 300 cycles. In comparison, P-ALC tended to show decrease in relative dynamic elastic coefficient immediately after the start of freeze-thaw, and it dropped to 68% during 30-60 cycles.

Changes in weight are shown in **Fig. 10**. The weight of any specimen tended to increase from the start of the test, and any of the high-strength lightweight concretes reached saturated conditions at 90 cycles. P-ALC was considered to have reached threshold water saturation degree due to water absorption before the start of freeze-thaw, and abrupt deterioration proceeded before 30 cycles from

the start of freeze-thaw, and water absorption seemed to have accelerated following the damage of fine structure.

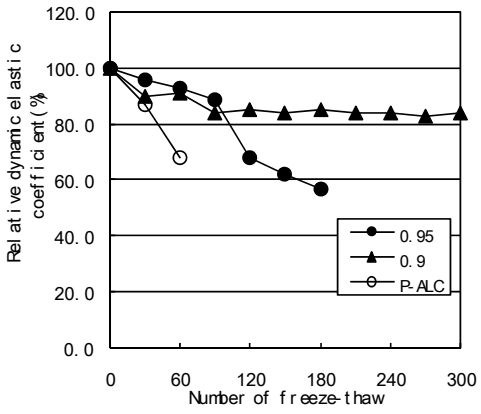

Fig. 9. Changes in relative dynamic elastic coefficient in in-water freeze and in-water thaw.

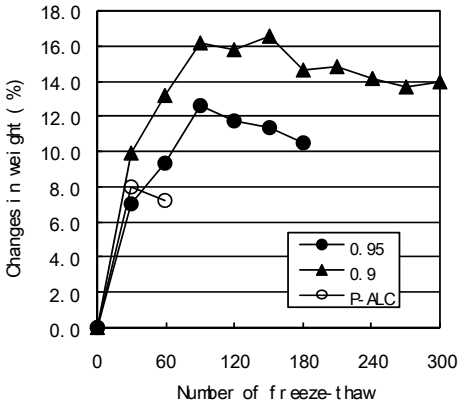

Fig 10. Changes in weight in in-water freeze and in-water thaw.

4 CONCLUSIONS

This study aimed to make full use of the advantages of ALC such as lightweight and dimension stability, and to further pursue high strength and high durability (freeze-thaw resistance). As a result, the following conclusions have been obtained on the high-strength lightweight concretes with absolute dry density of 0.9-0.95 g/cm^3.

(1) Using cement and siliceous materials as well as a high-performance AE water-reducing admixture, mortar with reduced water-powder ratio could be manufactured. By treating this mortar inside an autoclave, the high-strength lightweight concrete with high relative strength of approximately threefold of P-ALC could be obtained. The main constituent of hydration product of the high-strength lightweight concrete was calcium silicate hydrate.

(2) When manufacture efficiency as manufacturing conditions is considered, by using an accelerated curing admixture (calcium aluminate : anhydride = 1:1), demolding at 40°C for 60 min became possible. These conditions are advantageous as industrial production process.

(3) By mixing foams, lightweight product could be obtained and freeze-thaw resistance was improved, as in the case of ordinary concrete [Hama *et al.* 2005].

(4) Intense scaling as seen in P-ALC was not observed.

(5) Even in the severe test based on in-water freeze in-water thaw, the high-strength lightweight concrete with a density of 0.9 g/cm^3 retained 80% of relative dynamic elastic coefficient even after 300 cycles. Under normal use conditions, strength lowering and deterioration due to freeze damage will hardly occur.

ACKNOWLEDGEMENT

In performing this study, we received cooperation of Assoc. Prof. Hama, graduation thesis student Mr. Tomoya Sato, and fifth graders of Architecture Science Division, all at Kushiro National College of Technology. We would like express heartfelt gratitude to them.

Gérard Debicki [3]

T 11

ABSTRACT

This research integrates a global program, which is interested in the improvement of the performances of building materials in hot dry climate zones by the beneficiation of the local natural resources. The local resource used in this research is the male date palm surface fibre (MDPSF). This paper provides mechanical and physical properties of MDPSF, and flexural properties of MDPSF reinforced concrete. Regarding the mechanical performance of more common vegetable fibres, the MDPSF has average mechanical properties and a weak elasticity modulus.

The volume fraction and the length of fibres reinforcement were 2-3% and 15-60 mm respectively. The study revealed that increasing the length and percentage of fibre in reinforced concrete improves the post-crack flexural strength, but decreases the first crack.

The durability of MDPSF reinforced concrete was investigated according to its flexural properties and some scanning electron micrographs at the fibre-matrix interface zones. Two curing types were used: 1- In hot-dry climates, 2- Initially 14 days in water then in hot-dry climates. As a result, the durability of the SDPF reinforced concrete loosed in the first cure, but an improvement of its first crack strength is obtained with the second cure and appropriate cement.

1 INTRODUCTION

The date palm (*phoenix dactylifera)* is the one of the most cultivated palms around the world. It is commonly found in the Afro-Asiatic dry-band, which stretches from North Africa to the Middle East. It has a good tolerance to cold and dry-hot climates. Date palms have a fibrous structure, with four types of fibre: leaf fibres in the peduncle, bast fibres in the stem, wood fibres in the trunk and surface fibres around the trunk. Surface fibres were chosen in this study as it seemed most suitable for exploitation. After annually trimming operations, enormous quantities of palm fibre are thrown away, except on a smaller scale where it is used for artisan products.

The local natural resource, used in this study (surface date palm fibres) for reinforcement of concrete are from Ouargla which is situated in the south of Algeria, and where a part of the tests conducted in this study were completed. Oaurgla is characterized by a hot-dry climate during summer. Table 1 provides the average climatic data for Oaurgla, where it is evident that the temperature in the day is very high (up to 43°C), the daily amplitude between day and night regularly reaches about 18°C, and the humidity level stays very low. Furthermore, the site is located in a zone having an average wind velocity of 8 –16 km/h. In fact, most materials used for construction, especially concrete, are sensitive to and adapted with difficulty to hot-dry climatic conditions. Research [Soroka 1993; Kriker & Bali 1992] indicates that mechanical properties of conventional concrete, particularly the flexural strength, decrease with time under similar climatic conditions. In addition, previous work [Alekrish & Alsayed 1994] indicates that conventional concretes and mortars exhibit a high level of shrinkage and cracking in this type of environment.

According to the results of various research studies on more common vegetable fibres, [Swamy 1988; Cook 1980; Khenfer *et al.* 2000; Savastano & Agopyan 1999] the presence of natural fibres in concrete is beneficial for flexural properties. In addition, in a previous work [Kriker *et al.* 2005] it has been shown that firstly, the male date surface palm fibre (MDPSF) has the greatest tensile strength amongst the other types of date palm surface fibres. Secondly a direct exposure of MDPSF concrete to hot dry conditions reduces its mechanical performance.

The aim of this study is to investigate the flexural properties of concrete reinforced with male date palm surface fibres produced for use in a hot-dry climate. It also endeavours to examine the possibility of utilizing these local natural resources in local construction. In addition, the paper examines the effect of curing (wet, hot dry and mixed environment) on the durability of MDPSF reinforced concrete. The durability of MDPSF reinforced concrete at a later-age is evaluated by the variation of their flexural strengths and some scanning electron micrographs at fibre-concrete interfacial zones.

Table 1. Monthly mean climatic data for Ouargla, Algeria.

2 MATERIALS AND METHODS

2.1 Materials

The natural fibres used are from the surface of the male date palm. The male date palm surface fibres are naturally weaved, and are retrieved from the trunk in the form of a nearly rectangular mesh (length

300-500 mm, width 200-300 mm) formed with three superposing layers. It is easy to separate them into individual fibres when these are placed in water. Table 2 present the upper, lower, and mean physical properties of MDPSF as well as the coefficient of variation (CV). Regarding these results, the MDPSF has a porous structure capable of absorbing a great quantity of water.

Table 2. Physical properties of MDPSF [Kriker et al. 2005].

Property	Lower-upper	Mean-CV (%)
Diameter (mm)	0.1-0.8	0.45-54.43
Bulk density [kg/m^3]	512.21 -1088.81	900-17.64
Absolute Density [kg/m^3]	1300 - 1450	1383.33 - 5.52
Natural moisture content (%)	9.5-10.5	10-5.00
Water absorption after 5 min (%) under water	60.05 – 84.12	74 –14.02
Water absorption to saturation (%)	96.83 – 202.64	132.5 – 20.56

Table 3 provides the mechanical properties of MDPSF. Compared to the information obtained from literature on the mechanical performance of more common vegetable fibres [Savastano & Agopyan 1999; Tolêdo Filho *et al.* 2000; Bentur & Akers 1989], MDPSF have only average tensile strength and a lower elastic modulus.

Table 3. Mechanical properties of MDPSF [Kriker *et al.* 2005].

Condition	Natural			
Fibre type	Specimen's length (mm)	Tensile Strength (MPa)	Elongation (%)	Modulus of Elasticity (GPa)
MDPSF	100	170±40	16±3	4.74±2
	60	240±30	12±2	5.00±2
	20	290±20	11±2	5.25±3

Portland cement (CPA-CEM I 52.5) was used according to the NFP 15-301 standards, and having the following physical properties: Fineness = 385 m^2/kg; Initial Setting time = 200 min; and, σ_C at 28days = 50MPa. Table 4 gives the chemical properties of this cement.

Table 4. Chemical properties of used cement.

SiO_2	AL_2O_3	Fe_2O_3	MgO	CaO	Na_2O	SO_3	K_2O	Loss on ignition
20.29	4.60	2.98	1.66	65.24	0.30	2.70	0.99	2.80

Natural sand having a bulk density of 1660 kg/m^{3}and a maximum size of 5 mm was used in the mix formulation. As well, a natural aggregate having a bulk density of 1610 kg/m^{3}and aggregate minimum and maximum size of 5 and 10 mm respectively was used .

2.2 Specimen Fabrication

Concrete specimens with dimensions 70x70x280 mm were used for flexural strength. Table 5 gives the mix design proportions of concretes. For the mix design of the concrete without fibres (control formulation), the experimental method recommended by [Lesage 1974] and [Gorisse 1978] was used to obtain the optimum sand-aggregate ratio. For all mixes of concretes containing fibre, the mass of cement and sand was kept equal to that of concrete without fibres. The volume fraction of fibres in concrete was varied but the mass of fibres plus aggregates was maintained constant. With a

workability established according to the VB time equal to 20±5 s and slump equal to 70±10 mm, the water quantity was adjusted to adapt the mix with the given percentage of fibre content. The volume fraction of fibre was 2% and 3%. In fact, when the volume fraction of fibres increased, the demand for water also increased due to absorption of water by the fibres. For each mix, the fibre lengths were 15 and 60 mm. The variation of workability with fibre length was slight. A conventional horizontal axis Zyklos mixer was used to mix the concrete composites. The fibres used in the concretes were washed beforehand with tap water and dried in free air.

The production of composites was carried out as follows: in order to facilitate their separation, the fibres were initially immersed in 10% of the total volume of water required for 5 min,. At this stage, the rate of saturation of fibres was about 56%. The sand, aggregates, plus 30% of water were mixed for 30 s in a running mixer. Then, the fibres were added together with 30% of the water and mixed for 3 min. This was done slowly in order to obviate the possible clumping of fibres. After adding all the quantity of cement, the remaining water was added during the next 2.5 min.

In order to investigate the relation between volume fraction of fibre in the mix and the importance of the nominal fibre length, four types of fibre concretes were prepared in addition to concrete without fibre. The concretes were referenced by the following notation: N%-L, where N is the volume fraction and L is the length in mm of fibres. For example 2%-60 refers to volume fraction, N = 2% and fibre length, L = 60 mm. The filling of the moulds and the vibration using a vibrating table were carried out in accordance with standard NFP18-409.

2.3 Curing Conditions

The specimens were initially cured in the laboratory for 24 hours under normal climatic conditions: temperature, T = 20±2°C, and relative humidity, RH = 65±5%. After demoulding, they were cured until the test date in two types of environment. For the first type of environment (referenced: Curing 1), the test specimens were placed 28 days in water at 20±2°C followed by curing in a wet chamber at 20±2°C, with the RH = 100%. For the second type of environment (referenced: Curing 2), they were placed 14 days in water at 20±2°C followed by a hot dry room at 32±2°C and RH = 28±2%. The hot dry room was used to simulate the mean temperature and humidity of the environment of Ouargla (Table 1). The concrete specimens were tested at 28, and 180 days. Six replicate specimens were tested for each parameter setting.

Table 5. Mix design proportion.

Materials	Mix 1 (0%)	Mix 2 (2%)	Mix 3 (3%)
Cement (kg/m^3)	400	400	400
Aggregate (kg/m^3)	1000	982	973
Sand (kg/m^3)	750	750	750
Water (kg/m^3)	240	270	290
MDPSF (kg/m^3)	0	18	27

2.4 Test Methods

The mechanical properties (tensile strength, elongation and the modulus of elasticity) of fibres were determined in accordance with standards NF EN ISO 5079, under the following climatic conditions, T=20±2°C and RH = 65±2 %, and using an Instron universal testing machine equipped with a 250 N load-sensor and two LVTD displacement transducers at a cross-head speed of 0.5 mm/min.

Test data were digitally recorded and reduced using a numerical chain data acquisition system connected to a device that plotted the force-deformation curve. For each fibre length, tests were performed on thirty fibres.

The flexural strength properties were determined with an experimental set-up in accordance with standard NFP 18-409, using an Instron universal testing machine and a four-point test configuration, with 210 mm span and crosshead rate of 0.1 mm/min. The system was equipped with a load-sensor of 50 kN and two LVDT displacement transducers. These continuously recorded to a numerical data acquisition system, which made it possible to determine the deflection at the mid-span of the specimen as function of loading.

The flexural properties were evaluated using four parameters:

- The first crack strength (FCS) determined from the load at the first visible crack using equation (1).

$$FCS = 6M_0/bd^2 \quad (1)$$

Where M_0 is the failure moment of the test specimen at the first visible crack (P_0) and b and d are the width and depth of the specimen respectively. P_0 is the maximum load of the load-deflection- curve in the elastic range.

- The maximum post-crack flexural load (P_{max}) carried by the composite after the first crack.
The concrete was tested at the following ages: 28 and 180 days for flexural strength. Six specimens were used for each test.

3 RESULTS AND DISCUSSION

3.1 Flexural Properties

Table 6 provides the mean and the coefficient of variation (CV) of the first crack strength (FCS), the maximum post-crack flexural load (P_{max}), for concrete formulations cured under Curing 1, and 2 conditions. The results showed that, for both Curing 1 and 2 curing conditions and for each concrete type, the FCS continues to increase with age. However, when the length and the percentage of fibres increase the FCS decreases. Therefore, the 2%-15 fibre-concrete type presents the maximum FCS, which remained lower than that of the concrete without fibres. In addition the FSC of concrete cured in Curing 1 conditions is lower than that of concrete cured in Curing 2 conditions. This is due to the thermo activation brought about by this last cure. In fact, it has been noted in a previously completed work [Kriker & Bali 1992] that the Curing 2 conditions improved the FSC of conventional concrete.

The examination of toughness properties represented by the P_{max}, (Table 6), show that for each term (28 or 180 days) the P_{max}, increases with an increase in the length and percentage of fibres incorporated in the mix, with the maximum P_{max}, being obtained with the 3%-60 fibre-concrete type for both Curing 1 and 2 conditions. However, for each concrete type, the P_{max}, decreases with age; this is probably caused by the loss of tensile strength of fibres in an alkaline environment. It is noticed that the P_{max} of the concrete conserved in Curing 1 slightly exceeded those cured in Curing 2 conditions. The relatively losses of P_{max}, between 28-180 days of concrete cured in Curing 1 conditions are slightly lower than that of concrete cured in Curing 2 conditions. For example, for the concrete mix that yields the largest P_{max} (3%-60), the loss of P_{max} between 28-180 days for this mix is 32%. When comparing to literature results, about durability of more common vegetable fibre-concrete, according to flexural properties, it's can reveal that the MDPSF-concrete, conserved in Curing 1 or 2, has a low durability. That is probably due for the reasons already exposed in our former research [[Kriker et al; 2005], principally to the mediocre mechanical performance of MDPSF.

That can be explained by observations derived by Gram [1983], where it was revealed that the transport of hydration products from the matrix to the fibres was accelerated by a thermo activation process. Therefore, the durability of fibres in the concrete cured in Curing 2 conditions should be more greatly affected than those cured in Curing 1 conditions.

In addition, we compare the flexural properties (FSC, Pmax) of the concrete cured in Curing 2 conditions with those cured continuously in a hot, dry environment [Kriker *et al.* 2005]. One can see that cure in Curing 2 conditions has a beneficial effect on the flexural performance of fibre-concrete at early curing times (up to 28 days). However, for longer-term cure, the effect is only beneficial in respect to the FSC of the fibre-concrete.

The mean bending load-deflection of MDPSF-reinforced concretes at 180 days when cured in Curing 2 conditions is presented in Figure 1. At the beginning of the loading cycle, the behaviour is elastic up to the first crack strength (FCS) is attained. Beyond the first crack strength, the recorded deflection around 0.05 mm, the initiated crack had an unstable growth leading either to separation of the body into parts when there is no fibre, or to a macro-crack with a deflection around 0.5 mm, when the fibres could stop the crack growth. This crack instability could be connected with the elastic modulus of the MDPSF-fibre. After that, the load became nearly constant with increasing bending deflection.

Table 6. FCS and P_{max} for MDPSF-concretes as a function of time and type of cure.

	Concrete types (%-length of fibre)					
Flexural properties	Curing (Time d)	0%-0	2%-15	3%-15	2%-60	3%-60
FCS (CV) (MPa)(%)	C. 1(28)	7.6 (7)	6.5 (12)	5.50(15)	6.02(11)	5.34(13)
	" (180)	8.4 (6)	7.4 (9)	6.30(11)	6.82 (9)	6.21(13)
	C. 3 (28)	7.9 (7)	6.7 (5)	5.80 (6)	6.30 (5)	5.60 (7)
	" (180)	8.7 (3)	7.6 (4)	6.50 (4)	7.22 (6)	6.40 (3)
P_{max} (CV) (kN)(%)	C. 1(28)	--	0.80(19)	1.69(12)	1.18(11)	2.96 (3)
	" (180)		0.70(27)	1.40(11)	0.99(30)	2.02(19)

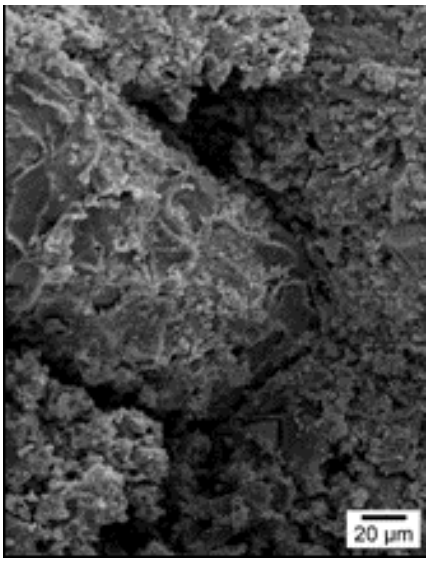

Fig. 1. Load-Deflection at 180 days in Curing 2

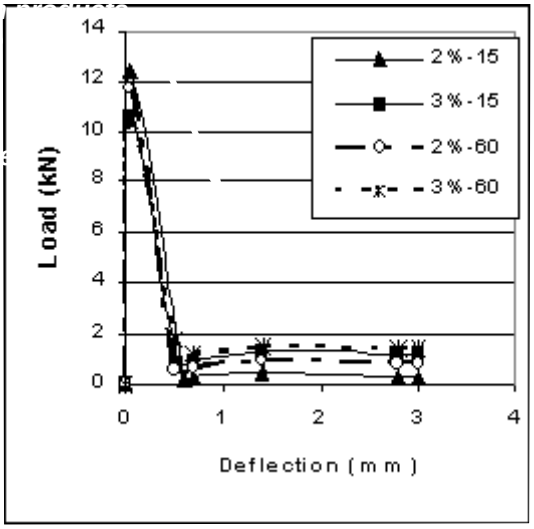

Fig. 2. Scanning electron micrograph at the fibre-matrix interface of MDPSF-concrete cured for 3 months in Curing 2 conditions.

To explain the fibres-matrix adhesion, Fig. 2 presents the scanning electron micrograph at the broken surface, at the fibre-matrix interface of some typical fibre-concrete conserved during three months respectively in Curing 2. Observing those microstructures of the fibre-matrix interface, it can be seen that the voids around the fibres of concretes is not large. In addition, Fig. 2 shows the uniform deposition of hydration products on all fibre surfaces. Those observations confirm the uniformed deposit of alkaline hydration products on surface of the fibre in Curing 2. Those also explain why the flexural properties of MDPSF-concrete after the first crack at long term in Curing 2, is slightly lower

than that in Curing 1. In fact, the durability of MDPSF was more affected by cement alkaline products in Curing 2 than that in Curing 1. That confirms also the findings of [Tolêdo Filho *et al.* 2000] and [Bentur & Akers 1989], regarding mineralization of vegetable fibres due to migration of hydration products, especially calcium hydroxide after natural wet ageing. Like shown it surface of fibre on Fig.3.

4 CONCLUSIONS

The Afro-Asiatic dry band is rich in date palm fibres that could also be utilized in local material construction products. However, when compared to the mechanical performance of more common vegetable fibres, the male date palm surface fibres (MDPSF) have average tensile strengths and lower elastic modulus.

Based on the results derived in this study, for all Curing 1 and 2 conditions and for each concrete type, the initial crack strength (FCS) continues to increase with cure age. However, for each cure period (28 or 180 days), the initial crack strength of the concrete without fibre is greater than those of the fibre-concretes.

The initial crack strength (FCS) of concretes cured in Curing 2 conditions (14-d in water at 20°C; hot dry room 32°C and RH = 28%) is slightly greater than that of fibre-concretes cured in Curing 1 conditions (28 days in water at 20°C; curing in wet chamber at 20°C and RH = 100%). This can be attributed to the thermo activation process and hence to the enhanced formation of hydration products of concretes cured in Curing 2 conditions. For those reasons, after the initial crack, the flexural properties (P_{max}) and the durability of the fibre-concretes cured in Curing 2 conditions were lower than that of those cast in Curing 1 conditions.

The Curing 2 cure condition has a beneficial effect on the early strength (28-day) performance of fibre-concretes in hot dry climate. However, over the longer-term the beneficial effect is only achieved in respect to the initial crack strength (FSC). Some other treatments of MDPSF and matrix are then necessary to improve their durability, especially after the first cracking. This will be investigated in a future paper.

Cement Industry and Concrete Technology in Algeria: Current Practices and Future Challenges

Said Kenai [1]
Ahmed Attar [2]
Belkacem Menadi [3]

T 11

ABSTRACT

In this paper, the development of cement industry in Algeria, the production process and the types of cement produced are presented. A summary of ongoing research on cement replacement materials such as limestone, slag and natural pozzolana is given. The current field practices in concrete technology are discussed. Durability issues related to the local hot environment conditions, aggressive soils and underground water and site practices are highlighted. The lack of river sand is highlighted and the use of crushed sand with limestone fines as sand replacement in concrete is discussed. Statistical analysis of concrete quality on site is analysed showing variability of construction materials quality, poor workmanship and lack of proper quality control procedures. A number of ongoing challenges for concrete technology and cement industry are identified and recommendations are proposed suggesting a way forward.

1 INTRODUCTION

Algeria is facing a serious housing shortage which is estimated at more than one million units. Hence, it is undertaking a vast five year construction program including the construction of housing units, 1200 km of motorways, three new cities around the Algiers region and other basic infrastructure such as schools, universities and hospitals. This program has raised many challenges to the construction industry. Among the challenges are the availability of good quality local construction materials, quality control on site, and durability.

.

Algeria is situated in a high seismic zone and its climate is hot and dry in summer especially in the southern regions. Some regions in the south and the west are known of their aggressive underground water soils. In addition, most of the construction projects are located on the aggressive sea environment of Mediterranean coastal region which is 1200 km long. Concrete is the main construction material used in most of these projects and hence its durability could be affected if precautions are not taken in preparing specifications to withstand these harsh environments.

In this paper, a review of the cement and concrete industry in Algeria is given. Concrete durability issues are discussed and field practices reviewed. A number of ongoing challenges for concrete technology and cement industry are identified and some recommendations suggesting the way forward are proposed.

2 CEMENT INDUSTRY IN ALGERIA

The first cement plant in operation in Algeria was a small wet processing plant which dates back to 1901 with an annual production capacity of 50 000 tonnes/year which was later modernised. Until 1962, there were three cement plants with a total annual capacity as low as 800 000 tonnes and hence a consumption of about 80 kg per capita [Stiti, 1999]. Today, in 2008, there are fourteen (14) cement plants in operation producing more than 13 million tonnes annually and hence 400 kg per capita consumption as compared for example to 350 kg per capita produced in Germany [Cement International, 2005]. Up to 50% of the deliveries are in the form of bulk cement and the remaining portion in the form of bagged cement. All cement plants are now using the dry process. Most factories use natural gas as energy carrier. The two newest cement factories are now owned by the multinational company Lafarge, and all the remaining cement plants are state owned but with some shares held by different multinational companies. Table 1 provides a summary of the production capacity of all cement plants.

The cements manufactured in Algeria are Ordinary Portland Cement type CEMI, CEM II/A, CEMII/B with two strength classes: 32.5 and 42.5. In addition, sulphate resistant cement is produced in the Ain-Kebira plant and white cement is produced at a new cement plant located in Sig. The use of cement composites can decrease the production costs, the CO_2 emissions, eliminates the costs of dust disposal and reduces environmental pollution. Hence most cement plants are using limestone, natural pozzolana or slag in a proportion of 10 to 15% by weight of cement. Fly ashes and silica fume are not available but are imported for special projects. Table 2 gives typical chemical and mineralogical compositions of some of these cements.

3 CEMENT REPLACEMENT MATERIALS

Given the large supply of slag, natural pozzolana and limestone, most cement plants are using these materials as cement replacement materials. The chemical composition of Algerian slag, natural pozzolana and limestone are presented in Table 3. A summary of the undergoing research on these materials is given here.

3.1 Slag Cement

Slag is available in the MITTAL steel factory of El-Hadjar and is used either as aggregates in road construction or as cement replacement materials in some cement plants. The production of slag is estimated at about 0.3 Million tonnes/year. The reactivity of the Algerian slag is low and hence the optimum recommended level of cement replacement is about 30% by weight [Kenai & Amrane, 1996]. Local materials including slag were used to produce good self-compacting concrete. The addition of slag by substitution to cement was found very beneficial to fresh self-compacting concrete. An improvement of workability was observed up to 20% of slag content with an optimum content of 15%. Workability retention of about 60 minutes with 15% of slag content was obtained.

Table 1. Cement plants in Algeria, current production capacities and additions used.

N°	Cement plants	Production year	Current Production (tonnes/year)	Additions used
01	Meftah	1901	800 000	Limestone

Table 2. Typical chemical and mineralogical compositions of Algerian cements

Composition	Cement Type			
	A	B	C	D
Chemical				
SiO_2	21.53	21.50	20.32	20.92
CaO	66.87	65.52	64.34	61.74
MgO	1.08	1.05	0.56	1.58
Fe_2O_3	3.24	2.84	3.20	3.43
Al_2O_3	5.57	5.13	4.71	5.33
Loss on ignition	0.26	2.02	4.26	1.65
SO_3	1.09	1.53	1.26	1.83
Insoluble residue	0.06	1.60	1.14	1.35
Free CaO	0.30	0.39	0.21	2.17
C_2S	12.35	15.45	20.30	16
C_3S	65.33	56.58	50.59	56
C_3A	8.28	8.79	7.70	5.65
C_4AF	9.85	8.63	9.55	12

3.2 Natural Pozzolana

Natural pozzolana is being used for cement manufacture by at least six cement plants. These cement plants add usually about 15% of natural pozzolana cement replacement by weight. Natural pozzolana

have been widely used as a substitute for Portland cement in many applications because of their advantageous properties which include reduction in heat evolution, decreased permeability and increased chemical resistance. According to Ghrici et al [2006], binary and ternary cements with natural pozzolana have lower chloride permeability and lower sorptivity and hence better durability than ordinary cement or limestone cement (Figs.1& 2). However, natural pozzolana is often associated with shortcomings such as the need for moist-curing for longer periods of time and a reduction of strength at early ages and up to 28 days.

Table 3. Chemical and physical properties of slag, Natural pozzolana and limestone

Element	Slag	Natural Pozzolaan	Limestone
SiO_2	40.1	46.9	1.78
CaO	42.2	9.38	54.3
MgO	4.7	2.84	0.20
Al_2O_3	6.0	16.6	0.79
Fe_2O_3	2.0	9.37	0.34
SO_3	0.15	0.36	-
MnO	2.6	-	-
K_2O	1.2	-	-
Loss of Ignition	-	5.79	42.5

3.3 Limestone Cement

The strength development of mortar mixes containing varying amounts of limestone fines (LSF) is shown in Figure 3. In this experimental study, cement was partially replaced with 0, 5, 10, 15, 20, 25 and 30% of crushed limestone fines (LSF). The binder to cement and the water to binder ratios were maintained constant at 1:3 and 0.55 respectively. Compressive strength testing was conducted at 2, 7, 28 and 90 days of curing. The results showed that there is a decrease in strength with increasing amounts of LSF up to at least 30%, regardless of the age of curing.

All mortars, with and without LSF, show an increase in strength with the age of curing. This increase is mainly due to the evolution of the hydration of cement with time. No decrease in strength was observed with the age of curing for mortars containing LSF. At the age of 2 days, mortars with limestone fines (0, 5, 10, 15, 20, 25 and 30%) show comparable compressive strength to mortar without fines. This can be explained by the physical and chemical effect of limestone particles on the development of the mortar strength of cement. The improvement in compressive strength can be also attributed to the acceleration of the hydration of C_3S in particularly with finer limestone fines and the formation of carboaluminates [Kenai, 1997].

At the age of 28 days and 90 days, compressive strength decreases with the increase in the content of limestone fines. The replacement of cement by LSF beyond a content of 15% shows a noticeable decrease in compressive strength. This reduction in strength is due to the dilution effect.

4 CRUSHED SAND

Recently, there has been an increasing interest in using crushed sand from limestone quarries in concrete construction to overcome inherent deficiencies in river sand in particular regions of Algeria. Crushed limestone fine sand is a by-product of the quarry process and typically does not have a significant demand due to its high fines content that exceeds the standard allowable limit of 5%. The fines are particles whose diameters are less than 80 µm. For this reason, most of the fines at present are destined to landfill. In Algeria there is around 1010 aggregate quarries with a total annual production of 68 million tonnes of which about 47% goes to the building sector and 33% to roads and motorways. Around 15 millions tonnes of sand are produced in these quarries as a by-product

containing 8 to 25% of fines (i.e. < 80 µm), mainly used in road construction and usually sold at a lower price (about the third). The demand in sand is estimated at 25.1 million tonnes in which 16 millions for concrete for building construction and 9.1 millions for road construction [Kenai, 1999].

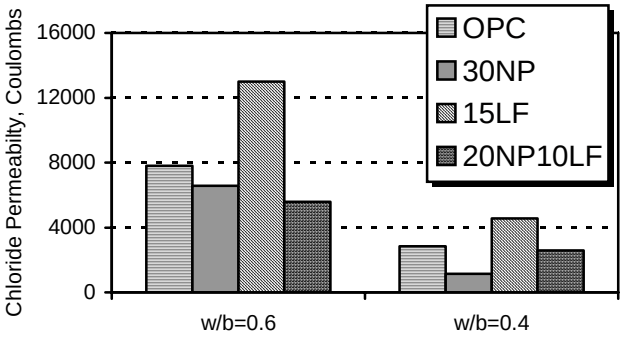

Figure 1. Chloride permeability of concrete at 28 days

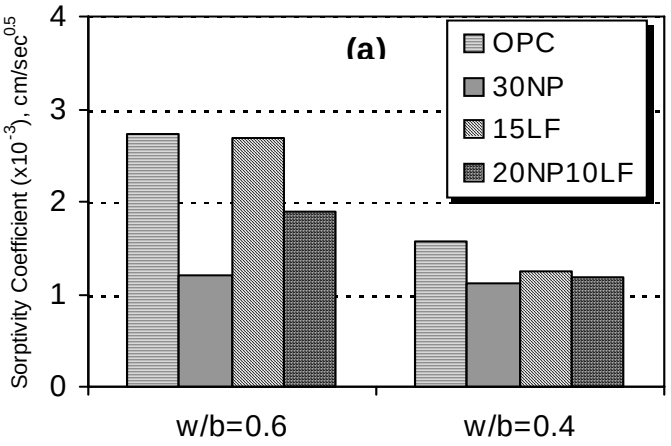

Figure 2. Sorptivity coefficients of concrete at 28 days.

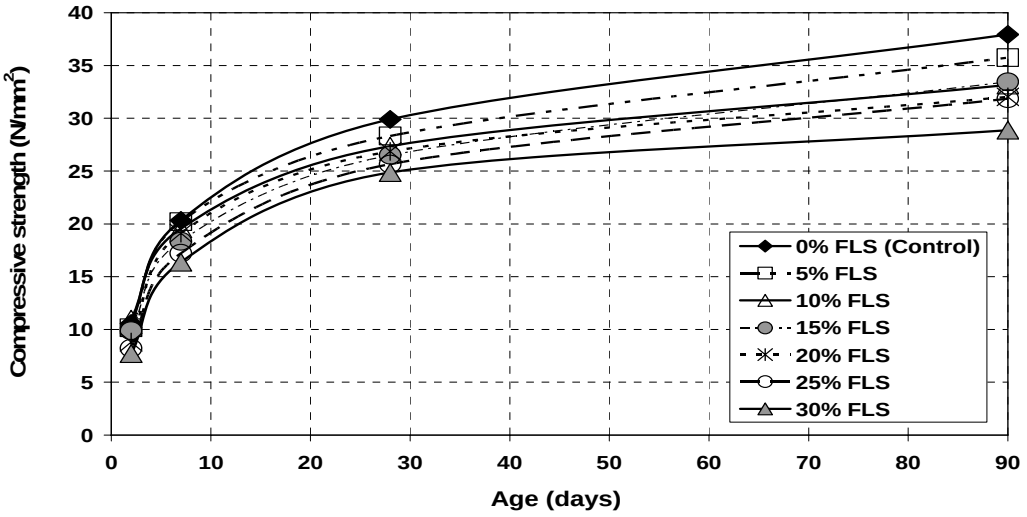

Figure 3. Strength development of mortars containing varying amounts of limestone fines.

Crushed sand is very abundant in limestone gravel quarries and its use could significantly decrease the materials cost of concrete, eliminate the dust disposal cost, reduces environmental pollutions and dilapidation of natural resources. Other countries such as Spain, France and Argentina also experienced similar shortage. For this reason, standards have increased the fines allowable limit in crushed sand. For example British standards (BS 882) allow up to 15% of fines in sand whereas ASTM C33 sets the limit to less than 7%. In addition, up to 35% of limestone fines are allowed in European cements according to EN197-1 (1996).

An experimental investigation was undertaken and showed that up to 15% of fines content in crushed sand could be used without adversely affecting concrete strength. Comparable water absorbed capillary were obtained for all concrete mixtures and higher values were observed in concretes with lower cement fineness when 15% of fines were used. The resistance to chloride-ion penetration and gas permeability decreased for all concrete mixtures with the inclusion of 15% limestone fines as sand replacement. The presence of 15% limestone fines as partial replacement of fine aggregate cause an increase in chloride ion penetration and gas permeability whereas reduces water permeability. The higher chloride-ion penetration and gas permeability of crushed sand concrete with 15% of limestone fines means that its use in structures exposed to marine environment should be limited [Menadi, 2008].

5 CONCRETE QUALITY ON SITE

The fast growing needs for buildings and structures has led to less quality control and the use of defective materials and hence produced much defective concrete. Statistical studies on building failures showed that the main causes of building failure and deterioration were design deficiencies, poor workmanship and low quality concrete [Kenai, 1999 & 2004]. Concrete compressive strength test results at the age of 28 days at 41 construction sites of more than 2300 test results during the period of 1987 to 1994 showed that 77% of the results were less than the required 25 MPa. The coefficient of variation was in about 60% of the sites more than 20% indicating a high variability of concrete strength and hence a lower degree of quality control on concrete mix design, concrete materials and concreting operations. The standard deviation varied from 2.8 to 6.0 MPa with more than 36% of the sites at more than 5 MPa. The analysis of the strength of cement in an Algerian plant during the period of 1989 to 1995 showed a higher variability of strength (coefficient of variation of 7.2% and a standard deviation of 3.7 MPa) compared to 3% and below 1.5 MPa respectively in Swedish cements [Fagerlund, 1994]. This showed that many aspects of basic good concreting practice need to be improved. The standard of quality control was unsatisfactory with poor workmanship by lack of supervision and lack of care resulting in honeycombing, lack of cover and bad finishes [Kenai & Bahar 2003].

It should be noted that data for concrete used in the construction of bridges showed lower variability, higher strength and better quality control because of the use of ready mixed concrete. The use of ready mixed concrete (RMC) could improve concrete quality on site and reduce irregularities observed. Strength irregularities are usually reduced with the use of RMC and hence cement consumption could also be reduced. In Sweden, there are more than 200 RMC factories with an annual production capacity of 3000 m^3. The spread of use of RMC has decreased cement consumption by 25 to 35% during the period of 1965 to 1985 [Fagerlund, 1994]. The variability in strength was low; standard deviation was 2.6 MPa to 3.5 MPa for a concrete class of 25 to 40 MPa. Cement consumption was only 210 kg/m^3 for 20 MPa concrete; 235 kg/m^3 for 25 MPa concrete and 265 kg/m^3 for 30 MPa concrete as compared to the Algerian average consumption of 350 kg/m^3 for 25 MPa concrete.

6 ALGERIAN RESEARCH NEEDS IN CEMENT AND CONCRETE

There are a lot of new challenges and research needs for the next two decades. The research priorities in cement and concrete are to be seen in the context of industrial and university perspectives and also national strategic perspectives:

- Emphasis should be given to local concrete making materials and durability and deterioration issues. There is a need to test the performance of the available materials and to find cheaper alternative materials.
- Replacing the river sand which is lacking by alternative sands such as dune, crushed or sea-dredged sands is important. National panels have been recently set up, by both the Ministry of Housing and the Ministry of Public Works, to look at these issues.
- Durability should address local conditions such as marine environment, hot dry climate and sulphate attack. The development of specifications and local design guidelines for easy use by designers and constructors to ensure long-term durability should also be addressed.
- The effect of local cement replacement materials such as limestone fines, natural pozzolana and metakaolin on the durability of concrete in different environments has to be investigated furthermore for the development of more durable materials with minimum maintenance costs. The development of ternary cement is also to be considered.
- The increased expenditure on repair and rehabilitation of concrete infrastructure and the ageing of some concrete structures has to be addressed by assessing existing concrete structures and developing suitable repair and strengthening techniques and materials.
- Development of equipment and non destructive techniques to monitor the rate of deterioration of concrete structures at an early stage is necessary. There is also a need to the use of modelling by neural networks and expert systems to predict the service life of both existing and new structures.
- The high strength, high elastic modulus and low density and high resistance to corrosion of carbon fibre relative to steel has a promising use for structural strengthening and the assessment of the performance of case studies under local aggressive environments at long term is needed.
- The development of high performance concrete and self compacting concrete using local materials is important.
- The development of environment friendly materials by using recycling demolition and construction waste and developing composite cements to reduce CO_2 emission which has a green house effect.
- Roller Compacted Concrete (RCC) has been used in three dams and there is a need to develop appropriate mix design, testing procedures and construction technique for RCC for use in pavements and dams.

These research needs are to be undertaken through industry and cooperation and exchange of staff. Universities should aim to develop suitable training skills and highly trained people in the field of concrete technology.

7 CONCLUSION

A review of the cement industry in Algeria has been undertaken. An emphasis was given on some ongoing research results on the performance of slag, natural pozzolana and limestone cements. Quality of concrete on site was discussed and the variability of strength and the lower quality of control on site highlighted. The Algerian needs in research on cement and concrete for the next two decades are identified in the context of industrial and university perspectives and also national strategic perspectives.

Selection of the Mix Constituents to Produce a Highly Performing and Durable Concrete Material

Mohamed Chemrouk [1]

T 11

ABSTRACT

Concrete is a mixture of aggregate, cement and water. In Algeria in recent years, the negative effects of an excess of mixing water in concrete have been made clearly evident. A number of structures were found to be vulnerable following the collapses observed during the Boumerdes-Algiers earthquake in 2003. Following these events, there has been a singular interest for improving the structural properties of the concrete manufactured in Algeria, and the means necessary to achieve this with the use of local materials in a cost effective manner.

It is well known that high performance concrete requires a low water/cement ratio as compared to normal concrete. This reduction in the quantity of mixing water reduces micro structural voids in the concrete, making it both denser and more compact. The degree of compactness and density of the hardened mass, which is enhanced by the use of ultra-fine materials, reduces the permeability of concrete, and with it, risks from external chemical attacks. The loss in workability, resulting from the reduction in the mixing water, is compensated by the use of adequate superplasticisers compatible with the cement.

Indeed, it is possible to produce a high performance concrete in the shorter term (early strength requirement) as well as the longer term (durability) provided specific measures are taken in the selection of aggregates based on specifications for shape, size, strength, stiffness and mineralogy, in the choice of a potentially active cement, and in the preference for a reduced quantity of mixing water. This paper provides information on a method that produces concrete material having a 28-day compressive strength of 65 MPa based on locally available (region of Chlef in Algeria) ingredients. In the context of this work, high performance is used to mean concrete having strengths greater than 40MPa.

1 INTRODUCTION

Concrete is a material in perpetual evolution, starting from empiricism in its early uses to a more scientific rationalisation today. In the early days, its use as a construction material has been conditioned by security. And then, with time, durability of constructions made with this material became a second factor as important as the first, conditioning the use of such a material. The same 'durability' factor is strongly linked to the 'economy' factor which is, at our days, continuously improving. Indeed, the possibility of building safer for the longer term and with less cost is an equation with three variables and for which the solution is an approximate one, with its precision continuously improving as advances in material technology are achieved.

Concrete can be very performing at our days; compressive strengths well in excess of 80 MPa have been achieved throughout the world and the same concrete used in real structures [Malier 1992]. This was made possible by the reduction of micro structural voids in the material; such voids are often filled with water, in excess at the early age, which evaporates with time under climatic effects. The denseness of the concrete material, which is improved by the use of ultra-fine materials, improves impermeability and, hence, reduces the risks of chemical attacks by external agents on the concrete and steel.

The reduction of voids is due to the reduction of the quantity of mixing water, part of which hydrates the cement particles and the excess helps provide a workable fresh concrete. With the development of superplasticisers, it is possible to improve the workability of fresh concrete, hence compensate the loss of this rheological property and thus reduce the quantity of excess water to a strict minimum. For this to be achieved, it is advised to carefully study the constituents of the mix in order to minimise water absorption by the aggregates, and make the cement react totally and effectively with the mixing water; the activity of a given cement never attains 100%. Other properties of the aggregates are also important for achieving a highly performing concrete and will be further examined in subsequent sections of this paper.

The qualification of 'high performance' is, however, used in this paper with a relative meaning since a concrete material considered as ordinary in one practice may be considered as high performance in another practice. In this work, based in Algeria, a concrete material having a compressive strength of more than 40 MPa [Ansari, 2002] is considered a high performance material.

2 HISTORICAL EVOLUTION OF THE MATERIAL

Despite the fact that high performance concrete (HPC) is considered as a relatively new material, its development has been gradual through the years. With the continuous development of the material technology, the definition of 'performance' itself has evolved. Earlier on, the term “high strength” referred to a concrete of 30 MPa and more. Afterwards, it was possible to obtain a concrete with strengths between 40 MPa and 50 MPa in the laboratory.

At the end of the seventies, a concrete with a compressive strength of 60 MPa was industrially produced in some developed countries and the idea of 'high performance' was born with this type of concrete. From this point on, interest was placed on the mechanical behaviour of the material under load and its interaction with the environment. However, for years, concrete having strength in excess of 40 MPa was available only in few places, hence very rare. This explains why until very recently most of the national codes dealing with the design of reinforced concrete structures considered compressive strengths not exceeding 40 MPa. Nowadays, the latest versions of some of these design codes go up to 60 MPa where strengths in excess of 80 MPa have been achieved in some real structures.

3 SELECTION OF THE INGREDIENTS FOR THE DESIGN OF HPC

It is evident that, in the absence of a precise method for the formulation a HPC, it is not with any one type of aggregate, or any one type of cement or, indeed, with any given water reducer that such a material can be obtained. The work described here provides means to fabricate this material and consists in:
This work traces a way to help elaborating this material; it consists on:

- A rigorous choice of the mix constituents, reflecting qualitative aspects
- The proportioning of these constituents, reflecting quantitative aspects

Indeed, up to now, there has not been any 'miracle recipe' to obtain a high performance concrete.

3.1 Aggregates

The aggregates occupy about 70% of the concrete volume and, hence, have a direct influence on the material properties both at the fresh state and at the hardened state.

3.1.1 Fine Aggregate: Sand

The fine aggregate to be used for the confection of a HPC should have a fineness modulus higher than 2.8 . A fineness modulus smaller than 2.5 makes the concrete 'sticky' and difficult to compact and hence, less resistant. Moreover, fine aggregates with a smaller fineness modulus have a more important specific surface and this requires more water. A continuous grading gives a better results in the longer term. The sand particles should have a round shape or at least a cubic one and should not contain flat or elongated shapes. The specific surface would hence be reduced and this in turn will reduce the quantity of mixing water required. Irregular shapes require more water and should be avoided. Round shapes increase also the compactness of the material and with it the resistance and in the longer term the durability of the material.

3.1.2 Coarse Aggregate

The selection of coarse aggregate depends on many factors such as the particle shape and size, the strength, the stiffness and the mineralogy.

3.1.2.1 Shape and Size. Crushed aggregates have a rougher surface than natural gravel and develop a better bond with the cement paste and hence result in a better strength. The gain in compactness of round shaped gravel is overweighed by their poor bond with the cement paste. However, irregular shapes in the crushed aggregates may 'punch' the cement paste under the effect of external loads and also require more mixing water for the concrete to be workable in its fresh state. For a HPC to be achieved, the ideal aggregate should be a crushed one, with a clean surface, having a regular shape, hence a reduced angularity, containing less flat or elongated particles since these shapes are very weak in resisting cracking [Gutierrez & Canovas 1996, Hamrat & Chemrouk 2003] and require more water.

For the size of aggregate, it has been shown that [Hamrat 1994, Hamrat & Chemrouk 2003] for an optimum strength with a reduced water/cement (w/c) ratio and a higher quantity of cement, the maximum size of aggregate should be kept between 9.5 and 12.5 mm. Smaller size aggregates would induce less stress concentration at the cement paste around the aggregate. Moreover, a higher difference between the elastic modulus of the cement matrix and that of the aggregate would aggravate such stress concentration.

3.1.2.2 Mechanical Strength. To produce a high strength concrete, aggregate should not break or crush before the hardened cement paste. A stronger aggregate is necessary to achieve higher strengths for concrete [Iravani 2000, Chemrouk & Hamrat 2002]. Using weaker aggregate will induce failure planes through the aggregate that adds to those possible through the cement paste and through the bond between the aggregate and the cement paste.

3.1.2.3 Stiffness of Aggregate. Higher differences between the modulus of elasticity of aggregate and that of the hardened cement paste induces a stress concentration around the aggregate which can affect

negatively the bond between the two constituents of the hardened concrete. To reduce such an negative effect, the aggregate used in HPC should have an elastic modulus comparable to that of the hardened cement paste. This will minimise the differential deformation at the aggregate-cement paste interface, often a source of failure of concrete.

3.1.2.4 Mineralogy of Aggregates. The bond between the cement paste and the aggregate is the determinant factor for the development of higher strengths in concrete and hence the mineralogy of aggregate should be such that it would promote such bond. Some types of aggregates such as the calcareous ones react chemically with the cement paste and as a result the bond between the two constituents is improved. On the other hand, harmful reactions between the aggregate and the cement paste such as the alkali-granulate reaction, can take place resulting in cracking and deterioration of the concrete over the longer term, hence affecting its durability.

3.2 Cement

Portland cement is important for the production of HPC. To obtain a higher resistance, it is desirable to finely grind the clinker. This increases the proportion of hydrates in the hardened concrete and reduces the proportion of passive cement particles. However, the proportion of hydrates is conditioned by the quantity of water. The fineness of cement increases the degree of hydration and hence increases the strength of concrete. Finer cement results in a higher specific surface. However, an excess fineness causes the risk of an early set and a higher heat of hydration that in turn could induce thermal cracking, particularly for mass concrete. For a high performance concrete to be achieved, the specific surface of the cement should be in the order of 3500 cm^2/g to 4000cm^2/g.

Among the four essential chemical constituents of Portland cement (C_3S, C_2S, C_3A, C_4AF), tricalcium Aluminate (C_3A) is the first one to hydrate followed by the tricalcium silicate (C_3S), the principal factor in the development of higher strengths. The rapid hydration of C_3A results in early age strengths for concrete. However, such a rapid hydration causes an early stiffening of concrete and hence results in a loss in workability [Punkki et al. 1996 & [Hamrat 1994]. Consequently, for high performance concrete to be achieved, the cement should contain less C_3A and the proportions of this constituent are recommended to be well below 10% [Hamrat & Chemrouk 2003].

3.3 Superplasticisers

Water, evidently a key of concrete, fulfils two functions:

- Chemically, in that it contributes to the development of the hydration reaction.
- Physically, it provide flow to concrete.

An ideal concrete would be a material in which the quantity of water is only that portion strictly necessary for the hydration of the cement and which, at an early age, and precisely before the setting of the cement paste, fulfils the flow requirements for the concrete to be placed. However, the present types of cements can not produce such an ideal concrete since the hydration reaction starts immediately after adding mixing water, and hence well before the placing of concrete in the formwork. Completely eliminating the C_3A component on the cement directly in the production phase is very costly. This explains the practice of using a surplus of mixing water to facilitate the placing of concrete.

To reduce the quantity of water used, superplasticisers, which are products of organic chemistry, have been used. These dispersants have properties that can result in a sensible reduction of the quantity of mixing water used (up to 30%) by reducing the liquid trapped in the floccules of cement particles. The superplasticisers can keep the concrete workable sufficiently long to enable it to be properly placed in the formwork (up to 45 min) [Boulmelh 2002, Karouche 2001]. It is to be noted however, that cement rich in C_3A has difficulties in maintaining workable concrete even when using a higher proportion of the dispersants. This seems to be the case for Portland cement produced in Algeria for which the proportion of C_3A is higher than 10% [Hamrat & Chemrouk 2003].

Depending on the reactivity of the cement, the proportion of superplasticisers should vary between 1% and 3% by weight of cement used [Hamrat & Chemrouk 2003, Boulmelh 2002]; a very reactive cement needs more water for the concrete to be workable and consequently needs more dispersant liquid. An excess amount of superplasticisers can have a negative effect on concrete and bring about segregation, bleeding or delayed setting. It is recommended to use these superplasticisers [Malier 19992] in two portions, 1/3 of the quantity added with the mixing water and the remaining 2/3 added on site just before placing the concrete in the moulds or the formwork.

3.4 Mineral Additives (Ultra-Fines)

Ultra-fines are mineral additives having a smaller granularity than that of cement; they are often added to a concrete mix and play a double role :

- As an inert filler that, once incorporated in the mix, inserts itself between the cement particles, thereby reducing the quantity of water and in turn increasing the density of the cement paste.
- As an active agent, whereby these combine partially or totally with water or with some cement compounds such as the alkaline or lime. This reduces the risks of formation of swelling gels and the risks of alkali-granulate reaction which affects the durability of the material in the longer term.

Mineral additives which can be used with cement in a proportion not exceeding 30% are typically quarry products such as calcareous-based fillers and siliceous fillers, silica fume, fly ash and blast furnace slag. In addition, these mineral additives attenuate the heat of hydration and hence reduce the risks of higher differential temperature responsible for early cracking. They also moderate some of the negative effects which result from the use of superplasticisers, i.e., mineral additives reduce the risk of bleeding or segregation when superplasticisers are used.

4 APPLICATION: PRODUCTION OF HIGH PERFORMANCE CONCRETE WITH LOCAL INGREDIENTS

To produce a highly performing concrete from the point of view strength as well as for long term performance (durability), the quantity of water used in the mix should be reduced since a higher proportion will evaporate leaving voids that weaken the hardened concrete; the ideal being to reduce the quantity of mixing water to that strictly necessary for the hydration reaction. Such an ideal is, however, far from being achieved despite advances in materials technology.

As an application of the present study, this section consists of providing information on specifications for producing a high performance concrete using local materials common to the local construction industry in the region of Chlef situated in the central western part of Algeria. After a number of preliminary tests, a crushed calcareous aggregate with a maximum size of 15 mm was used. The aggregate particles were angular and elongated and hence could not allow for a higher reduction in the quantity of mixing water. Furthermore, subsequent compression tests revealed that these aggregate shapes resulted in failures through the aggregate particles themselves (inter-granular ruptures).

A river sand having a specific density of 2.65 and a fineness modulus of 2.9 was used in the mix. It is Malier [2002] suggests that a sand with a fineness modulus greater than 2.8 should be used for producing HPC since it requires less mixing water.

The cement used in producing the present HPC is that locally produced and is an ordinary Portland cement conforming to the Algerian Norm NA 442, which itself is an extract from the French Norms (AFNOR) namely NFP 15-302 and NFP 15-442. This cement, however, contains a higher proportion of tricalcium aluminate C_3A (more than 10%), a constituent which hydrates very rapidly causing an early stiffening of the fresh concrete and hence inducing a loss of workability. Indeed, the HPC

produced in the laboratory had difficulties to be workable for a sufficient time to allow for its transportation and use on site.

A liquid superplasticiser of the type "Meda-Fluid", locally produced, was used in a quantity of 2% by weight of cement. This superplasticiser was added to the mix aggregate-cement-water [Malier 1992]. The accidental and irregular shapes of the aggregate particles used in the mix formulation, in addition to cement containing a higher proportion of C_3A did not allow for a higher reduction of the quantity of mixing water. A water/cement ratio of 0.40 was used as compared to ratios between 0.6 and 0.7 for ordinary concrete which may have even more water considering the generally hot and dry climate of the region. The aggregate/cement ratio was 3.75.

Tests for compressive strength and indirect tensile strength were carried out on cylindrical concrete specimens (150x300 mm). All the concrete tests were undertaken at different ages (i.e., 1d, 3d, 7d, 14d, 28d, 56d) to allow monitoring of the strength gain with age. Each result represents the average of three specimen tested. Table 1 gives results obtained for the compression as well as the tensile splitting strengths. Figure 1 shows the strength gain in compression over time.

Table 1. Strength evolution for a High Performance Concrete having W/C=0.40 and A/C=3.75.

Age (days)	1	3	7	14	28	56
Compression (MPa)	20	27	40	52	60	64
Tension (MPa)	1.9	/	3.2	/	4.1	4.2

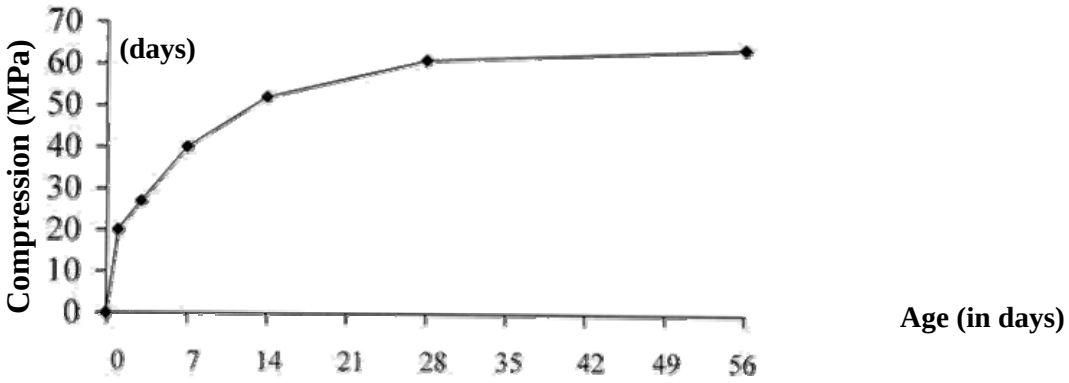

Figure 1. Strength gain with age for High Performance Concrete

The present work, as provided in Table1 and Fig.1, shows that concrete could be even more versatile, with compressive strengths more than twice that of ordinary concrete, leading to savings in materials as well as in overall cost. In this good quality dense and low permeability concrete, causes of deteriorations will be minimised and the material would become more durable at the longer term and hence fulfils the requirements of a sustainable built environment [Chemrouk & Attari 2003].

5 CONCLUSION

With societies increasingly focussing on sustainable development in our day to day life, building less expensively and targeting longer periods with consideration to reducing any negative environmental effects are indeed approaches that are gradually incorporated as part of the construction industry. In this sense, high performance concrete is gradually emerging as a defiant building material. However, formulating this building material is more complex than ordinary concrete owing to the addition of

supplementary parameters in the mix (superplasticisers – mineral additives) and to the qualitative aspect required. The cement paste and aggregate dominate quantitatively and qualitatively the formulation of high performance concrete. The former parameter is strongly related to the water/cement (W/C) ratio which varies between 0.6 and 0.7 for ordinary concrete.

For economical considerations and with the aim of producing a viable high performance concrete, the aggregate/cement ratio (A/C) should vary between 3 and 4 and that of the water/cement ratio should be below 0.4. The resulting loss of workability would be compensated by the use of an adequate superplasticisers. Without dispersants in the form of superplasticisers, concrete can not be of high performance since, with less mixing water, the fresh mix would be too stiff and hence difficult to fill in all the gaps in the formwork or moulds even when mechanical compaction is used, and particularly with cement containing a high proportion of C_3A.

With a careful selection of the mixing ingredients and taking advantage of the continuous advance in the materials technology, it is possible to produce concrete having strengths in the order of 60MPa to 80 MPa. With a more carefully studied selection of aggregate type, a lesser reactive Portland cement (containing less C_3A), the use of mineral additives such as silica fume, the addition of 3% of superplastisers compatible with cement, it is even possible to obtain strengths in excess of 80 MPa. With such strengths, the W/C ratio would vary between 0.3 and 0.25, depending on the type of aggregate used.

Effects of Landfill Leachate on the Properties of Self-Levelling Cement Mortars

Francesco Colangelo [1]
Raffaele Cioffi [1]

T 11

ABSTRACT

In this work the behaviour of special mortars immersed into strongly aggressive solution is reported. The study is very useful to predict durability of a new typology of concretes, called self-compacting, which can be cast and compacted without external vibration and thus are especially suitable for building deep-laid poles and waterproofing separators. Specifically, five mixtures, one ordinary (reference) and four self-levelling, containing several mineral additions were prepared and tested. All the specimens prepared have been characterized before and after the immersion in municipal solid waste landfill fresh leachate (condition of maximum aggressiveness). Then, specimens have undergone compressive and flexural strength tests and determination of water absorption, capillary absorption and porosity. The results of analyses carried out on cured specimens, even if after relatively short exposure times (365 days), allow obtaining interesting information on durability requirements for concrete employed in confining landfills.

1 INTRODUCTION

The existence of uncontrolled landfills necessarily implies the requirement for safety actions. Due to the remarkable technical difficulties and the cost of such operations, the isolation of the contaminated site is often preferable in respect to the total removal of materials or to their reclamation in situ. The isolation action is carried out by a macro-encapsulation made by means of vertical waterproof (bulkheads) and horizontal deep (depth buffers) shields. The bulkheads must be notably impermeable in order to block the leachate of contaminants or rather to send them to interception and treatment points.

Containment and encapsulation must be thought as feasible technical solutions, in line with the present particular laws in force [Directive 1999/31/CE]. Such techniques can be used as emergency safety actions to reduce and/or limit contamination within a site reclamation which needs medium-long times. They can also be useful tool for cleaning, favouring the site check or avoiding unwanted spreading coming from the application of the techniques themselves.

The vertical waterproofing systems often have structural requirements linked to the site stability, thus their mechanical strength must be good and steady over time. In these cases concrete products in the form of cast in situ adjacent poles are normally used, because of their low cost, simplicity of the technique and quick execution. This work is part of a local project on the reclamation of uncontrolled landfills subject to landslides.

1.1 Background and Objectives

Once the isolation has been realized the possible contact with several aggressive substances for concrete (sulphates, chloride, etc), able to damage its functionality, must be considered.

The chemical analyses carried out on leachates coming from several landfills located in the Campania region of Italy have shown that to obtain efficient containment systems, it is necessary to use concretes protected with a suitable coatings. This, of course, is only possible for the pre-cast components and not for those casted in-situ. In the present work, self-compacting concrete (SCC) has been used to obtain high durable materials that resist the transfer of leachates. [Ouchi, M., & Okamura H. 1999, , Collepardi M. 2003, , Ambroise J. *et al.* 1999, www.britishsafetycouncil.co.uk /safetymanagement/news/vibration.htm].

This paper reports on a series of preliminary studies in which on Self-Levelling Mortar (SLM) have been considered as a containment and encapsulation medium. Following the physical and moisture transport characterization of specimens, these were then placed in a fresh solution of landfill leachate. This experimental method was used to simulate accelerated conditions as might be expected in real situations where the concrete would be in contact the soil mass saturated with landfill leachate. Specimen placed in the leachate solution for a period of 1-year following which further tests were used to characterise their relevant performance characteristics including compressive strength development, water absorption and capillary absorption.

2 EXPERIMENTAL

2.1 Materials

The basic constituens of the SLM mix included different proportion of the following materials: cement, blast furnace slag, silica fume, limestone power and fine aggregate. The cement used was CEM II/A-L 42,5 R conforming to European Standards EN-197/1, and manufactured by Italcementi (Salerno, Italy). The aggregate used was river sand 4-mm maximum size. The blast furnace slag (GBFS) was a granulated product ground to a Blaine fineness of about 4500 cm^2/g, with a particle

size ranging from 1-10 μm and with basicity coefficient [Kb=(CaO+$MgSO_4$)/(SiO_2+Al_2O_3)] equal to 1.08. The silica fume (SF) was a commercial material produced by ELKEM – Norway. Values for the chemical composition and specific surface area of all the above materials,including powdered limestone, are proviced in Table 1; L, SF and BFS refer respectively to limestone, silica fume and blast furnace slag.

The superplasticizer (SP) used was an acrylic-based product having 40% solid content and a specific gravity of 1.2 kg/dm^3. It was used in all the SLM mixtures and its amount was proportioned to ensure a constant workability. The water content of SP was considered during the mix-design phase. To enhance stability an inorganic Viscosity Modifying Agent (VMA) was also used in all SLM mixtures [Khayat K.H. & Guizzani Z. 1997, Rols S. *et al.* 1999].

Table 1. Chemical composition and specific surface area of the limestone cement, slag, silica fume and limestone powder.

Oxides (%)	CEM II	GBFS	SF	L
SiO_2	20.56	35.16	93.00	0.30
Fe_2O_3	3.21	1.40	0.70	-
Al_2O_3	4.88	10.76	0.80	0.10
CaO	60.93	41.91	0.20	55.10
MgO	1.62	7.68	0.60	0.50
Na_2O	-	0.11	0.60	-
K_2O	-	0.14	1.00	-
SO_3	2.78	1.92	-	-
TiO_2	-	0.32	-	-
L.O.I.	5.76	1.78	1.50	43.00
Specific surface area, cm^2/g	3970	4500	200000	4250

2.2 Mixtures Proportion

Four SLM mixtures were designed in addition to a conventional mortar (CM). A vibrating table was used to prepare specimens cast with CM. Table 2 shows mixture proportions for all the mortar specimens. In this table, the first part of the mixture code gives information on the mineral additions contained in the mortar, while the second part indicates the kind of mortar (SLM for Self-Levelling and CM for Conventional Mortar). The mixtures used presented similar proportions in terms of the aggregate to cement ratio.

Table 2. Mortar mixture proportions.

	Composition, g						
Mix code	Sand (mm)	CEM II	BS	SF	L	SP	VMA
CM	1956.3	525.0				7.9	
SLM	1883.2	591.0				5.5	2.4
L-SLM	1910.4	547.5			54.8	6.4	2.4
SF-SLM	1879.8	567.0		45.4		8.4	2.5
BS-SLM	1913.3	547.5	54.8			7.0	2.4

The water to cement ratio was kept constant at 0.5 for all the mixtures, moreover the water/ (cement + powder) ratio was similar for all SLMs. The total amount of binder (including cement, ground limestone, blast furnace slag and silica fume) was about 600 g.
For all mixtures 40 x 40 x 160 mm^3 specimens were prepared and cast. After casting the specimens were cured for 24 hours and then removed from the moulds and moist cured at 20 °C. After 28 days, test specimens were dipped in a leachate solution whereas the control specimens were stored in

laboratory conditions to be used as reference specimens. The volume ratio between the specimens and the aggressive solution was 0.33.

The main chemical characteristics of the leachate solution are reported in Table 3.
According to UNI EN 206-1, the leachate solution used is classified as a chemically strong corrosive agent. The exposure classes for concretes subject to chemical attack by natural soil, groundwater, sea water and waste water are assigned as follows: XA1-chemically weak corrosive ($SO4^{2-}$ concentration ≥ 200 and ≤ 600), XA2-chemically moderate corrosive ($SO4^{2-}$ concentration ≥ 600 and ≤ 3000) and XA3-chemically strong corrosive ($SO4^{2-}$ concentration ≥ 3000 and ≤ 6000).

Table 3. Chemical composition of leachate solution.

pH	8.2
Conducibility	18.06 mS
C.O.D.	1880 mg/l
Salinity	8768 mg/l
Sulphate	5169 mg/l
SiO_2	24.5 mg/l
Phosphate	58.2 mg/l
Fe	0.6 mg/l
Ni	<0.1 mg/l
Pb	<0.1 mg/l
Cu	<0.1 mg/l
Cr	<0.1 mg/l
Zn	<0.1 mg/l
Cd	<0.1 mg/l

2.3 Methods

In order to prepare all the mortar mixtures, a 3-dm^3 mixer was used. After mixing, fresh mortars were employed to determine the slump flow. The slump flow test measures the mean diameter of mortar spread after removal of the slump cone. A spread of at least 250-mm diameter is required for self-levelling mortars [Bignozzi M.C. *et al.* 2003]. All the mixtures prepared were characterized by slump flow values according to this limit and did not show any segregation phenomena.

Water and capillary absorption were also measured. Capillary absorption is described by the capillary absorption coefficient. It was measured following the procedure given in the Italian standard Normal - 11/85. Three specimens (40 x 40 x 160 mm^3) were used for each data point and dried to constant mass. Their water uptake was measured for 3 days. The mass of water absorbed per unit area is plotted as a function of the square root of time. The capillary absorption coefficient is the slope of this straight line.

Water absorption was determined by complete immersion of specimens in water at atmospheric pressure whereas the total porosity of the specimens was measured using a mercury intrusion porosimeter (Thermo Finnigan 140-240).

To evaluate the strength development, compressive tests were carried out after 7, 28, 90 and 365 days of curing in water. The specimens were kept covered with a wet cloth and a plastic sheet during the first 24 hours; after this period, they were cured in water until the test age. The specimens were dried in air for two hours prior to testing. Four prismatic specimens (40 x 40 x 160 mm^3) were broken for each data point. A 150 kN capacity compressive testing machine was used according to Italian Standard UNI EN 196-1.

Furthermore, another set of compressive tests were also carried out on mortars that had completed a 28-days water cure and thereafter had been immersed for 11 months in leachate solution. As well, following the long term contact with the aggressive solution the specimens were evaluated to determine changes in mass variations, the degreeof water absorption,porosity and coefficient of capillary absorption; the surface damages to the specimen were also observed and recorded.

3 RESULTS AND DISCUSSION

3.1 Compressive Strength Development

The compressive strength development up to one year's curing for all the mixtures is shown in Figure 1. The 365-day strengths obtained ranged from 60.6 to 82.1 MPa.

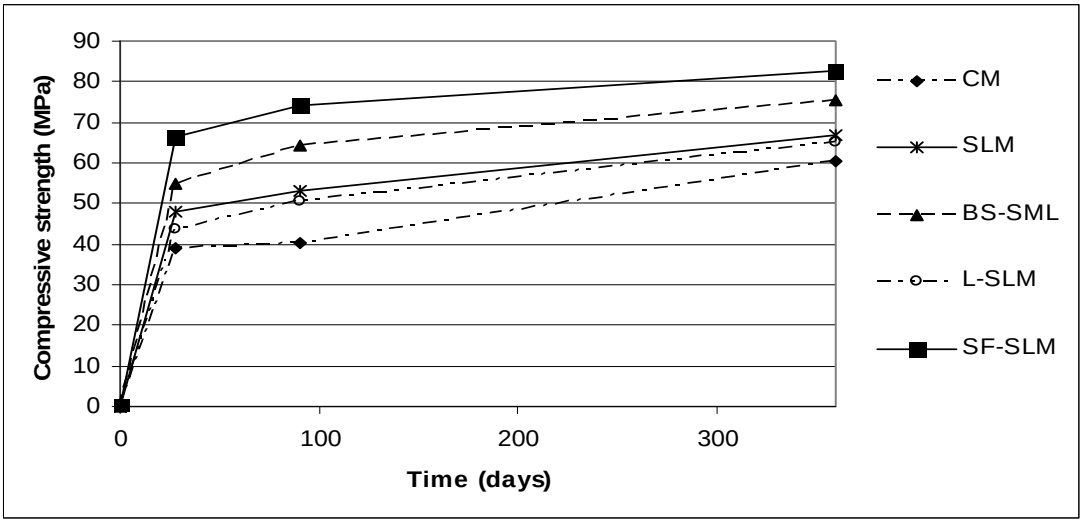

Figure 1. Compressive strength development with age, Mpa.

The maximum strength value was recorded for the SF-SLM mixture(Silica Fume-SLM), whereas the lowest was for the CM (Conventional Mortar) mix. The addition of silica fume gave higher compressive strength, at both early (7 days) and late ages, compared to other mineral additions. This is in agreement with the previously reported results by the authors in the case of SCC specimens [Colangelo *et al.* 2004]. However, as stated in literature, [Klug Y. & Holschemacher H. 2003] SLMs displayed a higher compressive strength than the conventional mortar mixes, regardless of the type of addtion used.

3.2 Durability

The values measured for the total porosity percentage of the specimens after 28-day water cure, are as follows: 11.74%, 10.85%, 5.61%, 10.70% and 6.17% for the mixtures CM, SLM, SF-SLM, L-SLM and BS-SLM, respectively . The lowest and the highest values observed in the case of SF-SLM and CM, respectively, are in agreement with the mechanical behaviour showed above. After 340-days of exposure to leachate a small reduction on total porosity has been observed for all mortars tested. Specifically, the values became 10.94%, 10.15%, 5.34%, 10.08% and 5,97% for the mixtures CM, SLM, SF-SLM, L-SLM and BS-SLM, respectively. The decrease in compressive strength after leachate immersion is shown in Figure 2.

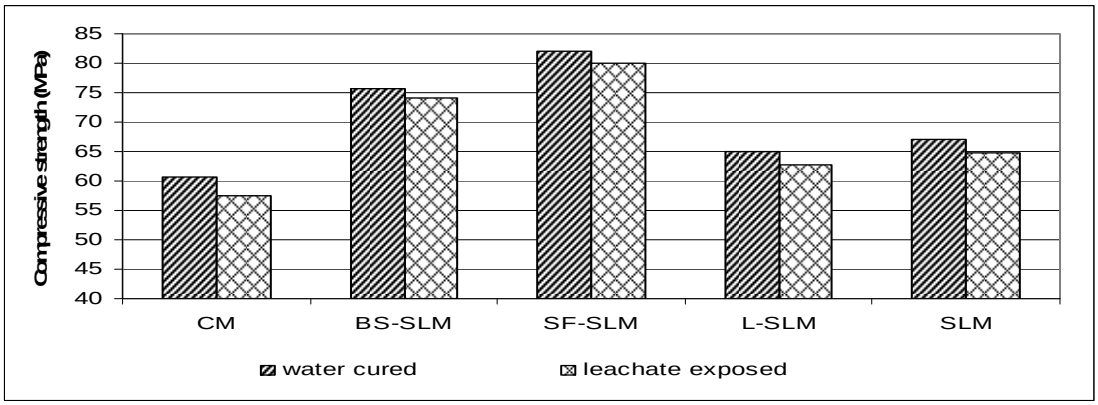

Figure 2. Compressive strength of mortars after water curing and leachate immersion, Mpa.

All the mixtures tested show a decrease of a few percentage points in terms of strength. In particular, the SLM mixtures shows a better result than the CM mixture, with decreases equal to 5.0%, 1.9%, 2.7%, 3.7% and 3.3% for mortars CM, BS-SLM, SF-SLM, L-SLM and SLM, respectively. There are no significant differences between the control (365-day water cure) and the exposed (28-day water cure and 11 months exposure to leachate) specimens in terms of water and capillary absorption and variation in unit mass as shown in Table 4 and in Figure 3, respectively.

Table 4. Water absorption and capillary absorption of mortars.

	CM	SLM	L-SLM	SF-SLM	BS-SLM
Capillary Absorption (water cured) - mg/cm^2· √s	0.51	0.48	0.41	0.31	0.35
Capillary Absorption (leachate exposed) - mg/cm^2·√s	0.55	0.51	0.43	0.32	0.36
Water Absorption (water cured) - %	1.71	1.74	1.47	1.11	1.14
Water Absorption (leachate exposed) - %	1.80	1.79	1.50	1.13	1.16

It can clearly be seen that the BS and SF SLM mixtures show a enhanced behaviour in comparison to the other mortar mixes given that the coefficient of capillary absorption and percentage of water absorption is respectively less than 0.36 mg/cm2• √s and 1.16%, even after leachate immersion.

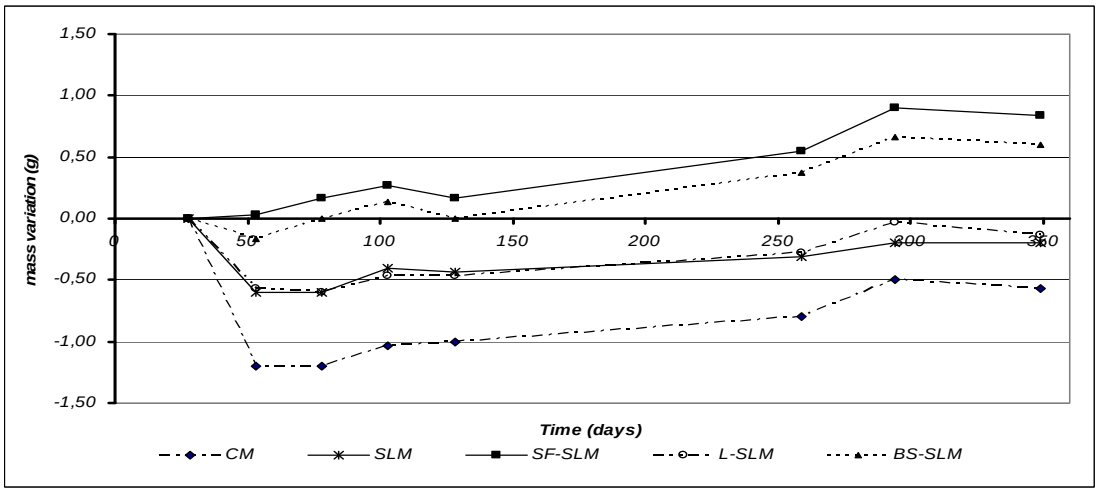

Figure 3. Mass variation of mortars at fixed times during leachate immersion, g.

The following pictures show the CM specimen (left) and SLM one (right) after 340-day to exposure to the leachate solution. It is possible to observe that there are no cracks in the specimen and the decay only involves the surface of the mortar.

Figure 4. CM specimen (left) and SLM one (right) after 340-day to exposure to the leachate solution.

4 CONCLUSIONS

The self levelling mortars investigated in this study show a good resistance to the presence of aggressive solutions,typical of leachates that emanate from municipal solid waste landfills. The use of these kinds of mortar mixtures, typically characterized by their high mechanical strength, make it possible to specify these mortars for the design of bulkheads used in landfills. In has been shown that, the attack by the leachate solution on the cement paste is only superficial and do not alter the physico-mechanical properties of the mortars. Moreover the use of mineral additivies can considerably improve the behaviour of the mortar mixtures when in contact with such type of leachates.

F.Zakaria[3]

T 11

ABSTRACT

Malaysia as the world's largest exporter of palm oil has been facing problem in disposing palm oil fuel ash, a by-product of palm oil mill since many years ago. The discovery made by researchers of Universiti Teknologi Malaysia last century in revealing the potential of this waste as a partial cement replacement in normal concrete has stem more efforts towards studying the possibility of using it in lightweight concrete production. Currently, investigation conducted proved that this material also can be integrated as a partial cement replacement material producing lightweight concrete known as Palm oil fuel ash cement based aerated concrete which possess adequate strength with lower density than OPC aerated concrete. This paper illustrates the durability aspect of this new agro blended cement based aerated concrete in terms of resistance towards aggressive chemicals such as acid and sulphate. Aerated concrete cube consisting 20% palm oil fuel ash and control specimen with 100% OPC were cast and then subjected to water curing for 28 days before immersed in the hydrochloric solution prepared using 0.3% hydrochloric acid having 99% concentration. The pH of the solution was controlled to about 2 throughout the immersion period of 1800 hours. The durability performance of the cubes involved the measurement of weight loss at a different period of immersion in the solution. In order to study the performance of this material in sulphate environment, a set of control specimen and another one consisting the same proportion of POFA were prepared before water cured for 28 days. Sulphate resistance of the binders was evaluated by measuring the expansion of mortar bars after immersion in 10% sodium sulphate solution for the period of 6 months. Finding will be discussing the performance of POFA cement based aerated concrete in both acidic and sulphate environments.

1 INTRODUCTION

Concrete, the oldest manufactured construction material used in building work all around the world has occupied a unique place with its unquestionable application use in the construction industry. This construction material has been subjected to endless research throughout the century thus resulting in fruitful findings which successfully lead to creation of value added concrete materials fulfilling to customers requirement. The availability of high-tech telecommunication network system nowadays, has indubitably assist active knowledge dissemination specifically among researchers involved in concrete research area, resulting in sharing of fascinating ideas such as converting worthless industrial or agricultural by-product available to be partially cement or sand substitute constituent. Implementation of unique ideas has results in discovery of new type of environmental friendly concrete with lower cost than the existing concrete or able to offer more benefits than the original one.

In Malaysia, aerated concrete which began to capture the interest of local contractors due to its lightness and easier handling during building process has also subjected to innovation process. In early 21st century, Faculty of Civil Engineering from Universiti Teknologi Malaysia has become the pioneer in the country attempting to integrate waste material in gas concrete production which well known as aerated concrete. The study on utilization of waste as partial constituent in aerated concrete started off with Arreshvhina [2002] whom integrated slag, a industrial waste as cement replacement and then followed by Mat Yahaya [2003] whom partially substituted sand partially with agriculture ash. The current researcher, Abdullah [2006a] has incorporated palm oil fuel ash as partial cement replacement successfully producing POFA cement based aerated concrete possessing satisfying strength. This approach is one of the effort to make use of the palm oil fuel ash, a by-product of palm oil mill that is generated abundantly in increasing volume throughout the year since Malaysian palm oil industry continue to grow in order to meet the customers demand. This achievement will have the double advantage towards palm oil mill whereby development of this material could increase the palm oil industry earnings and also a means of disposing the waste.

Glancing through on the discovery of POFA as a alternative constituent for cement production, Hussin & Abdul Awal [1996] has successfully manage to incorporate palm oil fuel ash as partial cement replacement for normal concrete enhancing the strength and durability of the new modified material known as POFA concrete. Then, usage of this material was broaden to other types of concrete when Sata, Jaturapitakkul and Kiattikomol [2004] successfully integrated a very finely ground POFA as partial cement replacement to produce high-strength concrete. Succeeding the findings, Faculty of Civil Engineering again discovered that it is possible to add palm oil fuel ash up to 30% as partial cement replacement in a type of concrete categorized as lightweight concrete known as POFA cement based aerated concrete [Abdullah et.al 2006b]. Though, few properties of this material has been looked into [Abdullah et.al 2006a, Abdullah et.al, 2006c, Abdullah et.al, 2006d] but durability aspect of this material still silent and this issue will be discussed in this paper.

2 MATERIALS AND EXPERIMENTAL PROGRAMME

2.1 Materials

Materials used in this study consisted of ordinary Portland cement, fine sand, POFA, aluminium powder, superplasticizer and water. The fine sand was local river sand that has been oven dried at the temperature of 110ºC for 24 hours and then sieved before stored in airtight container. Aluminium powder which is a gas foaming agent and a powder form superplasticizer was also employed in all aerated concrete mixtures. The POFA used is a by-product obtained from burning the remaining of extracted palm oil fibers and shells from a palm oil mill owned by Yayasan Pembangunan Johor which is located in State of Johor. The collected ashes were dried in the oven at the temperature of 110ºC ± 5 for 24 hours to remove moisture in it before sieved and ground until 99% of the ashes passes 45µm sieve during wet sieve test. A single batch of ordinary Portland cement (OPC) classed ASTM Type 1

was used throughout the experiment. Both chemical compositions of the OPC and POFA used in this work are shown in Table 1.

Table 1. Chemical compositions of ordinary Portland cement and palm oil fuel ash.

Chemical Composition	*OPC (%)*	*POFA (%)*
Silicon Dioxide (SiO_2)	**28.2**	**53.82**
Aluminium Oxide (AL_2O_3)	**4.9**	**5.66**
Ferric Oxide (Fe_2O_3)	**2.5**	**4.54**
Calcium Oxide (CaO)	**50.4**	**4.24**
Magnesium Oxide (MgO)	**3.1**	**3.19**
Sodium Oxide (Na_2O)	**0.2**	**0.1**
Potassium Oxide (K_2O)	**0.4**	**4.47**
Sulphur Oxide (SO_3)	**2.3**	**2.25**
Phosporus Oxide (P_2O_2)	**<0.9**	**3.01**
Loss On Ignition (LOI)	**2.4**	**10.49**

2.2 Test For Acid Resistance

Aerated concrete cube specimens (70.6x70.6x70.6mm) having a mix proportion of 1:1 for cement and fine sand by weight with fixed amount of aluminium powder and superplasticizer were cast. Another set of specimen with ash was also prepared in a similar way where OPC was replaced, mass for mass, by 20% POFA. The water cement ratio for OPC aerated concrete mix for both mixes was adjusted in order to produce specimens which possess similar density as POFA cement based aerated concrete mix. Then, all specimens were demoulded after 24 hours before subjected to water curing for 28 days prior to immersing them into test solution as shown in Fig. 1. The durability performance of both OPC and POFA concretes were determined by measuring the loss of weights of the samples at different periods of immersion hydrochloric acid solution prepared using 0.3% hydrochloric acid having 99% concentration. The pH of the solution was controlled to about 2 throughout the immersion period of 1800 hours [Abdul Awal, 1998].

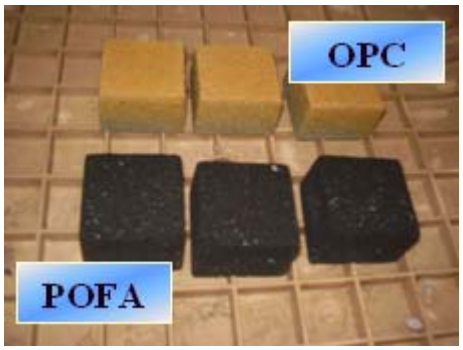

Figure 1. Specimens immersed in acid Hydrocloric solution.

2.3 Test For Sulphate Resistance

Data presented in this paper also include the durability performance of OPC aerated concrete acting as control and POFA cement based aerated concrete mortar bar immersed in 10% sodium sulphate solution. The procedure followed in conducting this test was in accordance with ASTM C1012-89. The design mix for OPC and POFA aerated concrete is similar to the design mix used for preparing cubes for acid test as mentioned above. Both samples either OPC or POFA were subjected to water curing for 28 days before immersed in the prepared sulphate solution. The performance of the specimens was evaluated in terms of expansion characteristic of mortar bars immersed in the sulphate

solution. Figure 2 illustrates few mortar bars ready to be measured for the expansion. Data reported in this paper were the averages of six measurements for both mortar bars and cubes.

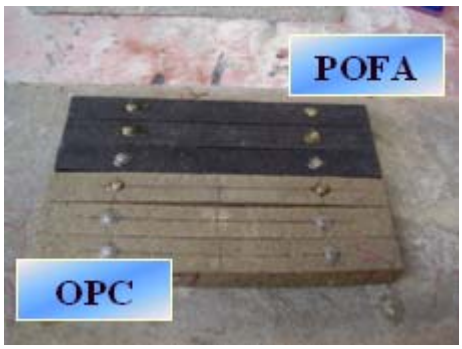

Figure 2. Mortar bar for Sulphate resistance test.

3 RESULTS AND DISCUSSION

3.1 Resistance to Acid Attack

The study on resistance to acid attack of aerated concrete cube specimens has been carried out by measuring the loss of weight of the samples continuously submerged in a 5% hydrochloric acid solution. Figure 3 reveals that aerated concrete with POFA exhibited better resistance towards the acid at all periods of immersion. Although both specimens begin to lose its weight as the period of immersion increased, percentage of weight loss for OPC cubes always higher than POFA specimen. In addition, the surface of OPC aerated concrete begins to soften and become loose. This fact has been highlighted by Zivica & Bajza [2001] whom mentioned that loss of mass is one of the signs of acidic attack, and crushing and dropping of material from concrete is one of the deterioration sign. By the end of the immersion period, OPC aerated concrete already loss 3.94% of its weight; POFA cement based aerated concrete on the other hand only loss 0.90%. It is interesting to note that surface of POFA cement based aerated concrete cube showed better surface condition than those with OPC aerated concrete in not only have considerable amount of surface softening but also faces loss of small particles on both surface and edges. Both visual observation and weight loss evidently analysis proves that POFA aerated concrete has higher resistance towards acid attack compared to control specimen.

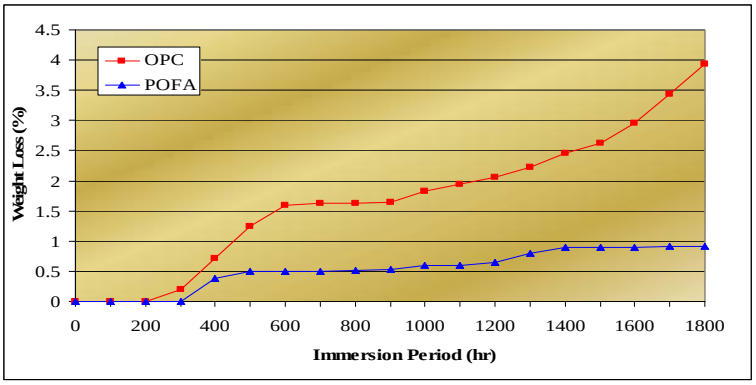

Figure 3. Comparative weight loss of OPC and POFA cement based aerated concrete specimens continuously immersed in Hydrocloric acid solution.

The better resistance of POFA specimen is expected not only because of the fact that POFA is being identified as a good pozzolanic material [Hussin & Abdul Awal, 1997] but also due to its low CaO content which is 4.24% in comparison to the high content of approximately 50% in OPC. Amount of

CaO presence in the binder material tend to play significant role in production of Calcium Hydroxide which is susceptible to acid attack finally leading to deterioration of hardened concrete material. This is because acid medium attacks mainly calcium hydroxide and then hydration products in cement matrix which leads to hydrolytic decomposition of hydration cement products followed by degradation of mechanical properties of cement based material [Zivica, 1999]. In addition, another researcher Mehta [1992] concludes that because of the higher content of CaO the hydration products of OPC contain about 25% CaOH which turns to be primarily responsible for the resistance of ordinary Portland cement exposed to acidic attack. As POFA contains a small amount of CaO, consequently the amount of CaOH would surely be less in the products of hydration.

3.2 Resistance to Sulphate Attack

Figure 4 shows the expansion patterns of POFA cement based aerated concrete and OPC specimen mortar bar throughout the immersion period in 10% Sulphate Solution. Basically, OPC aerated concrete bars had higher expansion value throughout the immersion period than that of POFA specimen bars. OPC mortar bar begin to exhibit significant expansion starting from 4th week when at the same time it was observed the development of crack at both end of the specimen. However, POFA specimen remains intact although there is slight expansion which is far lower than the control specimen. After 8 weeks of immersion period, it was noted that the expansion of OPC aerated concrete bar were 18.4 % having map cracks all over the specimens causing he mortar bars to disintegrate before measurement can be taken at the following week. On the other hand, POFA specimen bar expansion was as low as 1.92 % without any crack development on it. Elongation of OPC mortar bar compared to POFA specimen can be observed in Figure 5. It is justifiable for aerated concrete to exhibit significant expansion after four weeks exposed to Sulphate solution as compared to other types of concrete that been studied by Cao et.al [1997] and Abdul Awal [1998] that took more than 20 weeks for the specimens to exhibit similar pattern of failure as presented in this study. This is because aerated concrete which is a very porous material allows the sulphate solution to penetrate the internal structure of the material permitting fast response towards sulphate ion resulting in formation of cracks and elongation.

Discussing on the performance of OPC and POFA specimen, it is obvious POFA cement based aerated concrete mortar bar possess higher resistance towards Sulphate attack. Basically, the results obtained suggested that POFA as a partial cement replacement in aerated concrete could improve the sulfate resistance of this lightweight concrete. This is because according to Neville [1995] mortar or specimens having pozzolanic materials exhibit better chemical resistance that specimens with Portland cement due to the depletion of calcium hydroxide liberated during the hydration process, thereby reducing the amount of free calcium hydroxide for leaching and rendering the aluminium-beraing face inactive. Since POFA also a pozzolanic material, integrating it as partial cement replacement lead to reduction in the amount of C_3A, hence, all the aluminate bearing phases will accordingly be reduced. Basically, inclusion of POFA not only successfully reduce the amount of $Ca(OH)_2$ formed during the hydration of Portland Cement , which is susceptible to Sulphate attack but also the pozzolans presence reacted with the calcium hydroxide eventually reducing amount of $Ca(OH)_2$ that is susceptible to sulphate attack while at the same time producing a secondary calcium silicate hydrate (C-S-H).

Following that, the pozzolanic reactions contribute to space-filling process [Colak, 2003] whereby the secondary C-S-H formed were deposited in the pores making blended cement impermeable and therefore, the sulfate ions cannot easily penetrate through the concrete matrix which also become dense [Al-Amoudi, 2002]. Generally, addition of POFA not only decrease the amount of $Ca(OH)_2$ formed, but also contributed towards formation of concrete with lower permeability as a result of pozzolanic reaction that refines the pore structure and its capability to be filler because of its small particle size. This fact has been supported by Jaturapittakul et.al [2006] whom justified that use of POFA to replace Portland Cement not only decreases the $Ca(OH)_2$ content of hydrated cement but also serves as a filler and reduce voids between the aggregates and hydration products, leading to denser concrete.

On the other hand, OPC aerated concrete is susceptible to sulfate attacks due to its larger amount of $Ca(OH)_2$ and the condition of the pore structure which is bigger makes this highly permeable material possess lower resistance towards sulfate attack. The weakness of concrete consisting 100% OPC has been highlighted by Colak [2003] whom mentioned that the presence of Tricalcium Aluminate (C_3A) and Tetracalcium Aluminoferrite (C_4AF) contents in Portland Cement tend to react with sulfates to form ettringite which causes expansion and disintegration of the hardened Portland Cement pastes. As for the permeability aspect, Khatri and Sirivivatnon [1997] added that it is an important property that directly affects the durability of concrete against sulfate attack. This is because concrete with bigger pore structure due to existence of gaps among aggregates and hydrated product is more susceptible to penetration of sulfate because of its less permeable nature. In conclusion, it can be said that the lower amounts of calcium hydroxide in this agro blended cement based aerated concrete which also possess finer pore structure that reduce its permeability provides a considerable improvement in the durability of these composites towards sulphate attack.

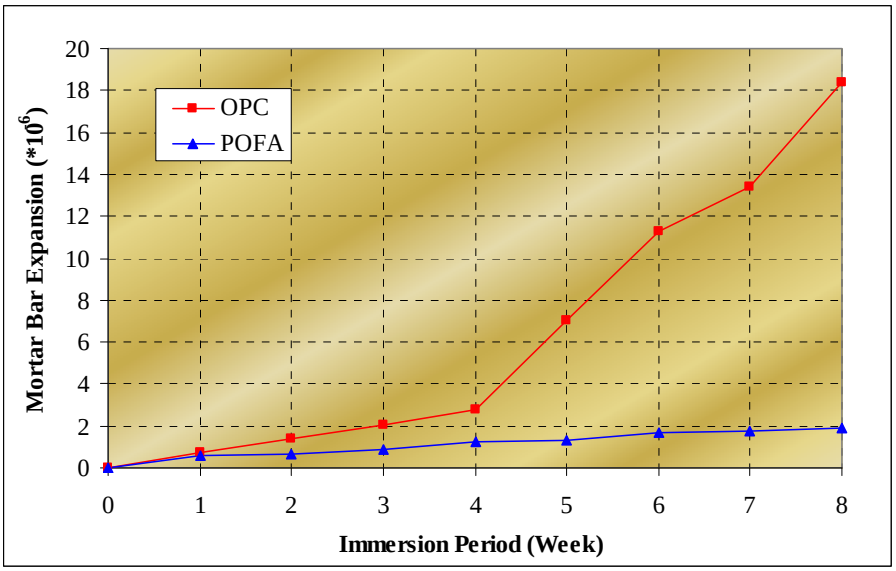

Figure 4. Expansion of OPC and POFA cement based aerated concrete mortar bar during the immersion period in 10% Sodium Sulphate solution.

Figure 5. OPC specimen expand more than POFA specimen.

3 CONCLUSION

The work presented in this paper indicates that both acid and sulphate resistance of aerated concrete improves with the integration of POFA as partial cement replacement material. Integration of POFA

which possess very low content of CaO is responsible to produce lower amount of Calcium Hydroxide which is susceptible to both acid and sulphate attack. Therefore, inclusion of POFA in aerated concrete not only able to reduce Calcium Hydroxide formed in the first place but also able to make use of the available $Ca(OH)_2$ during pozzolanic reaction thus successfully refine the pore structure of agro blended cement based aerated concrete eventually producing a more impermeable matrix as compared to specimen consisting 100% OPC aerated concrete. Conclusively, POFA cement based aerated concrete which consist POFA with lower amount of CaO play important role to make this material be superior in terms of acid and sulphate resistance as compared to OPC aerated concrete.

ACKNOWLEDGEMENTS

The authors would like to extend their gratitude to the entire management team of palm oil mill in Ladang Alaf owned by Yayasan Pembangunan Johor for the cooperation and support in providing the palm oil fuel ash samples. The contribution by the staff from Structure & Material Laboratory of Faculty of Civil Engineering, Universiti Teknologi Malaysia where the research was carried out is gratefully acknowledged. Financial support from the Construction Industry Development Board of Malaysia (CIDB) is greatly appreciated. The researcher also wishes to thank Universiti Malaysia Pahang for the provision of study leave.

Effect of the Type of Supplementary Materials and Viscosity Enhancing Admixture on the Durability of Self-Compacting Concrete

Mohammed Sonebi [1]
Vincent O'Donoghue [2]
Gerard Keogh [3]

T 11

ABSTRACT

Self-compacting concrete (SCC) is designed to exhibit high deformability and moderate viscosity to maintain homogeneity and adequate stability. Any concrete should have high impermeability and low chloride diffusion to reduce the risk of corrosion and enhance service life. Permeability of concrete is influenced by the porosity and the interconnectivity of pores in the cement paste and the micro-cracks in concrete, especially at the interface of the paste-aggregate. The movements of gases, liquids and ions through concrete is important because of their interactions with concrete constituents including pore water which can alter the integrity of concrete directly and indirectly, leading to the deterioration of structures. In this study, the effect of supplementary materials such as limestone powder (LSP), pulverized fuel ash (PFA), ground granulated blastfurnace slag (GGBS) and viscosity enhancing admixture (VEA) on the durability of self-compacting concrete was investigated. All mixes were design for strength grade C40. The filling ability, passing ability and segregation were measured by slump flow, V-funnel, L-box and column segregation tests. The concrete compressive strength was also evaluated. The air permeability, water permeability, capillarity absorption, carbonation, and freeze-thaw were used to assess the durability of SCC and compared to traditional concretes. The results showed that SCC mixes using GGBS or PFA had improved transports properties, greater resistance to freeze-thaw and carbonation than the traditional concretes.

1 INTRODUCTION

Self-compacting concrete (SCC) is considered to be one of the most rapidly emerging technologies in concrete. SCC is a material that meets a unique combination of performance and uniformity requirements that cannot always be achieved by using conventional constituents and usual construction practices [Sonebi & Bartos 2001, 2002, Sonebi et al. 2005]. The durability of concrete is mainly influenced by the transport of potentially aggressive substances. Majority of the influential properties of hardened concrete are related the quantity and characteristics of various types of pores in the cement paste and aggregate components of the concrete. The durability of concrete was assessed by measuring the permeation properties such as absorption, permeability. This described the movement of gases, liquids and ions through concrete, and it is important because of their interactions with the concrete materials and the pore water which can alter the integrity of concrete, leading to the deterioration and damage of structures. The carbonation and freeze-thaw of concrete are very important for reinforced concrete. This paper reports the results of the transport properties of SCC mixes by investigating the air and water permeability measured with Autoclam test, capillarity absorption, the freeze-thawing and carbonation resistance tested according to RILEM recommendations [CPC 18, TC 116].

2 MATERIALS, MIX PROPORTIONS, AND TEST METHODS

2.1 Materials and Mix Proportions

The SCC mixes investigated in this study were prepared with Portland cement (Class 42.5), either ground granulated blastfurnace slag (GGBS) or limestone powder (LSP) or pulverized fluel ash (PFA) added as the filler. The reference mixes were made with 100%C, 30%PFA, and 72%GGBS. The PFA was obtained from bituminous coal from a Northern Ireland power station. The limestone powder was produced from carboniferous limestone of very high purity and finer than cement. The limestone had grading of 99.8% < 125 μm and 83% < 5 μm.

A continuously graded crushed basalt aggregate with a nominal particle size of 5-20mm and a well-graded quartzite sand from Lough Neagh, with a fineness modulus of 1.95, were used. The typical relative densities of the coarse aggregate and sand were 2.9 and 2.72, and typical absorption values 1.2% and 1.18%, respectively. A copolymer-based superplasticiser (SP) was used. This had a solid content and specific gravity of 40% and 1.10, respectively. SP was used from 0.60% to 0.95% (by mass of binder). Diutan gum was supplied by Kelco-crete which is an anionic polysaccharide gum as used as viscosity enhancing admixture (VEA). It was used as powder at 0.05% (by mass of binder). No air entraining agent was used in the mixes. The mix proportions are summarised in Table 1.

2.2 Test Methods

The slump flow test, V-funnel and JRing and settlement segregation column were used to evaluate filling ability, passing ability and segregation of SCC [Bartos et al. 2002]. The resistance to segregation was measured by the column segregation test which consisted of a PVC column divided into three equal sections of 190-mm diameter and 170-mm height, held together with circular metal clamps. This was filled with concrete and left to rest for 15 min.

For the transport properties, the air and water permeability of concrete was measured on the preconditioned slabs (250 x 250 x 75 mm) using the Autoclam Permeability system. More details of the test procedure can be found in reference Basheer et al. [1992]. The capillary absorption test determines the rate of absorption of water through a concrete surface and was carried out on the moulded bottom face of two 100 mm cubes according to RILEM recommendations [TC 116] of determination of the capillary absorption of water in hardened concrete (TC 116). The cubes were preconditioned at 105 ± 5°C until constant weight (8-10 days). The uptake of water was measured through weight gain of the cubes at intervals of 10 min, 30 min, 1 hr, 2 hrs, 4 hrs and 24 hrs in contact

with water. The sorptivity (mm/√min) was determined for each mix as the slope of the capillary absorption vs. √Time.

* Slump (mm)

To determine carbonation rates, three cores 50mm Ø x 75mm deep were cut from each slab (250 x 250 x 75 mm). The slabs were cured in tank for three days then placed in sealed polythene bags and stored for 80 days. The cores were placed in accelerated carbonation chamber with relative humidity (65-70%) and temperature 20 ± 2ºC, and CO_2 =10%, for 6 weeks. The depth of carbonation was measured according to the procedure described in RILEM CPC-18. All specimens, after 6 weeks kept in accelerated carbonation chamber, were split and spread with phenolphthalein indicator. The mean value of carbonation depth of three cylinders was calculated. The RILEM test for freeze-thaw [Setzer et al. 1996], 100 mm diameter cylinders and 125 mm high was used. The curved surfaces were painted and sealed with an epoxy coating to prevent moisture movement from sides. The samples were placed in containers and immersed in 15mm of 3% salt solution for one week. The samples were then transferred to individual cylindrical containers for starting the test. A 5 mm depth of their samples was immersed in the test solution in individual containers. Each cycle of freezing and thawing was for 12 h. The scaled material from the test surface was collected, dried at 100°C for 24 h and weighed periodically during the test. This was continued for 100 cycles.

3 RESULTS AND DISCUSSION

3.1 Fresh and Hardened Properties

The results of slump, slump flow, JRing, V-funnel, segregation and compressive strength at 3 d, 7 d, and 28 d are given in Table 1. The required value of slump flow for all of the SCC mixes was achieved all up 650 mm. All the results of the T_{50}, V-funnel, J-Ring and segregation were considered to satisfy

the requirements from the European SCC guidelines [2005]. As expected, the development of the compressive strength was strongly affected by the W/B ratio and filler types. However, all mixes achieved the compressive strength required (Grade 40). The compressive strengths at 28 d were ranged between 30.8 to 57.6 MPa. The relatively faster strength development of SCC-LSP compared to TC-OPC, particularly at early ages, is believed to be mainly due to the inclusion of fine limestone powder, which may have an accelerating effect on C_3S hydration and early strengths. The SCC mixes containing GGBS, instead of limestone powder, had lower compressive strength at 3 days compared to 100% C, but developed higher strength at 28 days. This was due to the slower, but prolonged reaction (hydraulic and pozzolanic) between cement hydration products and GGBS, which contributes significantly to strength. It can be observed that SCC-PFA and SCC-GGBS resulted in a high compressive strength at 28 d compared to the corresponding mixes TC-PFA and TC-GGBS due to the higher binder contents and lower W/B in case of SCC-PFA (0.40 vs. 0.48).

3.2 Durability Performance

The results of air permeability and water permeability of all mixes are plotted in Fig. 1. All SCC mixes show lower air permeability compared with the traditional mixes and the GGBS-SCC mix had the lowest air permeability index (API) followed by PFA-SCC and LSP-SCC. VEA-SCC mix had slight higher air permeability than PFA-SCC and LSP-SCC mixes. It can be also noticed that TC-GGBS had lower air permeability than TC-OPC and TC-PFA mixes. The addition of GGBS, PFA and LSP improved the paste matrix (denser surface concrete) and improved the interfacial transition zone (ITZ) property where micro cracks mostly starts, with GGBS and PFA being more effective [Zhu, Bartos 2003, Sonebi & Ibrahim, 2007]. PFA reduces the number and the size of pores during the hydration process (increased degree of hydration) and LSP improves particle packing [Bosilijkov, 2003] reducing capillary porosity. The lack of pore filling effect/capability in SCC-VEA and higher W/B ratio, resulted in a higher capillary porosity and increased interconnection of pores but was lower than the TC-OPC and TC-PFA mixes

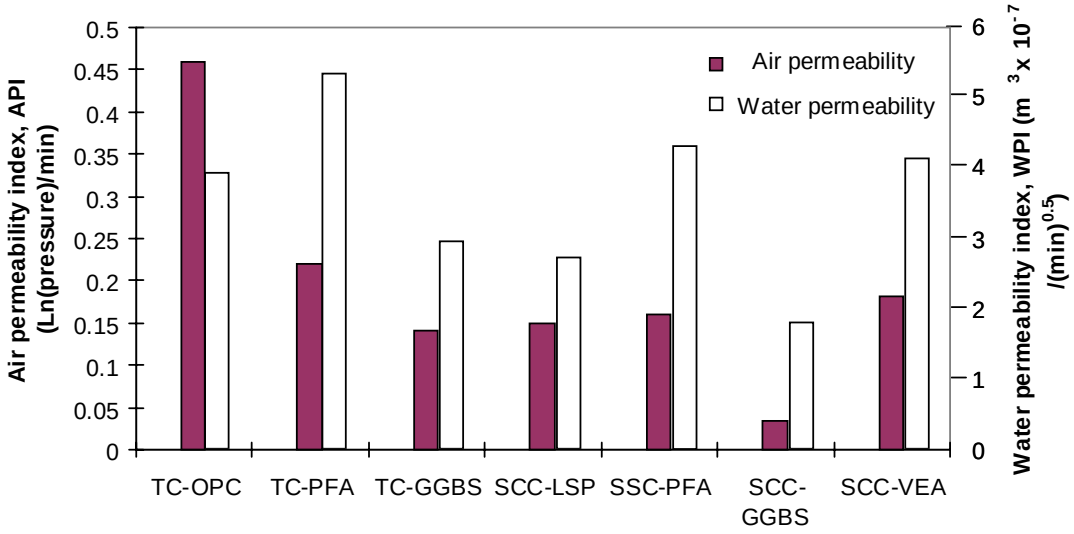

Figure 1. Variation of air and water permeability indexes (API & WPI) of all mixes.

The higher air permeability of TC-GGBS and TC-PFA compared to their corresponding SCC mixes could be due to the lack of homogeneity of TC-GGBS and TC-PFA as a result to the compaction process and their higher W/B ratio [Scrivener & Nemati 1996] and/or the lower binder to aggregate ratio (0.42 and 0.41 for TC vs. 0.56 and 0.67 for SCC) which means more poorer ITZ (more micro cracks within the concrete). The micro-cracks that occur in the ITZ are larger in width than most capillary cavities present in the cement paste matrix. These micro-cracks help to establish interconnections in the pore structure, increasing the permeability of the system. Higher coarse aggregate percentage also increases the bleed water trapping under the coarse aggregates which leads

to an increase in local w/c ratio (increase porosity) and increase permeability of the concrete [Basheer et al. 2005]. The protective quality index (Fig. 1) of SCC-GGBS was less than 0.1 which considered very good, and good for others SCC mixes (API < 0.5) [Basheer et al. 2005].

SCC-GGBS also had the lowest water permeability followed by SCC containing LSP, PFA and VEA, respectively. As in the air permeability test, the water permeability is affected by the amount and type of binder and W/B. The water permeability index (WPI) of SCC-GGBS was considered very good [Basheer et. al. 2005]. Similarly to air permeability test, TC-GGBS and TC-PFA mixes had higher water permeability compared to SCC-GGBS and SCC-PFA mixes which was caused by the compaction process, the higher W/B ratio of TC-PFA mix and most probably the lower binder to coarse aggregate ratio which contribute to capillary porosity and increase interconnection of pores.

The water permeability SCC-LSP and SCC-VMA was lower that that of TC-OPC. Tsivilis et al. [2003] suggested that, while air permeability was closely related with porosity, water permeability and sorptivity were more affected by the size and kind of pores which could explain the results. Further investigation of the microstructure and the surface quality is required to determine the pore size, distribution, and continuity more conclusively. It can be concluded that SCC incorporating GGBS or PFA led to a better water permeability which was due to the better interfacial zone and more refined pore structure of the paste matrix.

Fig. 2 presents the results of capillary absorption. It can be seen that SCC mix containing GGBS and PFA showed the lowest sorptivity value due to the pore filling effect of PFA's hydration products and refined structure of the cement matrix with GGBS. In the SCC-VEA the lack of pore filling ability by additional powder such as GGBS, or PFA or LSP, the higher W/B ratio and low binder/coarse aggregate ratio (0.46 vs. 0.56, 0.67 and 0.75) increased the porosity and led to the poorer ITZ area, which increased the interconnection of pores and therefore leading to higher sorptivity value. The SCC-LSP also had lower capillary absorption than SCC-VEA due to the improvement of packing density of concrete and having lower W/B ratio (0.33 vs. 0.58).

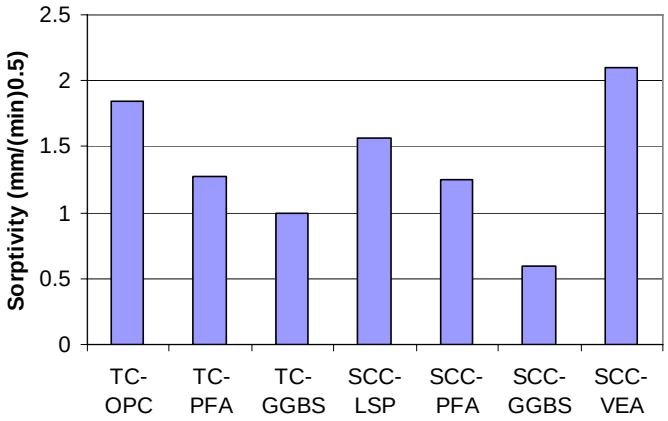

Figure 2. Variation of sorptivity of all mixes.

The carbonation depths of all SCC mixes are compared with the traditional concrete mixes as shown in Fig. 3. It can be observed that all SCC mixes exhibited lower carbonation depth, except SCC-VEA, compared to the traditional mixes. SCC mixes containing PFA and GGBS had the lowest carbonation depth due to the refined pore structure and more uniform interfacial transition zone (ITZ). SCC mix containing VEA exhibited high carbonation depth compared to SCC-LSP which they had similar compressive strength. Although VMA help to stabilize the components and control segregation, sedimentation and bleeding, the lack of pore filling effect/capability and higher W/B ratio results in a higher capillary porosity and increase interconnection of pores. Among SCC mixes tested in this study, having lower capillary absorption led to lower carbonation depth. This confirms other findings e.g. Audenaert and De Schutter [2007]. They reported that an increase in W/B, i.e. an increase in the

capillary absorption led to an increase in the carbonation depth of SCC. Anagnostopoulos et al. [2007] also reported that the improvement of carbonation of SCC is influenced by the W/B ratio, the composition and the amount of the binder system.

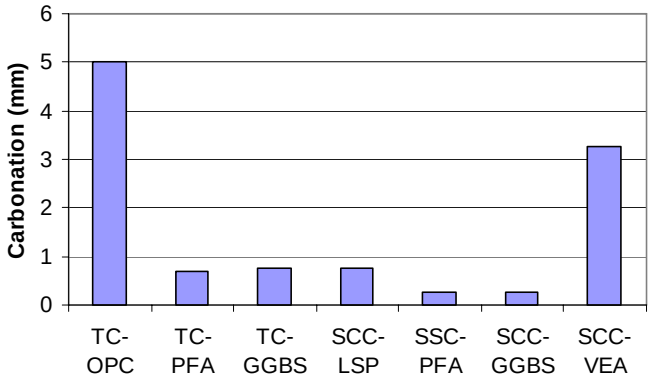

Figure 3. Variation of carbonation of all mixes.

Fig. 4 shows the variation of the freeze-thaw expressed as the cumulative scaling weight. The SCC-GGBS and SCC-PFA lasted through the 100 cycles of the test without being broken. The results indicated that SCC-GGBS and SCC-PFA mixes exhibited a greater resistance to freeze-thawing and sustained up 100 cycles compared to other SCC-VEA and SCC-LSP mixes which had higher weight losses at only 34 and 74 cycles, respectively. The cumulative scaling weights of SCC-GGBS and SCC-PFA after 100 cycles were only 26 g and 49 g, respectively. The SCC-LSP demonstrated better resistance than SCC-VEA. For example, it can be seen that for 200 g of lost of weight, SCC-LSP had resist until 36 cycles compared to 18 cycles for SCC-VEA. After 100 cycles, TC-GGBS had lost 3 times of weight compared to SCC-GGBS (81g vs. 26 g), and SCC-PFA lost only 50 g. SCC-PFA showed better resistance to freeze-thaw than TC-PFA. It can observed that SCC-LSP lost 300 g at 19 cycles of freeze-thaw compared to TC-OPC which it needed 42 cycles to loose similar amount of scaling. TC-PFA had performed well than TC-OPC.

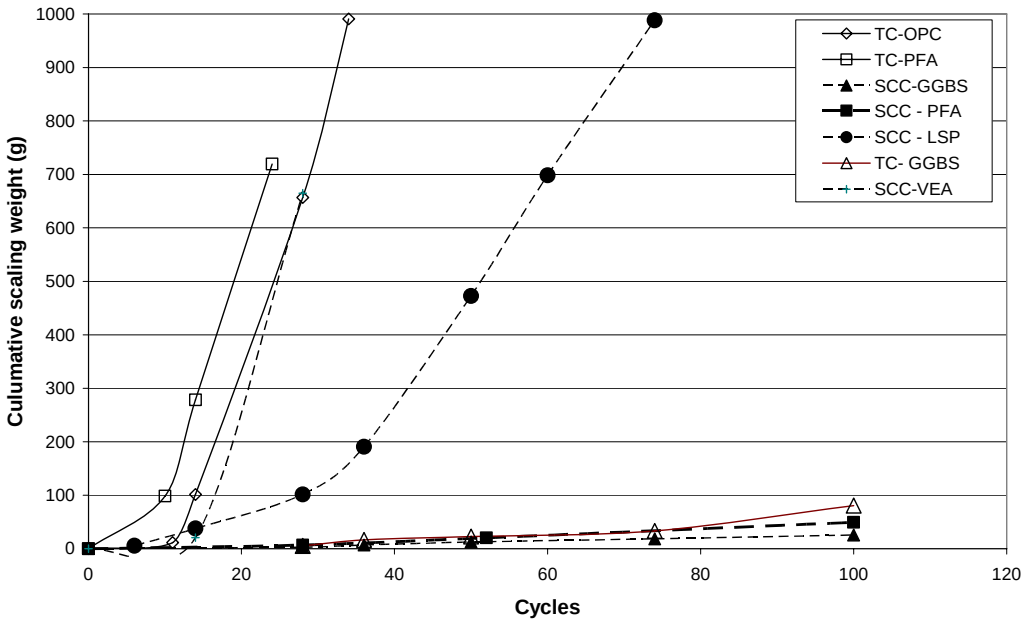

Figure 4. Variation of freeze-thaw of all mixes.

4 CONCLUSIONS

In this investigation, four SCC mixes have been investigated with three traditional concretes and the durability of these mixes was determined. The following conclusions can be drawn:

- The SCC mixes containing GGBS, PFA, LSP and VMA had lower air permeability compared to traditional mixes. For water permeability, SCC mix made with GGBS and LSP had the lowest water permeability compared to traditional concretes. SCC mixes containing GGBS exhibited better capillary absorption, but SCC-PFA demonstrated similar capillary absorption compared to TC-PFA. SCC-LSP indicated lower capillary absorption compared to TC-OPC. The highest capillary absorption was obtained with SCC-VEA.
- All SCC mixes except SCC-VEA demonstrated lower carbonation depth than the traditional concretes due to mostly to their lower W/B ratio and the type of binder which seems the main factors governing the carbonation.
- SCC-GGBS and SCC-PFA mixes showed the highest freeze-thaw resistance. However, SCC-LSP mix had better freeze-thaw resistance than SCC-VEA.
- Among the four SCC mixes, SCC mix made with VEA exhibited the highest air permeability, water permeability, capillary absorption, and the lowest resistance to freeze-thaw and carbonation. The SCC mix containing GGBS and PFA resulted in the best durability performance.

T 11

ABSTRACT

Deterioration of reinforced concrete structures caused by corrosion of steel bars is a major problem in concrete structural durability. Normally, the Galvanostatic method is used for accelerating steel bar corrosion in concrete for laboratory testing. However, the corrosion distribution on the steel bar is different when the corrosion is induced between using Galvanostatic method and under natural climate environment. Recently, artificial climate environment has been used to induce corrosion in the laboratory. This method is becoming important in assessing the durability of concrete structures, because of the same electro-chemical corrosion process and similar corrosion distribution on the surface of the steel bar between natural and artificial climate environment. In this study, two groups of reinforced concrete beams were degraded as a result of the corrosion of steel bars under artificial climate environment and using Galvanostatic method respectively. The test results between the two groups show obvious differences on the structural behavior based on identical width of corrosion cracking. Because the electro-chemical corrosion processes in the beams between the two corrosion ways are different, the different corrosion processes lead to the different corrosion distribution. Further comparison studies on the mechanical behavior of corroded bar, the bond strength and the corrosion distribution on the surface of steel bar verified the analysis of the electro-chemical corrosion process.

1 INTRODUCTION

Corrosion of steel reinforcement is one of the major causes inducing deterioration of reinforced concrete structures. Accelerated test technique of steel bar corrosion in concrete is significant for evaluating structural deterioration in laboratory. Galvanostatic method and artificial climate environment are used to accelerating steel bar corrosion in concrete. But two accelerated test techniques will lead to different corrosion distribution on the surface of the steel bar in concrete because of different corrosion process using the Galvanostatic method or under a natural environment. Different corrosion process will lead to different corrosion characteristics on the surface of the steel bar and different deterioration of the bond behavior between the corroded bar and concrete, and lead to different bearing capacity and ductility behavior of the structure.

In this research, the corrosion process and the differences of the structural behavior under climate environment and Galvanostatic method are studied. The purpose is to verify that the artificial climate environment will be an effective accelerated technique for the durability test instead of the Galvanostatic method. Identical reinforced concrete beams were corroded under the two accelerated corrosion techniques, and deterioration mechanism of corroded reinforced concrete beam was discussed.

2 EXPERIMENTAL INVESTIGATIONS

2.1 Reinforced Concrete Beams for Testing

The reinforced concrete beams employed for testing are divided into two groups. The first group (Group C) is corroded under an artificial climate environment; the second group (Group G) is corroded using the Galvanostatic method. The concrete composition, reinforcement and dimension of the test beams are identical in the groups. The structural behavior comparisons of the corroded beams are carried out under the same corrosion crack width caused by steel bar corrosion.

The dimensions of the test beams are b×h×l=100×160×1500mm, the concrete grade is C25, and the mix proportions by weight are C:S:A:W = 1:1.75:2.98:0.55. Normal Portland cement #32.5, river sand and coarse aggregate of crushed basalt stone with a maximum aggregate size of 16mm were used. The beam, shown in Fig.1, was simply supported with a span of 1.2m, and two concentration forces were applied on the span. The arrangement of reinforcement in the test beam is shown in Fig. 2, and the thickness of the concrete cover is 15mm. Three different corrosion-cracking widths were selected for the corrosion control and comparisons. The beams are loaded to failure after corrosion. The grouping of the specimens is shown in Table 1.

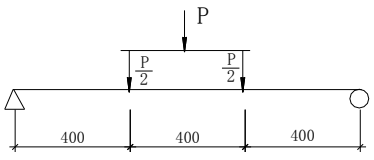

Figure 1. Arrangement of loading on the test beam

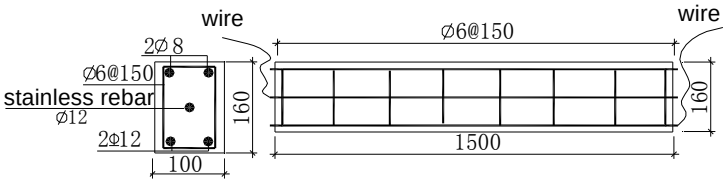

Figure 2. Arrangement of reinforcement

2.2 Artificial Climate Environment for Accelerating Corrosion

The corrosion process of the test beams under an artificial climate environment can be accelerated by way of high temperature, high humidity and repeated wetting-drying cycles. Corrosion of the test beams in this group was carried out in the artificial climate room controlled by a computer system. The artificial climate conditions in this testing were temperature T=40^{o}C, humidity RH=80%, and salt water (5% NaCl solution) spraying (1 hour) and infrared light shining (7hours) for wetting-drying cycle.

Table1. Comparisons of capacity and ductility of corroded beam.

Beam No.	Corrosion crack width mm	Yielding capacity P_y kN	Ultimate capacity P_u kN	Ductility f_y/f_u
Beam C-0	0.0	49.11 [1.00]	51.67 [1.00]	3.84[1.00]
Beam C-1	0.5	42.51 [0.86]	49.84 [0.96]	3.23[0.84]
Beam G-1	0.5	44.35 [0.90]	48.38 [0.94]	2.44[0.63]
Beam C-2	0.8	43.03 [0.87]	46.21 [0.89]	2.75[0.72]
Beam G-2	0.8	32.21 [0.66]	36.50 [0.71]	2.30[0.60]
Beam C-3	1.2	31.90 [0.65]	33.39 [0.64]	2.13[0.55]
Beam G-3	1.2	--	21.26 [0.41]	---

2.3 Galvanostatic Method for Accelerating Corrosion

The test beam is immersed in a solution of 5% NaCl for 7 days, and then direct electric current is impressed on the steel. The position of the corroding steel bar in concrete is higher than the level of the solution for avoiding the dissolution of oxidation products. The two bars (main tensile reinforcement in the beam) act as the anode and the stainless bar in the centre of the beam section acts as the cathode. The amount of corrosion and the current density can be estimated by Faraday's law based on the corrosion degree. A current of 1A (ampere) was applied in the corrosion process. During the corrosion process, the current density should be kept constant. The process was continued until the crack width achieved the desired value shown in Table 1.

3 STRUCTURAL BEHAVIORS OF CORRODED BEAMS

3.1 Capacity and Ductility

Fig.3 and Fig.4 show the comparisons of the structural behavior between non-corroded (no corrosion) beams and the corroded beams, and shows the comparisons of the structural behavior between the beams corroded under artificial climate environment (ACE) and using the Galvanostatic method (G method) based on the corrosion crack width 0.8mm or 1.2mm. The corresponding values of capacity and ductility are shown in Table 1.

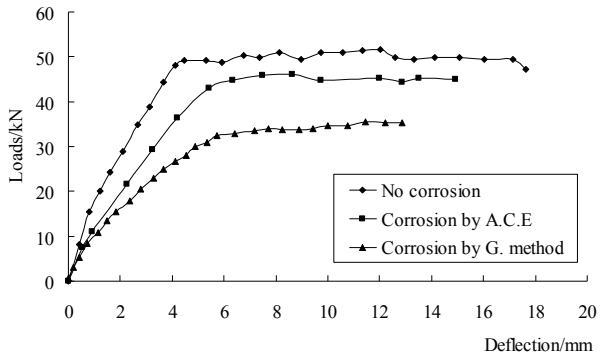

Figure 3. Comparisons of beam behavior under loading (Corrosion crack width 0.8mm)

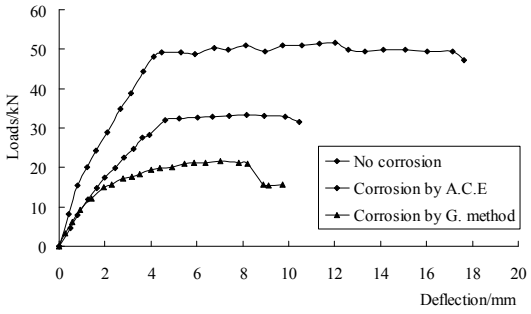

Figure 4. Comparisons of beam behavior under loading (Corrosion crack width 1.2mm)

In the Table 1, Group Beam C is corroded under artificial climate environment, Group Beam G is corroded using the Galvanostatic method; The value in **[--]** indicates ratio of the value of corroded beam and the value of no corrosion beam.

3.2 Failure mode of corroded beam

The corroded beams (Beam C-1, 2 and Beam G-1, 2) show similar failure mode. The mode shows that the tensile bar yielded first in the tension zone, and then underwent obvious plastic deformations of the bar, and finally, concrete crushed in the compression zone of the beam. This failure mode shows ductile characteristics.

When the corrosion crack width reaches 1.2mm, the comparison of failure modes between Beam C-3 and G-3 show a clear difference. Beam C-3 corroded under artificial climate environment still showed ductile failure characteristics. However, Beam G-3 corroded using the Galvanostatic method showed bond failure mode. This failure shown in Fig.5 is caused by bond failure of the main tension corroded bar.

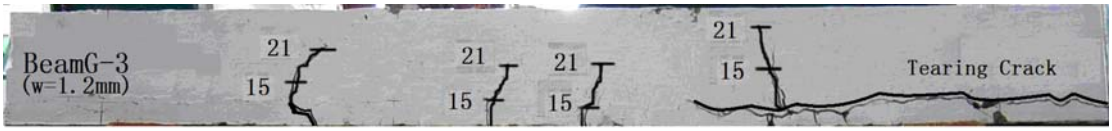

Fig. 5 Bond failure pattern

4 DETERIORATION MECHANISM OF CORRODED REINFORCED CONCRETE BEAM

4.1 Corrosion Characteristics on Surface of Steel Bar in Concrete

After the structural behavior testing, the samples for observing corrosion distribution were drilled from the beams. Figs. 6 and 7 show corrosion distribution along the surface of the steel bar under artificial climate environment and using the Galvanostatic method respectively. The corrosion shows nearly uniform distribution around the steel bar corroded using the Galvanostatic method, but the corrosion was found at the surface of the steel bar facing the concrete cover mainly under artificial climate environment.

Figure 6 Corrosion distributions under artificial climate environment

Figure 7 Corrosion distributions using the Galvanostatic method

4.2 Mechanical Behavior of Corroded Steel Bars

After the structural behavior testing, the beams were broken and the steel bars were cut and removed for testing. The mechanical behavior comparisons of the corroded bars based on the same corrosion crack width were carried out. Table 2 shows the comparison results. In the table, the nominal yield and ultimate strength are the measured tension force by the nominal section area of the steel bar. The toughness is the deformation near tension failure in the 100mm zone divided by 100mm .

The corrosion characteristic of the steel bar corroded using the Galvanostatic method is nearly uniform; the loss of the section area of the bar is main factor influencing the mechanics behavior. The pit corrosion characteristic is found on the surface of the steel bar corroded under artificial climate environment, the stress concentration of the steel bar under tension testing is main factor influencing the mechanics behavior.

Table 2. Comparisons of mechanics behavior of corroded bar.

Beam No.	Corrosion crack width mm	Nominal yield strength MPa	Nominal ultimate strength MPa	Toughness (%)
Beam C-0	0.0	373.3[1.00]	536.1[1.00]	27.5[1.00]
Beam C-1	0.5	337.9[0.91]	436.1[0.81]	22.3[0.81]
Beam G-1	0.5	340.2[0.91]	507.3[0.95]	24.2[0.88]
Beam C-2	0.8	326.4[0.87]	419.1[0.78]	18.4[0.67]
Beam G-2	0.8	306.7[0.82]	435.0[0.81]	21.5[0.78]
Beam C-3	1.2	279.5[0.75]	352.9[0.66]	16.7[0.60]
Beam G-3	1.2	273.3[0.73]	405.1[0.75]	19.8[0.72]

4.3 Deterioration of Bond Strength between Corroded Bar and Concrete

Fig.8 shows the bond strength under artificial climate environment is high than using the Galvanostatic method under the same corrosion crack width. The deterioration degree of the bond strength based on the same corrosion crack width is different between the two accelerated corrosion techniques due to the different corrosion distribution on the bar surface. The main reason is the corrosion shows on the surface of the steel bar facing the concrete cover only under artificial climate environment and shows nearly uniform distribution around the steel bar corroded using the Galvanostatic method. Therefore, the bond strength of the main tension bars in Beam C-3 was higher than that in Beam G-3, this is reason why results in different failure modes of the two beams.

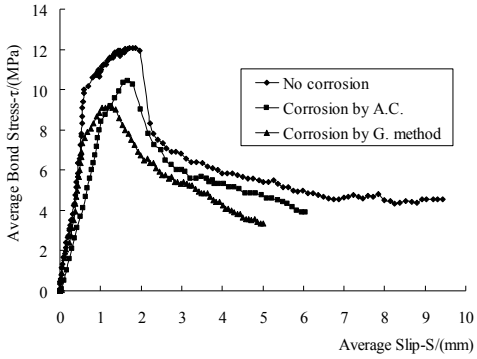

Figure 8. Comparisons of bond behavior (Corrosion crack width 0.8mm).

5 ELECTROCHEMICAL CORROSION PROCESS

5.1 Corrosion Process under Natural or Artificial Climate Environment

Chloride diffusion under natural or artificial environment is gradual processes proceeding from the concrete surface to the inside. The passivity of the steel bar facing the concrete cover is at first broken. Fig. 9 is a sketch of the corrosion process under natural or artificial environment, and shows that the anodes of electrochemical corrosion reaction is mainly located on the bar surface facing the concrete cover. Therefore, the corrosion distribution shown in Fig.6 mainly occurred on the surface of the steel bar facing the concrete cover under a natural or an artificial climate environment

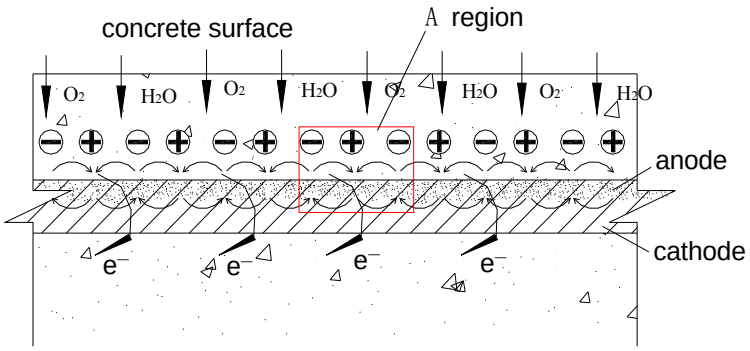

Fig 9. Corrosion process under natural or artificial climate environment.

5.2 Corrosion Process Using the Galvanostatic Method

Fig.10 shows the electrochemical process using the Galvanostatic method. In the reaction, the whole surface of the steel bar in concrete is the anode; the corrosion occurred almost entirely around the whole surface of steel. The corrosion characteristics shown in Fig.7 are almost uniform in distribution on the surface of the steel bar facing to and back of the concrete cover.

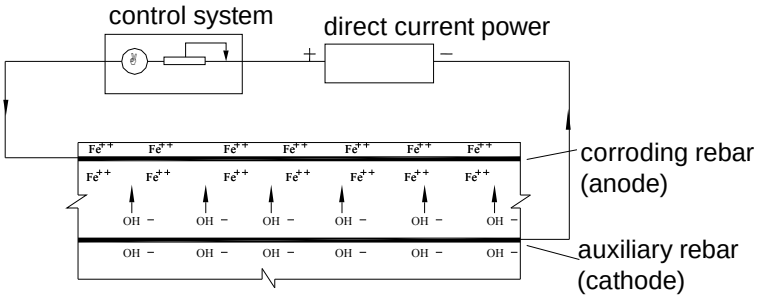

Fig 10. Corrosion process using the Galvanostatic method.

6 CONCLUSIONS

Based on the results of the experimental investigation using artificial climate environment and using the Galvanostatic method, the following conclusions are drawn:

(1) The steel bar in concrete can be corroded using the Galvanostatic method, but its electro-chemical corrosion process is different from the corrosion process under the artificial climate environment. The differences lead to different corrosion distribution on the surface of the steel bar. The corrosion mainly occurs on the surface of the steel bar on the side facing the concrete cover under artificial climate environment, however, the steel bar is corroded on the whole surface of the steel bar when using the Galvanostatic method.

(2) The corrosion of the main steel bar in the beam can reduce the bearing capacity and ductile characteristic, and can transfer the failure mode from under-reinforced beam failure to bond failure mode. Different corrosion characteristics on the surface of the steel bar, deterioration of the mechanics behavior of corroded bars and bond behavior of concrete and corroded bar are main reasons to cause the different structural behavior of the concrete beams corroded by two different methods of inducing corrosion.

(3) The corrosion process and corrosion characteristics of the steel bar under artificial climate environment are similar to that of corrosion under natural environment. Artificial climate environment as an accelerated laboratory test method is more representative than the Galvanostatic method.

Durability of Carbon and Stainless Steel Reinforced Concrete Members in Marine Environment

Toshihiko Yamamoto [1]
Toru Yamaji [2]
Seiji Mizuma [3]

T 11

ABSTRACT

This paper presents an experimental investigation of the carbon and stainless steel reinforced concrete beams in the marine environment exposed for five years. The corrosion resistance of carbon steels and alternative stainless steels under severe material, structural and environmental conditions was examined. Chloride was initially added to some specimens to examine the effect of internal chloride on the corrosion of steels. First, the specimens were subjected to loading and deformed to the limit displacement to examine the structural performance. The specimens had many cracks and the reinforcement yielded with scratches on the surfaces at the loading test. After that the specimens were exposed under seawater splash environment. In the exposure test an electric corrosion monitoring was conducted. The stainless steel reinforced concrete specimens with many cracks showed the outstanding durability in corrosion in the exposure test. Stainless steels were not affected by the internal and external chloride. The chloride content limit of the occurrence of corrosion for stainless steel is suggested from the test result to be more than 10 kg/m^3. In contrast, carbon steels were corroded heavily along with the cracks and lost the cross sectional area, especially in the outer lateral reinforcing bars. The monitoring was effective and in accordance with the test results. If use of the stainless steel for the structure of the marine under severe conditions is used with the monitoring system, it can become very effective.

1 INTRODUCTION

Although the life-time of concrete structures are expected to be long, the use of carbon steel does not always guarantee sufficient resistance to corrosion in severe environments. In spite of many experimental investigations of the corrosion of carbon steel have been done [Li et al. 2002, Paulsson-Tralla et al. 2002], its protection against steel corrosion has not yet been confirmed. To avoid corrosion, alternatively stainless steel can be used. Recently stainless steel reinforcements have been used in new construction and in repair work on existing structures to provide sufficient resistance to corrosion. Technical reports and standards on stainless steel have also been compiled [The Concrete Society 1998, ASTM 2001, BS 2001]. However, the information for designing and constructing stainless steel reinforced concrete structures is not sufficient. It is necessary to know the structural behaviors and corrosion resistance of stainless steel in concrete. In seismic zones, the post-yielding behaviors and the corrosion resistance of yielded stainless steel are important issues.

An experimental investigation was performed to examine the structural and durability performance of stainless steel reinforced concrete beams under severe loading and environmental conditions. First, a short-term loading test was conducted to examine the structural performance. Then, a long-term exposure test with the same short-term test specimens was conducted to examine the durability performance. Chloride was initially added to some specimens to examine the effect of internal chloride on the corrosion of steels. In the exposure test corrosion monitoring was conducted by an electrochemical investigation.

2 SPECIMENS AND MATERIALS

2.1 Specimens

The specimens are shown in Fig. 1 and Table 1. The specimens had a cross section of 180mm×300mm, 1750mm length, 1.74% flexural reinforcing ratio and 0.53% lateral reinforcing ratio. Stainless steel reinforcement was used for specimens S-1, S-2 and S-3. Carbon steel reinforcement was used for specimens N-4, N-5 and N-6. The specific concrete strength was 21 MPa for all specimens. The shear strength of the specimens was calculated by the Ohno-Arakawa equations [AIJ 1988] and exceeded the shear corresponding to the flexural strength [AIJ 1997]. In the concrete of specimens S-3 and N-6, chloride equivalent to 3.0 kg/m^3 of chlorine was added to examine the effect of internal chloride ions on steel corrosion. Two limit deformations for the loading test were set to produce different post-yielding situations of the specimens.

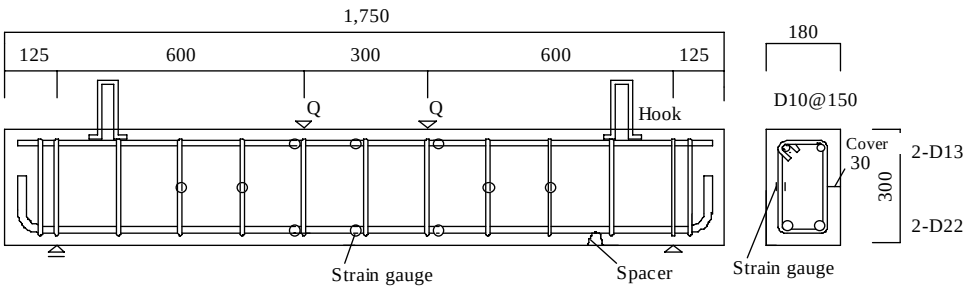

Figure 1. Specimen details (unit of length: mm)

2.2 Materials

The mix proportions and mechanical properties of concrete are shown in Tables 2. The concrete strength of the specimens was assumed to be the same as the test pieces taken at the time of casting.

and cured in a sealed condition. The strength of the concrete was 24.4MPa at the time of the loading test. Austenitic stainless steel SUS304 (Japanese Industrial Standard) was used. The chemical composition of the stainless steel is shown in Table 3. The mechanical properties of both reinforcing steels are shown in Table 4. Because stainless steels do not exhibit a well-defined yield point, the

proof strengths are determined as the stress at which the plastic strain equals 0.2% strain. The yield strengths of stainless steels and carbon steels are almost the same.

3 OUTLINE OF EXPOSURE TEST

3.1 Pre-Loaded Specimens

Before the exposure test the specimens were deformed under the load to certain limit deflections. The limit deflections at the centre of the specimens were 7.5mm (R=1/100) and 15.0mm (R=1/50), where R is the relative deflection angle between the specimen center and supports. They were assumed to be the deflections of the specimens at the fully yielded and ultimate strength, respectively. The concrete crack patterns of the specimens are shown in Fig. 2. Because the strengths of the stainless and carbon reinforcing bars were almost the same, the crack patterns were also about the same, except for the shrinkage cracks in N-6. The crack widths of the carbon steel reinforced specimens were relatively larger than those of the stainless steel reinforced specimens. The crack widths of specimens S-3 and N-6, which had the added chloride, were larger than those of specimens S-2 and N-5, which did not have chloride. The compressive side of the concrete of the 15.0mm deformed specimens crushed at the end of loading.

Table 5. Results of the loading test.

Specimen	Strength			Bar strain*			Maximum crack width	
	Calculated	Tested	Ratio	Longitudinal		Lateral	Front	Back

N-6	101	98.9	0.98	y	y	e	2.00	3.00

*y: yield, e: elastic

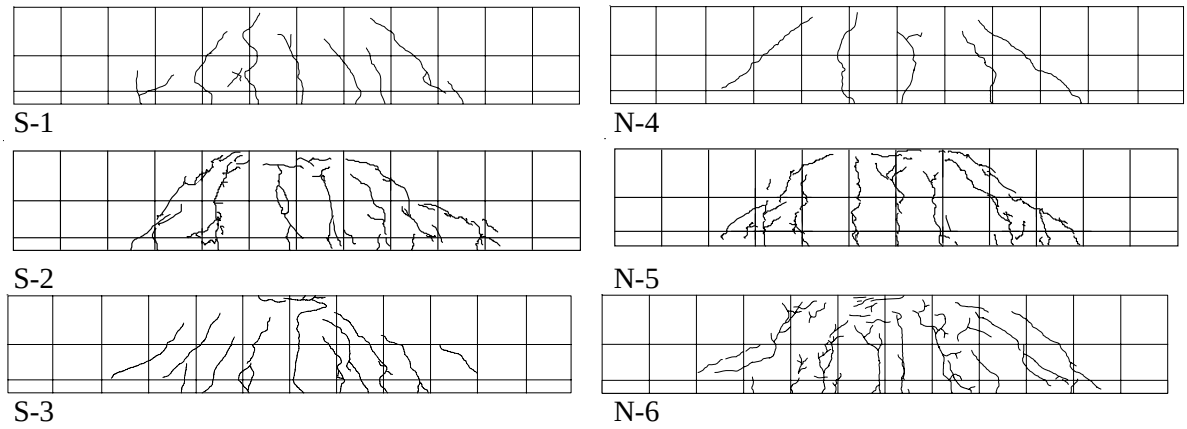

Figure 2. Crack patterns of the specimens

3.2 Test Procedures

The specimens were set on the exposure site in the Port and Airport Research Institute (Yokosuka, Japan) after pre-loading. The front face of each specimen was directed towards the sea. This test site was modeled as a splash zone in a marine environment. Seawater was splashed automatically by pumps twice a day for three hours, during the test. Visual observations and measurements of the half-cell potential were carried out periodically to investigate the corrosion of the stainless and carbon steel in the specimens. The measurement timing of the half-cell potential was three hours after the seawater splashing. The electrical connections to the steel bars in the concrete were made by a lead wire attached to the steel bars before the casting of the concrete. The reference electrode was a saturated KCl-Ag/AgCl electrode (SSE), which was placed on the concrete surface during the measurement. The probability of corrosion based on the half-cell potential is according to ASTM C876.

4 TEST RESULTS

4.1 Visual Observations and Steel Corrosion

The results of the visual observations and loss of steel cross sectional area are shown in Table 6. Three months after the exposure test, the iron rust was observed in the cracked regions of the carbon steel reinforced specimens. On the other hand no rust was observed in the stainless steel reinforced specimens. After the exposure test, specimens S-3 and N-6 (one year), S-2 and N-5 (three years) and S-1 and N-4 (five years) were broken apart to observe the corrosion condition. As time of the exposure became long, corrosion area and loss of the cross sectional area increased. No corrosion was observed in the stainless steels. The maximum loss of cross sectional area of the carbon steels increased with increase in the exposure duration. The maximum loss of the cross sectional area of the lateral bars of specimen N-4 was about one third.

Photo 1. shows the steels taken out from the inside of specimens S-2 and N-5. The carbon steels in the specimens were corroded heavily, especially in the center portion of the specimen. Figure 3 shows the corrosion area of the carbon steels of specimens N-4 and N-5. Due to the cracking, the longitudinal main bars corroded along the length. On the contrary, the longitudinal bars of the compression side only corroded near the center portion in specimen N-5 which concrete had crushed.

Table 6. Results of visual observation and steel corrosion

Specimen	Content Chloride	Exposure duration (year)	First rust (year)	Corrosion area*		Loss of cross sectional area**		
				D22 (%)	D13 (%)	D22 (%)	D13 (%)	D10 (%)
S-1	-	5.1	-	0	0	0	0	0
S-2	-	3.1	-	0	0	0	0	0
S-3	○	1.1	-	0	0	0	0	0
N-4	-	5.1	0.25	46	5	9	17	31
N-5	-	3.1	0.25	36	20	7	11	20
N-6	○	1.1	0.25	17	-	-	-	-

* Average ** Maximum

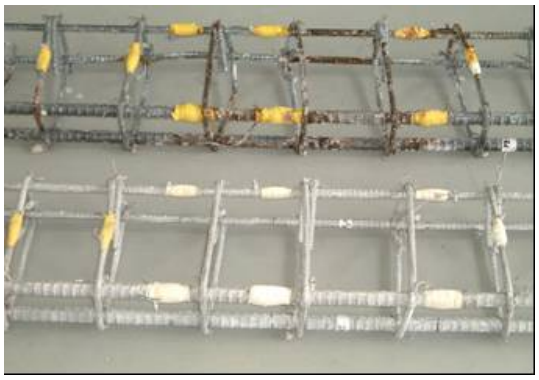

Photo 1. Steels taken out from specimens N-5 and S-2.

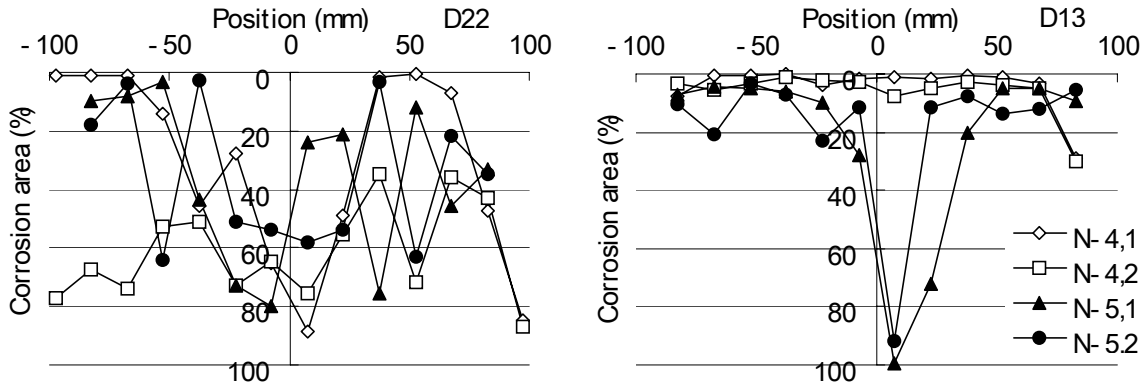

Figure 3. Corrosion area of the carbon steels

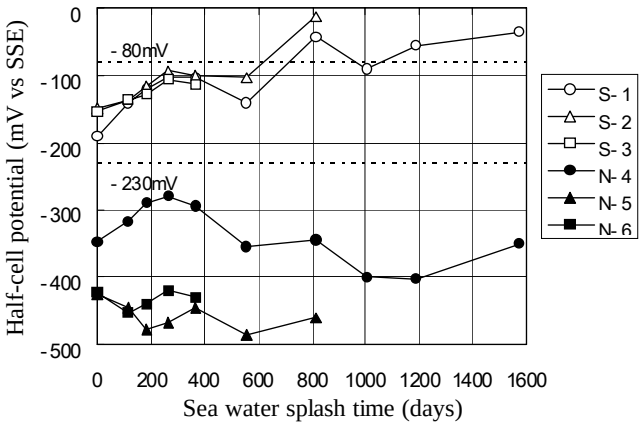

Figure 4. Changes in the half-cell potentials

4.2 Half-Cell Potentials

The changes in the half-cell potentials during the exposure test are shown in Fig. 4. These were measured in the center of the concrete specimens. The potentials of the carbon steel were more negative than –230 mV during the exposure test. The potentials of specimen N-4 which had deformed smaller deflection were more positive than those of specimens N5 and N6 with larger crack widths. The potentials of all the stainless steel reinforced specimens were more positive than the –230 mV measured during the exposure test. The half-cell potentials showed the same tendency as corrosion. Based on these results, the half-cell potentials are supposed to be useful for predicting the occurrence of steel corrosion.

4.3 Chloride Content

Concrete samples were extracted from the un-cracked part of specimen S-1 (upper and lower sides). The whole chloride content was measured by a constant-current titration way based on JCI-SC4 and is shown in Fig. 5. The chloride content was 5.0-7.0 kg/m^3 at the laterl reinforcing steel surface and 2.0-5.0 kg/m^3 at longitudinal main upper and lower reinforcing steel surface. The chloride content of each point exceeded the threshold of occurrence of corrosion (1.2kg/m^3) according to the JSCE standard specification [JSCE 2002].

The chloride content distribution of the cracked section around the reinforcing steel (crack width 0.70mm, central part of specimen S-1) was measured by EPMA (Electron Prove Micro Analyzer) and is shown in Fig. 6. The chloride content was about 10kg/m^3 except for the crack neighborhood and it was relatively high compared with that of the un-cracked concrete part. The corrosion of the carbon steel specimens was caused by this high chloride content. On the other hand, the stainless steel specimens did not corrode during the test. This result suggests that the chloride content limit of the occurrence of corrosion for stainless steel is more than 10kg/m^3.

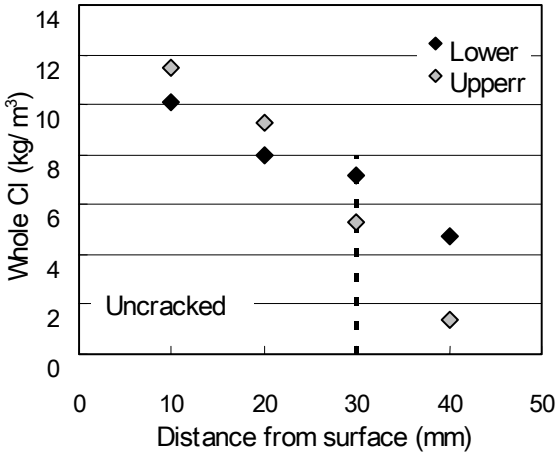

Figure 5. Chloride content of un-cracked concrete section (S-1 after five-year of exposure).

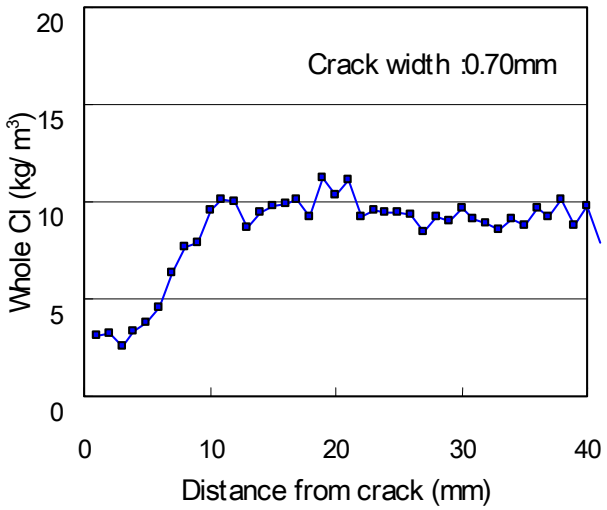

Figure 6. Chloride content of cracked concrete section by EPMA (S-1 after five-year of exposure).

5 CONCLUSIONS

Based on the loading and exposure tests conducted in this study, the following conclusions are derived.

1. The chloride content (whole chloride) of the un-cracked concrete section was 5.0-7.0 kg/m^3 at the lateral reinforcing bar surface. The chloride content of the cracked section near the longitudinal main bars varied from 3.0 to 10.0 kg/m^3.
2. The carbon steel corroded heavily due to high chloride content especially in the cracked and crushed section.
3. The stainless steel reinforced concrete specimens showed excellent durability in the exposure test. The chloride content limit of the occurrence of corrosion for stainless steel is suggested from the test result to be more than 10kg/m^3.
4. Electrochemical measurement of the reinforcing bars was effective and its results were in accordance with the visual test and broken apart results.

Long-Term Preserving Effect on Aggregate-Recovery-Type Completely Recyclable Concrete

Masaki Tamura [1]
Yoshinori Kitsutaka [2]

T 11

ABSTRACT

Japan's urban areas dense with structures have reached a stage at which demolished concrete is socially required to be recycled as concrete materials for the sake of sustainable preserving of urban structures in the present. Originally, concrete which has conditions in complete recycling allows repeated recycling similarly to steel and aluminum. " Aggregate-Recovery-Type Completely Recyclable Concrete", which proposed in this study, is designed to reduce the adhesion between aggregate and the matrix to an extent that does not adversely affect the mechanical properties of concrete by modifying the aggregate surfaces beforehand, thereby facilitating recovery of original aggregate. In order to re-collect high quality recycled aggregates with ease from demolished concrete, the concrete can be made with surface coated virgin aggregate. The coating agent can be expected to have the effect of decreasing adhesive strength between aggregate and paste, but not to the extent that mechanical properties of the concrete deteriorate much. In the related studies before, it had been already explained the fundamental properties and the modifying effectiveness of the prototype aggregate-recovery type concrete, so this study was highlighted the long-term underwater preserving effects of the concrete properties, which was relatively evaluated between the specimens of 28 days and 5 years. The compressive strength, elastic modulus, changes of strain, poisson's ratio, qualities of recoverd aggregate and so on were experimentally investigated by comparison with surface modifyng of aggregates and ages of concrete. As the results, the propeties of long-term preserving concrete were adequately filled with correspondence to material ages, the surface modifying effectiveness were fully maintained, and finally it would be expected to recover the high-quality recycled aggregate with ease under the long term preserving. This enables concrete to be recycled in a fully closed system expecting the reduced waste disposal of natural resources toward the future.

1 INTRODUCTION

Japan's urban areas dense with structures have reached a stage at which demolished concrete is socially required to be recycled as concrete materials for the sake of sustainable preserving of urban structures [Tamura *et al*,2005]. The use of recycled aggregate concrete for structures was standardized as Japan Industrial Standard(JIS) in 2007, improving the social condition for making a step forward from conventional recycling systems [Pietersen, H.G. *et al*,1999] based solely on cascade recycling of concrete lumps for road bottoming. This trend points to level-cycling of concrete, in which concrete turns into concrete again, on the road to achieving Completely Recyclable Concrete [Tomosawa *et al*,1986] (Fig. 1).

In the process of studying Cement-Recovery-Type Completely Recyclable Concrete(CRC) shown in the figure, the authors have already materialized actual structures that can be entirely recycled into cement materials when they are demolished[Tamura *et al*,2004]. Our ongoing study intends to develop concrete from which aggregate can be readily recovered. Also, design concepts involving environmental benefits from concrete structures during their service lives, such as for planting concrete, have now reached a stage of practical use as shown in the Table 1. The production of concrete structures integrating these technologies is currently being attempted.

Under such social circumstances in Japan, the authors have investigated the possibilities of fully developing the aggregate boundary stripping effect, while ensuring certain mechanical performances intended at the design stage, of Aggregate-Recovery-Type CRC to be recycled as aggregate when demolished [Tamura *et al*,2001]. In this study, such possibilities are explored in regard to concrete preserved for a long time based on the results of previous studies, thereby investigating the technical development necessary for preserving activities to be carried out for sustainable concrete structures.

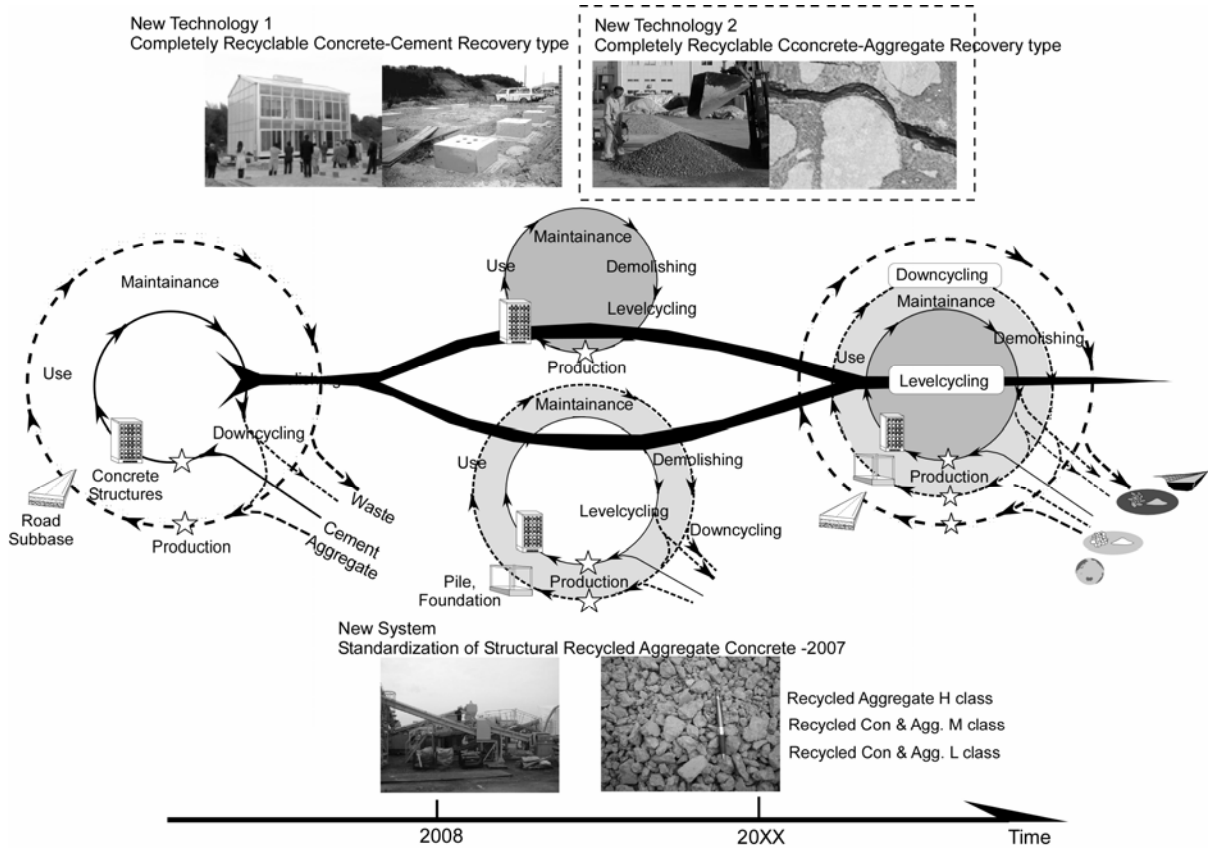

Figure 1. Sustainable concrete structure's material flow toward the future in Japan.

Table 1. The definition of Environment-harmonized concrete.

Environment-harmonized concrete refers to:

Concrete designed to improve and enhance over time the specific environments[*1] for all people involved [*2] while ensuring its basic performances[*3].

Notes

*1:Environments surrounding the whole activities related to concrete structures including the atmosphere, water, substances, flora, fauna, humans, and interrelationships among them. These include various scales of space from the global environment to local environments.

*2:All of the parties involved, such as builders including designers, constructors, and maintaining bodies, as well as users including the owner.

*3:Basic performances directly related to human physiology and safety, such as structural safety, durability, and usability.

2 AGGREGATE-RECOVERY-TYPE COMPLETELY RECYCLABLE CONCRETE

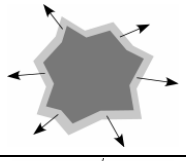
In order to circulate the entire amount of concrete in a closed system, concrete structures to be the sources of aggregate will become necessary in addition to those to be the sources of cement. “Aggregate-recovery-type CRC” is another type of concrete permitting complete recycling. It is designed to reduce the adhesion between aggregate and the matrix to an extent that does not adversely affect the mechanical properties of concrete by modifying the aggregate surfaces beforehand, thereby facilitating recovery of original aggregate. The adhesion of crushed stone with the matrix is generally stronger than that of gravel. Crushed stone therefore provides higher strength but comes with more cement paste when recovered. Also, gravel as a natural resource is being depleted. In consideration of both aspects of quality assurance and global environment protection, crushed stone is more suitable than gravel as the aggregate for surface modification.

Experiments were carried out to verify the aggregate-recoverability as described below: Table 2 gives the aggregate surface modification methods employed to easily recover original aggregate from concrete. Table 3 gives the properties of concrete components. Concrete types are listed in Table 4, while the items of experiment are given in Table 5. Three types of coarse aggregates with different particle shapes were treated chemically and physically to facilitate recovery from concrete. Chemical treatment involved inhibition of cement hydrate formation on the aggregate-paste interfaces. Physical treatment involved smoothing of minute irregularities on the aggregate surfaces to reduce mechanical friction by forming a membrane on the aggregate-paste interfaces. Surface-modified aggregate was prepared by uniformly spraying a modifier on the saturated-surface-dry aggregate, air-drying it, and then repeating the process three more times. As given in Table 4, 9 types of specimens were fabricated. The mechanical properties were measured at an age of 28 days[Noguchi and Tamura,2001] and 5 years. Finally, recycled aggregate was produced by simple crushing to grasp the recovery ratio and evaluate the quality of recycled aggregate.

Table 2. Surface modification treatments for original aggregate.

a) Chemical treatment

The principal ingredient of the coating agent is mineral oil emulsion. The agent hydrolyzes in alkali conditions of fresh concrete, forming acidic matter and indissoluble amalgam on the surface of the aggregate. The surface coating results in decreased amounts of cement hydrate, and leads to decreased adhesive strength between aggregate and paste matrix, allowing easy recovery of the original aggregate.



b) Physical treatment

The coating agent is a water-soluble synthetic resin emulsion, which is applied in process of abrasion, and which is chemically stable in fresh concrete. The uneven surfaces of virgin aggregate become smoother, the shape of the aggregate being roughly maintained. This has the effect of decreasing adhesive strength between aggregate and paste matrix.

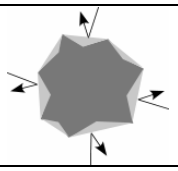


Table 3. Properties of concrete components.

Aggregate	Symbol	Type of Aggregate	Density (g/cm^3)	Water Absorption (%)	Weight of Unit Volume(kg/l)	Solid Volume for Shape Determination (%)
Fine	S	Crushed sandstone	2.62	1.71	1.44	55.8

2.1 Mechanical Properties of Concrete

Figure 2 and 3 show the measured compressive strength and elastic modulus of aggregate-recovery-type CRC at two material ages of the standard 28days and long-term preserved 5 years. The compressive strength of concrete made with surface-modified aggregate decreased regardless of the material ages. As for the specimens of the standard 28 days, series G with round gravel exhibited about 10% lower compressive strength than concrete made using untreated aggregate, indicating the relatively low effect of surface modification. On the other hand, Series L and S using angular crushed stone exhibited about 25% lower compressive strengths, indicating the significant effect of surface modification. Nevertheless, the compressive strength values of specimens containing surface-modified crushed stone were evidently higher than those of specimens containing surface-modified gravel. Mechanical interlocking between the aggregate and the matrix resulting from particle shapes evidently affects the strength. A similar tendency was observed in the elastic modulus. Moreover, it would be so

significant points that these mechanical tendencies were appeared almost equal as the long-term preserved specimens.
When a surface modifier is applied, the difference in the effect of particle shapes on the mechanical properties had confirmed to be widened [Tamura *et al*,2001]. The dependence of the surface-modifying effect on the water-cement ratio was also confirmed, with high strength mortar exhibiting greater strength reduction due to surface modification after long-term preserving. This may be because the increased strength of the matrix, together with the essential strength of aggregate, causes the crack-propagation zone to be predominantly formed in the weak portions at aggregate-matrix boundaries, leading to failure at a lower stress.

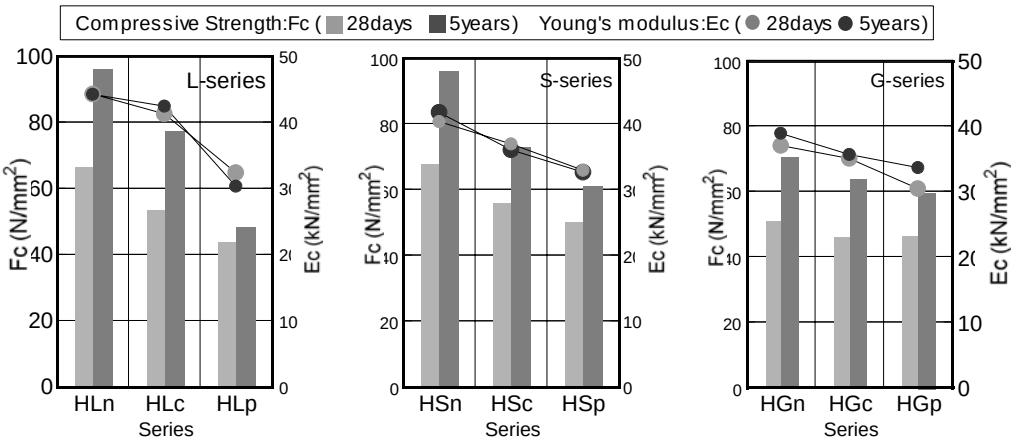

Figure 2. Relationship between Compressive strength(Fc) and young's modulus(Ec).

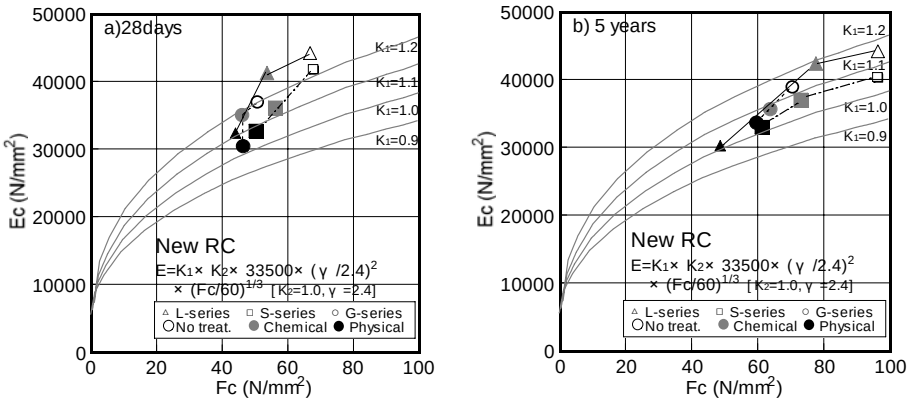

Figure 3. Relationship between Compressive strength(Fc) and young's modulus(Ec) of New RC equation.

2.2 Strain Properties of Long-Term Preserved Concrete

Figure 4 shows the Poisson's ratios related to the longitudinal strain and compressive strength, respectively. Figure 5 shows the strain distribution of concrete by each type of modification treatment. This section deals with concrete made using limestone aggregate in consideration of Japan's future aggregate availability.

Figures 4 reveal that Poisson's ratio of concrete with surface-treated aggregate increases with a strain of around 70% of the maximum strain of concrete with untreated aggregate, leading to an expansion phenomenon as Poisson's ratio exceeds 0.5. The compressive strength significantly decreases to around 75% and 50% with chemical and physical treatments, respectively. It can be said that deformation properties that are characteristic of modification and explicable by Poisson's ratio are present under compressive stress. On the other hand, these properties represent the aggregate surface stripping effect

being retained, which can be regarded as basic information for efficiently developing the confining effect of reinforcement.

The strain distribution shown in Fig. 5 includes the volumetric strain that expresses the volumetric changes of the entire substance in addition to the longitudinal and transverse strains. When focusing on a rectangular solid part of a homogeneous body, the volumetric strain expressed by Eq.(1) generally holds on the assumption that the strains in all directions are equal. By observing the volumetric strain, the point at which an unstable failure condition begins can be recognized. At this point, cracks on the aggregate boundaries predominate, connecting one another into major cracks in the process in which Poisson's ratio departs from around 0.2 and the stress conditions turn to expansion, with the volumetric strain turning to negative. When aggregate is untreated a), the volumetric strain does not turn to expansion until immediately before failure due to the effect of chemical bonding on the boundaries, which is characteristic of crushed limestone. Though this poses no problem in regard to the mechanical properties of concrete, such a concrete is prone to brittle failure, resulting in a low possibility of recovering aggregate. On the other hand, when aggregate is treated [b] and c]], the crack onset point, at which the volumetric strain turns to expansion due to the boundary stripping effect, is clearly recognized, indicating the occurrence and progress of internal cracks. This suggests a possibility of avoiding brittle failure characteristic of high strength concrete. In such a case, the development of a crack deflection effect, with which cracks are deflected along the aggregate boundaries, is also inferred, suggesting the retention of properties beneficial for increasing the aggregate recoverability even under compressive stress.

$$\varepsilon = 3(1-2\upsilon)\sigma/E \quad (1)$$

where υ *: Poisson's ratio*

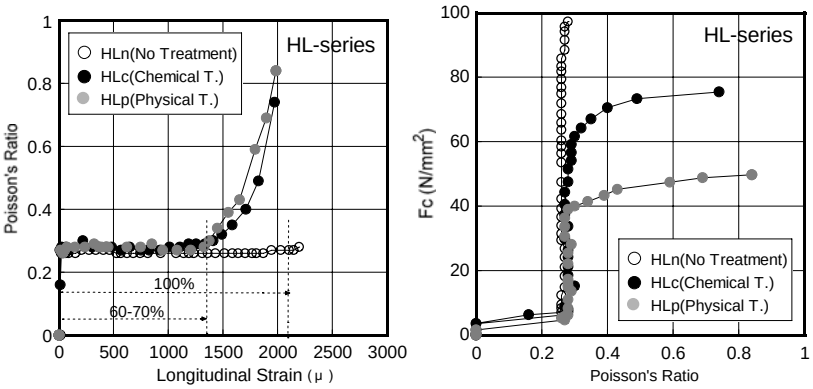

Figure 4. Poisson's ratios related to the longitudinal strain and compressive strength.

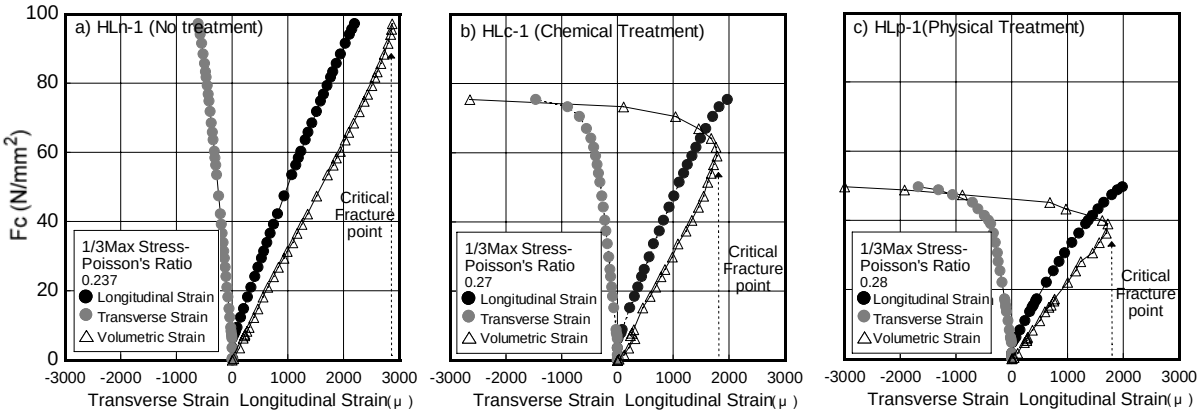

Figure 5. The strain distribution of concrete by each type of modification treatment.

2.3 Paste-Exfoliating Properties of Aggregate

The properties of cracked surfaces of concrete with aggregate surfaces modified to facilitate aggregate recovery were investigated to study the paste-exfoliating effect of surface modification.
Specimens were the same as those used in the experiment for mechanical properties. Binarized images of two-dimensional photographs of ruptured surfaces were also used to calculate the areas of stripped aggregate surface and cracked aggregate surface by image analysis to quantify the paste-exfoliating effect using Eq.(2). Figure 6 shows a binarized image distinguishing the mortar phase from aggregate phase of a cracked surface. Figure 7 shows the ratio of the area of stripped aggregate to the total ruptured surface.

$$R = Sp/(Sc+Sp) \times 100 \quad (2)$$

where R : Ratio of aggregate exfoliating (%)

Sp : Area ratio of stripped aggregate (%)

Sc : Area ratio of splitted aggregate (%)

When surface-modified aggregate is used, the ratio of aggregate exfoliating was greater than the case of untreated aggregate. This tendency was more evident with angular aggregate. In other words, both chemical and physical surface treatment of crushed stone aggregate led to less cracking through aggregate particles and more split along the aggregate-matrix boundaries than in the case of untreated crushed stone. This phenomenon was not observed in the case of concrete containing gravel. Accordingly, surface modification of aggregate was found to cause cracking to detour to weak boundaries between aggregate and the matrix, suggesting the possibility of easy separation of aggregate from the matrix.

These results of experiments indicate that the effect of aggregate surface modification is maximized when coarse aggregate having a low solid percentage to judge the particle shape, such as crushed stone, is used in a matrix having a high strength. Such a concrete, which normally poses a difficulty in recovering high-quality recycled aggregate, is expected to contribute to the increase in the aggregate recovery ratio and quality of recycled aggregate by surface modification treatment of aggregate.

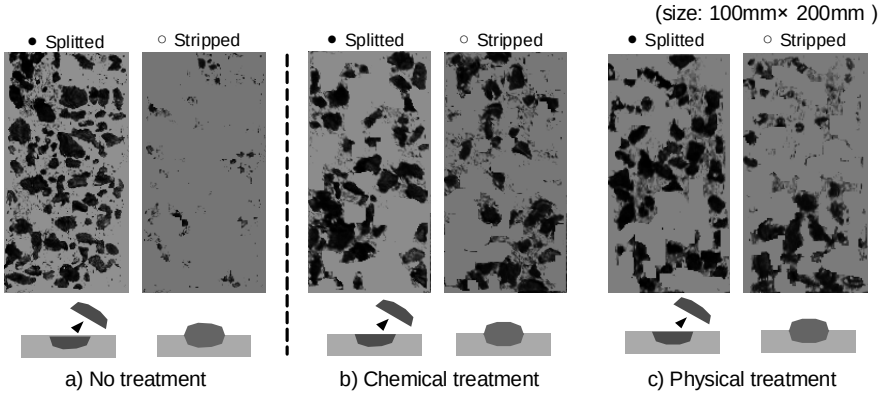

Figure 6. Image on the side of cracked concrete of Long-term-preserving CRC.

2.4 Recovery of Original Aggregate from Demolished Concrete

The same concrete as that used in the mechanical property tests was subjected to aggregate-recovery tests. Concrete was crushed in a two-phase process. The primary crushing was carried out using an improved jaw crusher having a mechanism that scrubs aggregate particles. The entire amount of the crushed aggregate was charged into a ball mill and subjected to scrubbing (secondary crushing) for a specified length of time. Recycled coarse aggregate 5-20 mm in diameter was sifted out of the

produced recycled aggregate to measure the density and water absorption. The percentage by mass of the original aggregate in the total recycled coarse aggregate was defined as the aggregate recovery ratio, and the value was determined.

Figure 7 shows the original aggregate recovery ratio of each concrete. The aggregate recovery ratio of concrete containing crushed stone was increased by aggregate surface modification regardless of the strength. The effect of chemical treatment was particularly evident. On the other hand, the effect of aggregate surface treatment was less evident in concrete containing round aggregate. No appreciable difference was observed between the aggregate recovery ratios of treated and untreated gravels in high strength concrete. Similar results were obtained for the density and water absorption of recycled aggregate. Improved quality of recycled coarse aggregate was confirmed when the aggregate was surface-treated.

In order to improve the resource conservability of aggregate in concrete, it is effective to use surface-treated aggregate. Though such a concrete generally tends to exhibit slightly low mechanical properties in the plastic zone, such as compressive strength, the separation of aggregate from the matrix can have a favorable effect from the standpoint of fracture mechanics in some cases. For instance, fracture of concrete can be made ductile by detours of cracking towards the aggregate-matrix boundaries in the case of certain aggregate types and water-cement ratios [Tamura *et al*,2001]. The surface treatment realizes recovery of high quality recycled aggregate with little adhering paste from demolished concrete by a simple crushing technique.

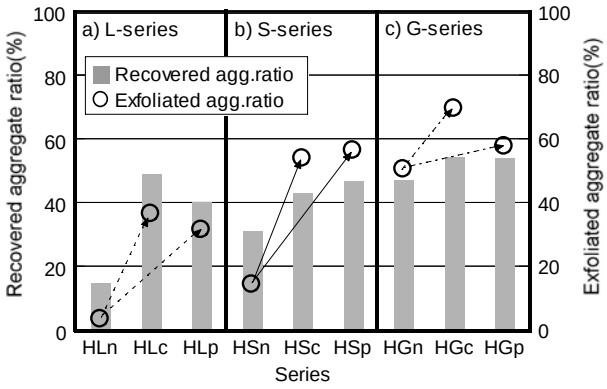

Figure 7. Area ratio of aggregate on the side of cracked concrete.

3 CONCLUDING REMARKS

Through the research and development for concrete recycling and investigation of the difficulties and problems of recycling practice for a long time, the authors learned that the above-mentioned two methods are vital for recycling to hold in Japan.
Efforts for closed-loop recycling have also begun in the fields of glass, gypsum board, and other construction materials. This trend will prevail in all fields in the future, eventually leading to a society in which materials recyclable in closed loops or disposable in a nature-friendly form expel those that are not, as in the case of chlorofluorocarbons driven out of the market.

ABSTRACT

On the basis of non-linear effect studies, new diagnostic and defectoscopic methods have been designed, which are based on the elastic wave non-linear spectroscopy. The non-linear acoustic spectroscopy brings new prospects into the acoustic non-destructive testing of material degradation. Poor material homogeneity and, in some cases, shape complexity of some units used in the building industry, are heavily restricting the applicability of "classical" ultrasonic methods. These linear acoustic methods focus on the energy of waves, which are reflected by structural defects, variations of the wave propagation velocity or changes in the wave amplitude. However, none of these "linear" wave characteristics is as sensitive to the structure defects as the specimen non-linear response. In this way, non-linear methods thus open new horizons in non-destructive ultrasonic testing, providing undreamed-of sensitivities, application speeds and easy interpretation. One of the fields in which a wide application range of non-linear acoustic spectroscopy methods can be expected is civil engineering. It is predicted that these advanced techniques can contribute a great deal to the improvement and refinement of the defectoscopic and testing methods in the building industry practice. The present paper deals with analyzing one of the non-linear acoustic defectoscopic methods from the viewpoint of its application to the concrete specimen structural integrity evaluation. Both intact specimens and specimens subject to various kinds of stress have been tested. The effect of structural defects on the elastic wave propagation has been studied.

1 INTRODUCTION

Thanks to the stormy development of concrete and reinforced concrete buildings taking place in the last century, the condition of concrete and reinforced concrete became a hot topic in the last decade. Concrete proved to be a durable construction material in the past, however, concrete structures often experienced degradation after years of service. Rehabilitation techniques have been developed in foreign countries for several decades showing a rapid development in general. However, the absence of an acceptable, relatively fast and cheap monitoring method, which would be capable of detecting structure faults at an early stage, thus making a simple and cost-effective maintenance possible, is still persisting [Maceck 2003].

Filling this gap, acoustic testing methods, rank among the most promising methods of building element and structure diagnostics. Non-linear ultrasonic spectroscopy methods are opening new horizons in the non-destructive acoustic testing of material degradation.

2 NON-LINEAR ULTRASONIC SPECTROSCOPY

On the basis of non-linear effect studies, new diagnostic and defectoscopic methods have been designed, which are based on the elastic wave non-linear spectroscopy. Existing linear acoustic methods focus on the energy of waves reflected at structural defects, analyzing the reflected wave energy, wave velocity or amplitude variations. It is to be emphasized, however, that none of these linear wave characteristics is as sensitive to the structural defect occurrence as the non-linear response of the material.

Recently, various papers are being published on the theoretical or experimental verification of different methods in some application areas. One may state that, on the one hand, and, regarding the topic complexity, the requirements for newly developed special instrumentation and a high potential application diversity, the research and development of the respective methods, the required instrumentation and, last but not least, practical applications of these methods, is still in its infancy. On the other hand, most published papers as well as our experience show these methods to be highly promising for both the defectoscopy and the material testing purposes in the near future.

One of the fields in which a wide application range of non-linear acoustic spectroscopy methods may be expected to take place is civil engineering. Poor homogeneity of materials and in some cases also intricate shape of the specimens, restrict heavily the applicability of the classical ultrasonic methods. Precisely these non-linear acoustic defectoscopy methods are less susceptible to the mentioned restrictions and one may expect them to contribute a great deal to further improvement of the defectoscopy and material testing in civil engineering.

2.1 Non-Linear Spectroscopic Methods

Non-resonance methods are used to study suppressed resonance specimens. These methods analyse the effect of non-linearities on acoustic signals propagating through them. These methods can again be split into two groups:

- measurements using a single harmonic ultrasonic signal (a single frequency f_1)
- measurements using multiple harmonic ultrasonic signals (usually, two frequencies f_1, f_2).

We pay attention to single harmonic ultrasonic signal measurement method which was used in experimental part. In this case, where a single exciting frequency f_1 is used (Fig. 1), the non-linearity gives rise to other harmonic signals, whose frequencies f_v obey the Fourier series formulas:

$$f_v = n f_1 \quad | \; n = 0, 1, 2, \ldots \infty \tag{1}$$

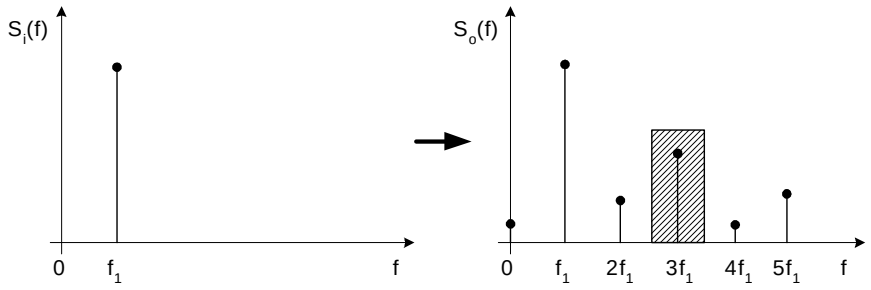

Figure 1. Frequency spectrum of a non-linear medium response

In general, these frequency component amplitudes are falling when the harmonic order natural number, *n*, is increasing. If the non-linearity effect is not entirely symmetrical, there can arise low-amplitude second and higher even-numbered harmonic components, whose amplitudes may be much lower than those of the odd-numbered ones. Among these emerging components, the third harmonic is the most distinctive one [Hajek and Sikula 2004]. Therefore, its amplitude is being evaluated most frequently.

2.2 Measuring Apparatus

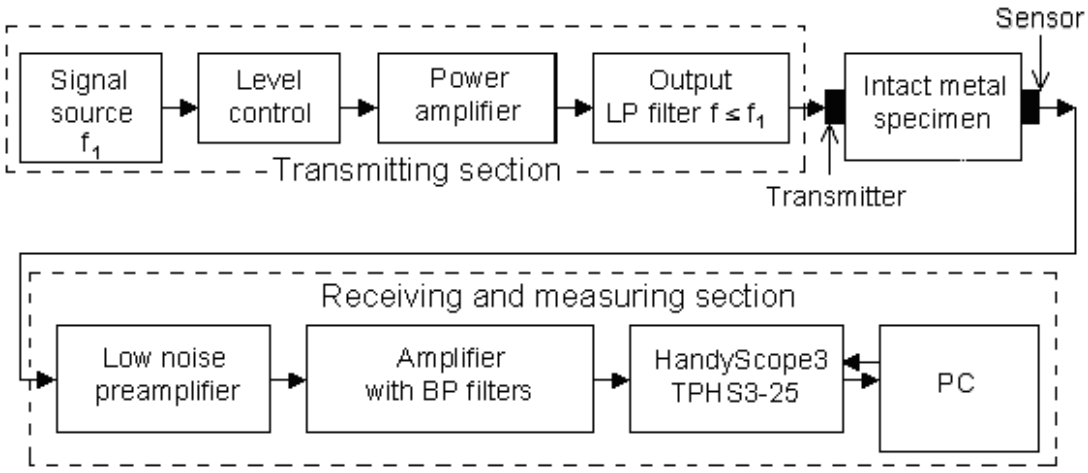

Figure 2. Block diagram of the measuring apparatus

Receiving section consists of piezoceramics sensor, low noise preamplifier with classical or differential input connector, amplifier with band - pass filters. These output signal are used for final evaluating. The starting measures were realized by normal spectral analyser in our case oscilloscope HandyScope3 TPHS3-25.

For the recorded data to be interpreted properly, each of the measuring instruments must meet following criteria [Prevorovsky and Abeele 2004]:

- High linearity of all instruments (generators, amplifiers, sensor, transmitter,…).
- High resolution in the frequency domain.
- High dynamic range (90 to 130 dB).
- Highly efficient filtration of detected signals (fundamental frequency suppression).
- Frequency range 10 kHz to 10 MHz.
- Optimized sensor and transmitter location.

A program package to control the measuring process and the data processing and evaluation makes an indispensable tool.

3 EXPERIMENT

3.1 Intact Concrete Specimens

In the first stage of the experiment, we tried to find out whether the high inhomogeneity of the material gives rise or does not give rise to non-linear phenomena. Two groups of specimen denoted A, B, featuring the same concrete mix charge. Each group comprised 10 specimens of dimensions 150 mm × 150 mm × 150 mm, the A group specimen having been aerated, the B group ones, non-aerated.

3.1.1 Measurement Results

Fig. 3 shows the results obtained from A-group specimens. It shows the frequency spectrum of the A3 specimen response to the harmonic ultrasonic excitation at a frequency of 29 kHz, as captured by K33 sensor. First five harmonic frequencies appear to be emphasized, their amplitudes decreasing with the serial number *n*. Similar results have been obtained from B-group specimens, as is seen in Fig. 4, showing the frequency spectrum of B4 specimen. Comparison of the diagrams show that aerated specimen of the A-group suppress the higher harmonic frequencies more intensely, which is apparently due to the air pores in the specimen structure. All of the specimens tested showed the same amplitude decreasing trend for the harmonic frequency increasing order.

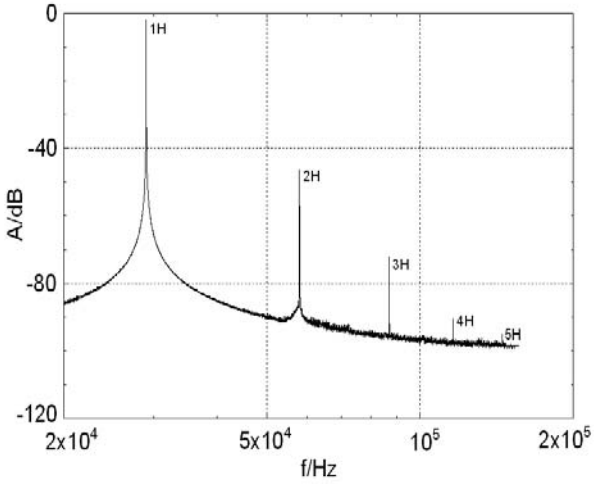

Figure 3. Frequency spectrum of A3 specimen.

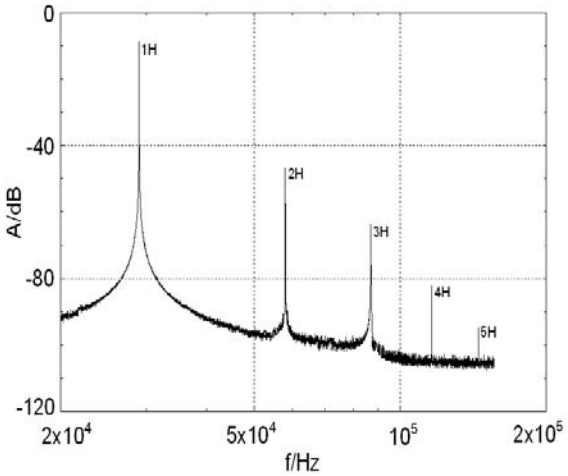

Figure 4. Frequency spectrum of B4 specimen.

3.2 Freeze-Thaw Cycle Degraded Concrete Specimens

In the second stage, we studied the concrete specimen structure having been stressed by thermal shocks. The concrete specimens were stressed by recurrent freeze-thaw cycles. Measurements were realized after 25 and 50 freeze-thaw cycles.

3.2.1 Measurement Results

The curve shown in Fig. 5 shows the A2 specimen's pre-degradation frequency spectrum. Its shape features a gradual amplitude drop, without any non-linear effects. The transfer characteristic, Fig. 6, which corresponds to the same specimen having been subjected to 25 freeze-thaw cycles, does show a non-linearity. It is becoming evident from a distinct drop of the fourth harmonic's amplitude (4H), which is exceeded by the fifth harmonic's amplitude (5H). The frequency spectrum shown in Fig. 7, corresponding to the specimen having undergone 50 freeze-thaw cycles, shows non-linearities, too. In this case, they consist in a drop of the third harmonic's amplitude and an increase of the fourth harmonic (4H). Fig. 8 shows the high harmonics' amplitudes relative to the first harmonic's amplitude for A2 specimen.

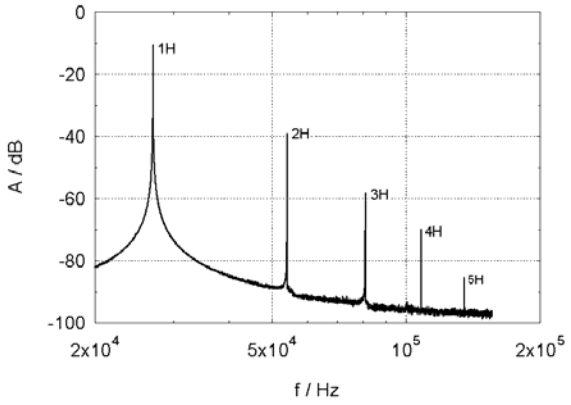

Figure 5. A2 specimen prior to degradation.

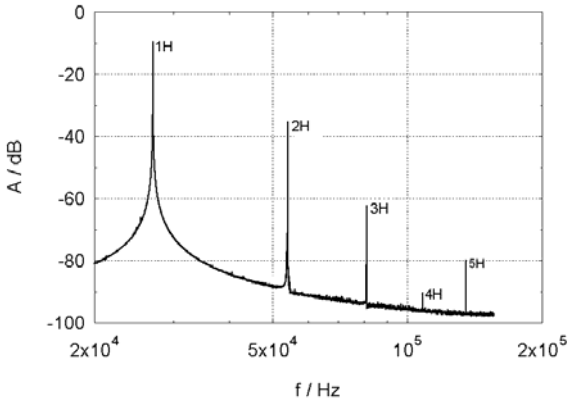

Figure 6. A2 specimen after 25 cycles.

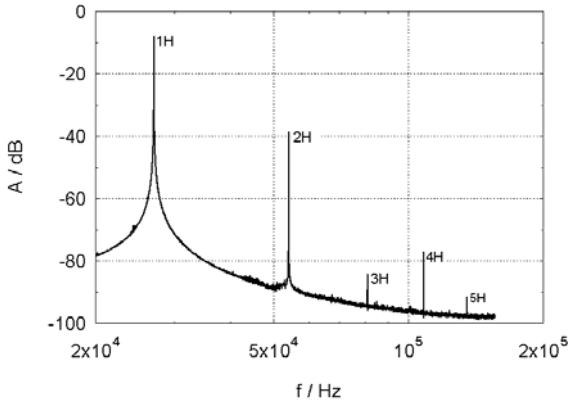

Figure 7. A2 specimen after 50 cycles.

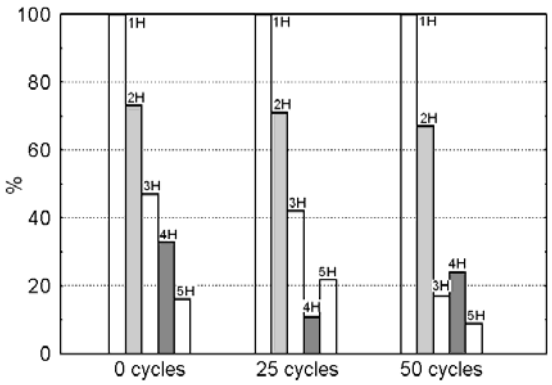

Figure 8. Relative amplitude values.

3.3 Polymer-Fibre-Filled Concrete Specimens

Finally, we tested concrete specimens of dimensions 100 mm x 100 mm x 400 mm which had been filled with polymer fibres. The specimens were examined for flexural tensile strength in a two-weigh pressing machine. The load test was terminated as soon as visible cracks appeared. These cracks closed again after the strain had been taken off. In the case of TP7 specimen a visible crack remained after the specimen had been relieved. The transmitter and sensor configuration is shown in Fig. 9.

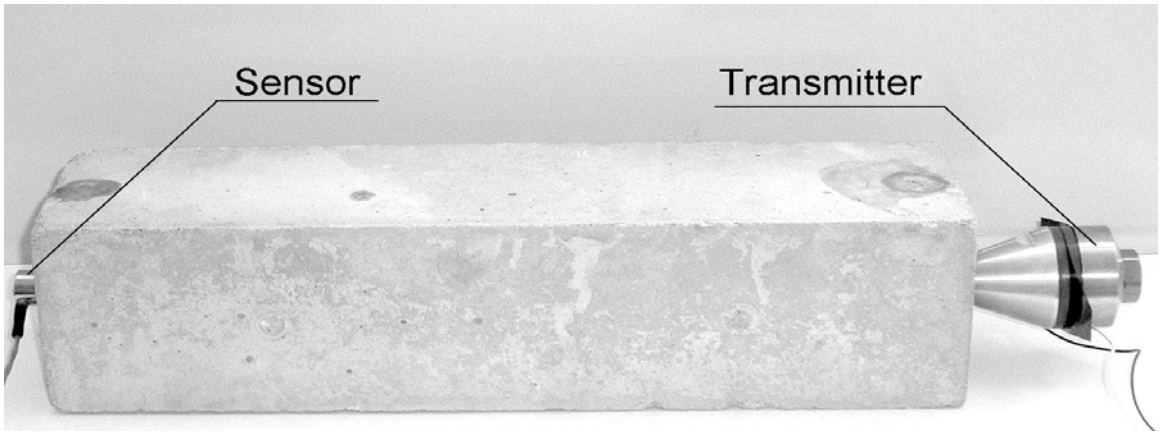

Figure 9. Location of the exciter and the sensor on the specimen under test.

3.3.1 Measurement Results

Pre-test measurements of TP7 specimen are shown in Fig. 10. The shape of the frequency spectrum corresponds to that of intact specimen and higher harmonic amplitudes are decreasing with their serial number. Fig. 11 shows the frequency spectrum of the same specimen after load test has been carried out in the pressing machine. When compared with Fig. 10, the response function shows the higher harmonic frequencies to have lower amplitudes. The fifth harmonic has disappeared entirely which is probably due to the structure-degradation-induced higher attenuation. Another change consists in emphasizing the second harmonic's amplitude with respect to the first harmonic as well as the third and fourth harmonic.

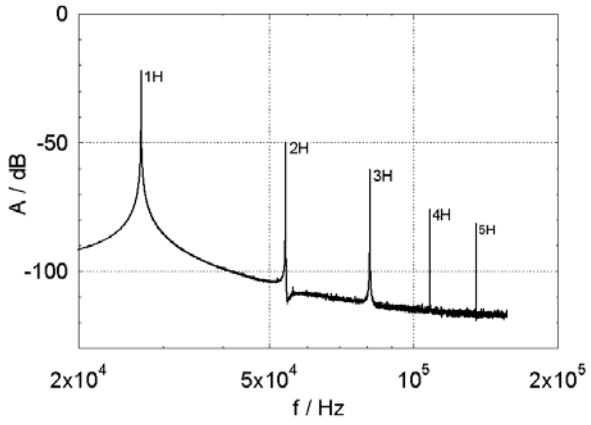

Figure 10. Pre-test frequency spectrum of TP7 specimen

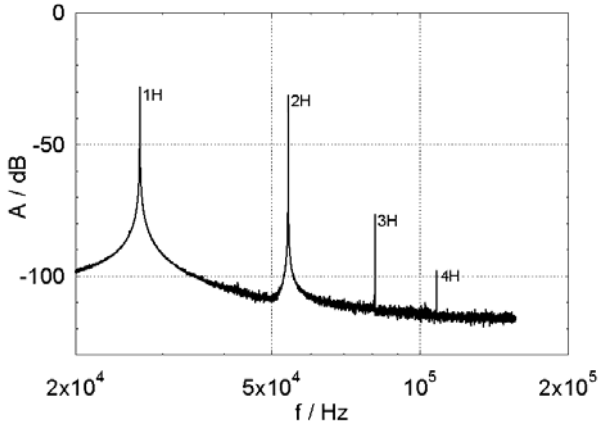

Figure 11. Frequency spectrum of TP7 specimen after load test

4 CONCLUSION

This paper presents our first results of concrete specimen structure testing by means of non-linear ultrasonic spectroscopy using a single exciting harmonic frequency.

To interpret properly the measuring results, the transfer function of the whole measuring set-up must be determined and all measuring instruments must comply with high quality standards. It is therefore essential to minimize any harmonic distortion in the signal pick-up and amplification path by eliminating any spurious signals ($3\,f_1$ parasitic signal, noise) from the measuring apparatus stages. It is to be noted that a perfect mechanical coupling must be ensured between the exciter and the specimen and, further, between the specimen and the pick-up element during the experiment setup process.

Our measurements show that the effect of a material inhomogeneity is very low in the case of non-linear ultrasonic spectroscopy, its non-linear effect being substantially lower than in the case of common defects.

Furthermore, it has been proved that structure defects, which are due to the freeze-thaw cycles as well as mechanical strain, give rise to non-linear effects.

In conclusion, it is to be emphasized that a perfect mechanical coupling must be ensured between the exciter and the specimen and, further, between the specimen and the pick-up element during the experiment setup process.

A Tool for Strength Durability Modelling of Glass Fibre Reinforced Concrete

Petra Van Itterbeeck [1]
Heidi Cuypers [1]
Phil Purnell [2]
Jan Wastiels [1]

T 11

ABSTRACT

Concrete composites with high ductility can be obtained by reinforcing cement pastes or mortars with fibres. When a glass fibre textile reinforcement is used in a cementitious matrix, the load bearing capacity of the concrete can be enhanced in such a way that steel reinforcement can be omitted. However, even today these concrete composites are subject to degradation of their mechanical properties with ageing, especially in a wet environment. Loss of tensile strength is the most important manifestations of this ageing. Over the years many researchers have tried to model the strength durability. Several models will be presented and discussed within the scope of this paper. Generally the prediction of the service life of GRC composites in various climates is essentially performed with an accelerated ageing technique. Immersion in water for various periods of time and at various temperatures going from 20°C to 80°C is the most commonly used accelerating environment. The changes in the mechanical properties induced by such an exposure are then assessed. These tests are widely used to evaluate and predict the long term durability. It is however not clear how many accelerating temperatures and time/temperature points are needed to achieve a reliable prediction taking into account the strength prediction model used, the number of specimens utilized to obtain the avaraged time/temperature points and the scatter inherently present on the tested specimens. Therefore it is the aim of this paper to present a theoretical procedure which allows the reader to establish how large the uncertainty is on a long-term real life prediction taking into account all parameters elaborated above.

1 INTRODUCTION

By reinforcing cement pastes with fibres, composites with improved ductility can be obtained. Moreover, when using a glass fibre textile reinforcement in cement the mechanical properties of the composite can also be improved in such a manner that it becomes a very suitable material for the production of thin elements with variable shapes. Unfortunately, these concrete composites are subject to degradation of their mechanical properties with ageing (Litherland *et al.* [1981], Purnell *et al.* [2001], Orlowsky [2005]), especially in wet environments. The most important manifestation of this ageing is the loss of tensile strength. Many have tried to determine the mechanisms which govern this ageing in order to further improve the strength durability. Following main mechanisms were identified: (1) chemical attack of the fibre, (2) growth of hydration products, (3) static fatigue. Improved materials have been developped of which the durability now needs to be predicted to enable the use in for instance structural applications.

The aim of this paper is to provide a helpful tool for researchers when faced with durability testing of Glass fibre Reinforced Concretes (GRC). Following questions will be treated: (1) which predictive models are available, (2) how is durability testing performed and (3) how many experiments need to be performed within an accelerated ageing testing program (how many accelerated ageing temperatures and data points within each temperature series) for a reliable prediction. To achieve this goal, first of all an overview will be given of the in literature available strength durability models and durability test programs for GRCs. In the second and main part of this paper a method will be presented to evaluate the sensitivity of the different strength durability models towards scatter on the measurements. This method will enable the reader to select a testing program that will provide a trusthworthy prediction of the strength durability. For illustrative purposes this method will be used on one of the models and the results will be discussed in some detail.

2 STRENGTH DURABILITY MODELS FOR GRCs

2.1 Background on the Different Strength Durability Models

Recent durability studies on GRCs (Purnell *et al.* [2001], Orlowsky [2005], Cuypers *et al.* [2006] and Cuypers and Orlowsky [2007]) assume a certain physical background is responsible for the strength losses recorded. They state that the failure stress will decrease with time due to the growth of flaws (nano-defects) inherently present on the surface of the glass fibres. The bulk failure stress of the glass fibres can then be calculated as a function of the flaw size and geometry of the largest flaw present in the fibre and this with the help of classical elastic fracture mechanics:

$$\sigma_t = \frac{K_{IC}}{A \cdot \sqrt{\pi \cdot a}} \tag{1}$$

Where: σ_t is the bulk tensile strength at time t (*in MPa*)
K_{IC} is the critical stress intensity factor (Mode I) (*in* $Nm^{-3/2}$)
A is a shape factor (*dimensionless*)
a is the flaw size at time t (*in nm*)

If one assumes that the critical stress intensity factor and the shape factor are invariable with time, the following general expression for the residual strength (S) can be constructed with the help of Equation 1:

$$S = \frac{\sigma_t}{\sigma_{t=0}} = \frac{1}{\sqrt{1 + \frac{X}{a_0}}} \quad \text{with:} \quad a = a_0 + X \tag{2}$$

Where: a_0 is the initial flaw size (*in nm*)
X is the flaw growth over a time span t (*in nm*)

σ_t is the failure strength at time t (*in MPa*)
$\sigma_{t=0}$ is the initial failure strength (*in MPa*)
S is the residual strength (*dimensionless*)

The presence of moisture and pH have been recognised by several authors as accelerating factors for this flaw growth. Starting from the basic assumptions described above, several models were constructed over the years. In this paper four of these models will be referred to as: (1) the kinetic model, (2) the diffusion model, (3) the non-linear model and (4) the combined model. The essential difference between these models is the general expression assumed for the rate of flaw growth.

2.1.1 The Kinetic Model

Some researchers (Purnell *et al.* [2001]) state that the growth of a flaw can be written as a linear function of the ageing time t:

$$\frac{dX}{dt} = k_1 \tag{3}$$

Where: k_1 is a temperature dependant rate coefficient (*in nm/day*)

This however is only valid when one assumes that the reaction between the glass and the environment is solely controlled by the reaction kinetics.

2.1.2 The Diffusion Model

Some researchers (Cuypers *et al*. [2006], Orlowsky [2005]) stated that the flaw growth decreases with time. This slowing down of the reaction and consequent decrease in strength loss rate might be the direct result of reaction products covering the surface of the fibres with time and/or of a bottle neck effect (the confined space within the growing flaw could possibly in combination with a deposition of reaction products within this flaw itself also limit the further reaction rate). Some researchers stated that the chemical reaction will be diffusion-controlled from the start Cuypers et al [2006]. In that particular case the flaw size growth can be expressed with the help of Fick's law of diffusion as follows:

$$\frac{dX}{dt} = \frac{k_2}{X} \tag{4}$$

Where: k_2 is a temperature dependant rate coefficient (*in nm/day²*)

2.1.3 The non-linear model

Other researchers (Cuypers and Orlowsky [2007]) suggested a non-linear progression of the flaw depth due to for instance a varying Zr content along the section of the fibres or a varying flaw shape with time. This assumption resulted in Equation (5), enabling the user to model the slowing down as well as the acceleration of a chemical reaction.

$$a = a_0 + (k_3 \cdot t)^n \tag{5}$$

Where: k_3 is a temperature dependant rate coefficient (*in* $(nm^{1/n})/day$)

This formula can be rewritten in a similar form as presented in equations (3) and (4). This will then result in the following expression for the rate of flaw growth:

$$\frac{dX}{dt} = n \cdot k_3^{\,n} \cdot t^{n-1} \tag{6}$$

2.1.4 The Combined Model

Some researchers (Orlowsky [2005]) state that the rate of degradation is initially determined by kinetics and becomes diffusion controlled in a later stage. In this particular case, following expressions for the rate of flaw size growth can be used.

$$\frac{dX}{dt} = \frac{1}{\frac{1}{k_4} + \frac{X}{k_5}} \tag{7}$$

Where: k_4 is a temperature dependant rate coefficient (*in nm/day*)
k_5 is a temperature dependant rate coefficient (*in nm/day²*)

2.2 The Rate Coefficients and Their Dependance on Temperature

Durability studies available in literature (Litherland *et al.* [1981], Purnell *et al.* [2001], Cuypers *et al.* [2006], Orlowsky [2005]) postulate that for classical cementitious mixtures (with Portland cement) one chemical reaction is responsible for the strength loss at all temperatures in the range of 20-80°C and that an Arrhenius type relationship exists between the rate of this chemical reaction and the temperature at which the test was carried out.

$$k_i = k_{0,i} \cdot e^{-\frac{E_{A,i}}{R \cdot T}} \tag{8}$$

Where: k_i rate coefficient of the chemical reaction i (*dimensions depend on the model used*)
$k_{0,i}$ reference rate coefficient of the chemical reaction i (*dimensions depend on the model used*)
$E_{A,i}$ activation energy of the chemical reaction i (*in KJ mol^{-1}*)
T temperature at which the test is performed (*in K*)
R gas constant (*in J mol^{-1} K^{-1}*)

Implementing this assumption back into the durability models presented above implies that each of the temperature dependant rate coefficients (k_1, k_2, k_3, k_4 and k_5) should present an Arrhenius type relationship in function of the temperature. Each of these temperature dependant rate coefficients can thus be written as function of two model paramaters (an activation energy $E_{A,i}$ and a reference rate coefficient $k_{0,i}$) which themselves are solely function of the material combination under study.

3 STRENGTH PREDICTIONS

3.1 Introduction

When faced with GRCs durability remains an important issue and should therefore already be taken into consideration during the design stage. Instead of testing specimens in real climatic conditions, specimens are stored in well controlled lab conditions. Specimens are immersed in hot water at temperatures ranging from 20°C-80°C for various periods of time. It was found over the years that this approach provides a good means for accelerating the degradation process and this without altering the processes which take place. When the experimental data is gathered an inverse method can then be used for the determination of the rate coefficients of the different models at each testing temperature (see section 2). First starting values are allocated to each of the rate coefficients. The rate coefficients are altered in a second step and the modelled strength predictions are compared with the experimental results through the Sum of Squares method (SS). The rate coefficients corresponding to the lowest value of the Sum of Squares are then retained. With those rate coefficients the Arrhenius assumption can be checked and the model parameters (activation energy and reference rate, see section 2.2) are determined for the model under study. In a final stage, the in the previous step determined model parameters are used for a strength prediction over the life time of the material. The strength loss occurring over an established period in a certain climate can be defined by for instance assuming that over the life time of the material an average temperature of the climate will occur in combination with a relative humidity of 100%. This method is a widely adopted approach for strength predictions. It is however not clear how significant the influence of the scatter of the measurements is on the strength predictions. Therefore, in the following section a sensitivity study will be presented which will enable the user to establish how large the error is on his or her predictions.

3.2 Sensitivity Study of the Strength Predictions

Experimental series of GRC tests generaly exhibit a large scatter. Coefficients of Variation (CV) of around 15% and above are not exceptional. A vast majority of the authors working on GRC materials also use only a limited amount of specimens per test series: series with 3 to 5 specimens are commonly used. The combination of a large scatter, a limited amount of specimens per temperature/time point, a small amount of tested accelerated ageing temperature/time points and a limited number of temperatures might greatly influence the strength predictions effectued on the basis of these experimental results. Therefore it is the aim of this paper to evaluate the influence of these parameters on the strength predictions. In order to achieve this goal a theoretical investigation was carried out. Two main parts can be distinguished in this study. First of all (see Fig. 1) for each group of number of temperatures and number of time/temperature points (at several times within a temperature serie) the number of possible combinations is determined (e.g. in the case of 3 temperatures and 4 time/temperature points being used: (1) 35 temperature combinations can be constructed with the 7 temperatures given in Fig. 1, (2) 210 time combinations can be obtained using the 10 time possibilities given in Fig. 1, (3) in total 7350 experimental combinations are thus possible with 3 temperatures and 4 data points from the range shown in Fig. 1).

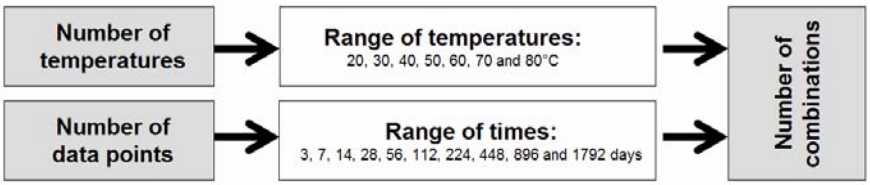

Figure 1. Scheme used to determine the number of combinations under study.

In the second part of the theoretical study the sensitivity to scatter will be determined for each of the possible "virtual" experimental combinations determined in the previous step. The 4 steps which have to be completed to achieve this goal are illustred in Fig. 2. First theoretical curves can be constructed (see step 0 in Fig. 2). The model parameters used in this paper to construct these theoretical curves are typical for traditional Portland cement mixtures (see e.g. Van Itterbeeck *et al.* [2007] and Cuypers *et al.* [2006]). In step 1 (see Fig. 2) the time/temperature time/temperature points of these theoretical curves will be shifted taking into account possible scatter on the results. For instance if 5 specimens are used per time/temperature time/temperature point, 5 values are determined at random but taking into account the probability distribution present on the results. For the distribution function, the scatter present on the reference specimens is taken as a reference. One could argue that scatter might evolve with ageing, but for a first calculation, using the scatter present on the reference specimens is more than adequate. Once all the data points have been shifted - taking into account the scatter present on the results in step 2 - the rate coefficients can be determined again with the same inverse method as the one discussed in section 3.1. From these rate coefficients the model parameters (activation energy and reference rate) can then be determined. Subsequently the residual strength after for instance 10 years of Belgian outdoor weathering can then be determined (e.g. for Belgium an average temperature of 11°C can be used). The procedure shown in Fig. 2 is now repeated 50 times for each simulated combination. Comparing the average residual strength after X years of outdoor exposure (S^{V}_{Xyears}) with the initial assumed theoretical residual strength (S^{T}_{Xyears}) will give an order of magnitude for the error on the prediction.

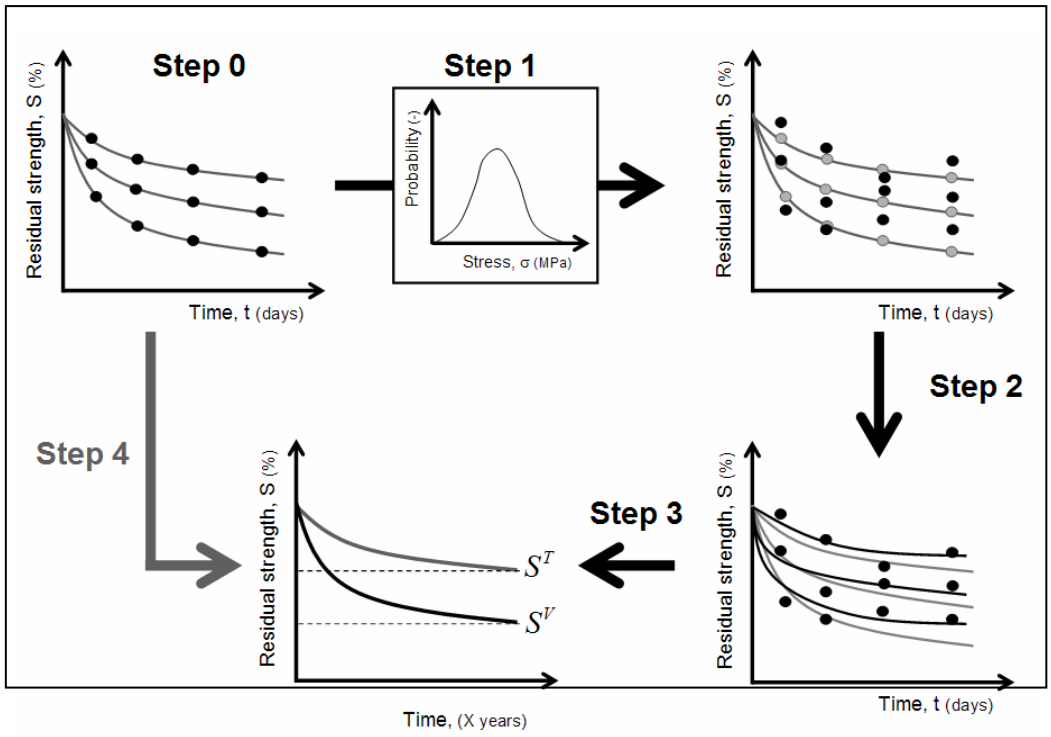

Figure 2. Scheme used for the sensitivity study

3.3 Sensitivity Study Performed on the Kinetic Model

The approach elaborated in the previous section was now adopted to check the sensitivity of the Kinetic model to scatter on the measurements. For part one of the calculations the same premises were used. The same range of temperatures and times were thus used as presented in Fig. 1. For part 2, 10 specimens were used with a CV of +/- 7% (own experiments on SIC specimens showed a Weibull distribution, the distribution parameters were taken from literature (Van Itterbeeck *et al.* [2007])). As starting/theoretical values for the model parameters for the Kinetic model the following were chosen: 82 kJ/mol for the activation energy and 8,84 nm day^{-1} for the reference rate. These values were obtained through the fitting of results from literature (Litherland *et al.* [1981]) on a large set of SIC specimens. For the determination of the residual strength, an exposure to 10 years of Belgian outdoor weathering was assumed (average annual temp of 11°C).

With the above mentioned input for each "virtual" experimental combination the residual strength due to scatter on the measurements was calculated 50 times and the average "virtual" experimental residual strength was determined. For each combination of number of temperatures and number of time/temperature point (within each temperature series) this resulted in a similar graph as presented in Fig. 3a. The results depicted in Fig. 3a show the results for all possible combinations with 3 temperatures and 4 time/temperature points when 10 specimens are used with a CV of +/- 7% (210x35=7350 combinations see section 3.2). The points represent the average of the 50 simulated values (7350 points). Through these points a 5^{th} degree polynomial was fitted in the X and in the Y direction. From this figure it can be clearly seen that some experimental test schemes should better be avoided. Using only high temperatures and longer periods of time most likely results in large underestimations of the residual strength. The graph also shows that if a mix of high and low temperatures is used the average residual strength predicted usually approximates the theoretical predicted residual strength, which is equal to 0,53 in this specific case. It should however be empasized that this graph only gives the average of the residual strength of 50 simulations, one should also consider the standard deviation on this average value since this might be quite high.

The results depicted in fig. 3a were summarized in fig. 3b into 2 points A and B, which are respectively representing the maximum and minimum values within fig. 3a. This procedure was repeated for several combinations (with 3 temperatures and different amounts of time/temperature datapoints) and these results are also summarized in fig. 3b. It can be clearly seen from this Figure that large underestimations can be obtained when only a limited number of time/temperatures points are under consideration and this even when a large number of specimens (10) per time/temperature "virtual" experimental value and a low CV (+/- 7%) are being used. It should be emphasized that the results presented in Fig. 3a and 3b were constructed based on the fact that the Kinetic model represents the real bahaviour of the flaw growth. The conclusions taken for this case are thus not necessarely similar for all possible material combinations.

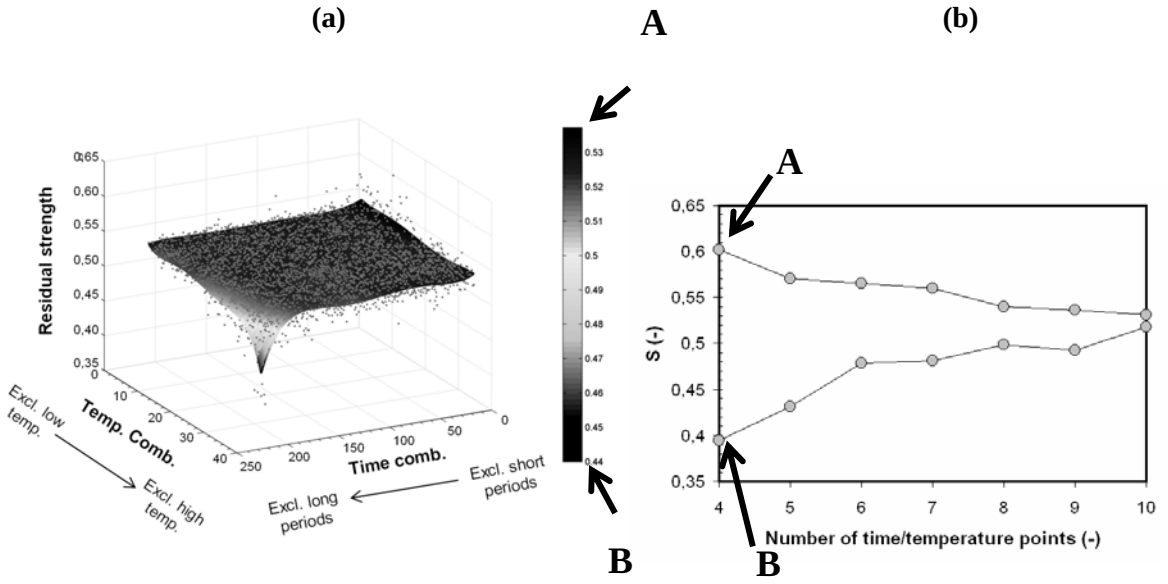

Figure 3. Results of the sensitivity study for the Kinetic model: (a) when 3 temperatures and 4 time/temperature points (within each temperature series) are being used (b) for all temperature and time combinations.

4 CONCLUSIONS

Over the years different strength durability models for GRCs have been developed. The four models presented and discussed within the scope of this paper are all based on a similar physical background, that the growth of flaws in the fibres due to chemical attack is responsible for the reduction in strength. All of these models also require a similar approach for the calibration. Specimens are immersed in hot water at temperatures ranging from 20°C-80°C for various periods of time and the residual strength is assessed after this exposure. Through an inverse method the rate coefficients of the models can be determined and the model parameters can be obtained. With these model parameters a strength prediction can be performed. In this paper a methodology was developed which enables the user to determine the uncertainty on his/her prediction as function of the number of acceleration temperatures and time/temperature points used, number of specimens which constitute the average values of each of the time/temperature points and the scatter inherently present on the tested specimens. Some preliminary results for the Kinetic model presented within the scope of this paper indicate that for this specific model some acceleration schemes are to be avoided (exclusively high temperatures in combination with exclusively high exposure times) since they can result in large underestimations of the strength. Large underestimations are also obtained when only a limited number of time/temperatures points are used and this even when a large number of specimens (10) and a low Coefficient of Variation (+/- 7%) are assumed. It should be emphasized once again that the results presented within the scope of section 3.3 were constructed based on the fact that the Kinetic model

represents the real bahaviour of the flaw growth. This is not necessarely the case for all possible material combinations. Therefore it is also necessary to perform this study on the other strength durability models.

The Sand Concrete: A Very Little Cracked Material

T 11

ABSTRACT

The observation of hardened sand concrete fragments under the sweeping electronic microscope (SEM) makes it possible to describe the material as being little fissuring with a good overall homogeneity and a good bond between cement paste and sand grains. This small fissuring character is confirmed by the very uniform kinetics of drying between the peripheral face and the heart of a test-tube. Indeed this uniformity of drying involves small hydrous gradients and thus low tensile stresses on the surface and consequently a low density of cracking. The evolution of the shrinkage deformation according to the rate of drying shows a perfect linearity thus proving the absence of notable cracks.

1 INTRODUCTION

The sand concrete is a material made from sand, cement, water and natural or industrial fillers. In a country like Algeria of more than two million km^2 with a very vast desert occupying most of the surface, the transport cost prices of stones or aggregates on hundreds of kilometres, can be very high. However precisely the Algerian south is very rich in sand of various grading as well as natural fines (Laghouat, Ouargla, etc.)

This new material can consequently replace the traditional concrete for economic reasons which we have just seen but also for specific qualities. Indeed its good workability implies a cheaper installation energy, its small granularity authorizes its use in the strongly armed structures and its beautiful surface aspect makes it possible to do without traditional rough-casting from where a certain profit out of cement, water, labour and painting.

The sand concrete, because of its appreciable resistances, 12 to 60 MPa, makes its use in manufacturing filler blocks (bricks, breeze blocks, hollow tiles, etc…) completely possible and preferable to ordinary concrete. The road field can also constitute a privileged place of the use of this material as well as the recoveries in ground work. The other interest of this material for a country as Algeria is the use of industrial fillers (phosphogypsum, glass and metal fibres, etc…) to increase the compactness of the sand concrete. The absorption of these industrial wastes is not only of economic interest but ecological interest as well.

In France, sand concrete finds its origins in the "agglomerated concrete" made by F. Coignet in the third quarter of nineteenth century. This material then consisted of sand, cement, lime and water. The retaining wall in Passy and the Coignet house in Saint-Denis, constitute the first applications of this technique which one also finds in the realization of the Port-Saïd tower in Egypt (height: 52 m) and a bridge in New York, as described in C.E.B.T.P.[1986].

The first granular correction attempts remain the prerogative of F Coignet which, for the needs of realization of certain parts of the Vanne aqueduct built between 1869 and 1872, mixed traditional fine sand with sand not used at that time because it was considered to be unsuitable for Construction.

In reality, according to Chauvin [1987], this technique was developed since decades in the ex-USSR, as testified by the achievements of the port of Kaliningrad at the beginning of last century and the bridge of Chernavski. This technique was taken again later, at the end of Second World War, by Professor Rebinder who allowed the use of this material in many fields (roadways, runways, filler blocks, architectural walls, floors, concrete slabs, etc…).

Indeed under the impulsion of this academician, the Soviet carried out certain technological tests on the sand concretes while being based in their work, in particular, on the parameters of aggregate grading, fineness of binders, reducers of water and the modes of vibration. Thereafter, this material fell in disuse because of the great mechanical resistances obtained by the use of large aggregates, but the shortage of coarse alluvial aggregates and the availability of large sand layers pushed to study a made cement and sand material to replace the ordinary concrete in certain fields (bricks, breeze blocks, hollow tiles, little requested structures, etc…).

The project "SABLOCRETE" (association for the promotion and the development of the sand concrete) tends, amongst other things, to optimize the exploitation of the sand layers, in fact rationalizing the use of sand and aggregates.

To date, the major concern as regards research on the sand concrete was directed towards the formulation of this one in order to obtain a good workability and good mechanical performances. Nevertheless a better approach of the material implies the knowledge of the microstructure, in particular the character with respect to cracking, object of this study.

2 TESTING CONCRETE

2.1 Composition

The component materials of our concrete as well as the fractions of each one of them are presented in [Table 1].

Table 1. Composition of the sand concrete (for 1 m^3)

Elements	*Sand: rolled-siliceous (Kg)*	*CPJ-CEM II /A-42,5 (Kg)*	*Calcareous filler (Kg)*	*Super plasticizer (l)*	*Water (l)*
Sand concrete	*1500*	*350*	*200*	*7*	*190*

2.2 Mechanical Characteristics

The compression test was carried out in accordance with French standard NFP 18-406. The tensile test was carried out in accordance with the French standard NFP18-400. The measurement of the elastic modulus was made by an extensometer equipped with cylinder and control in accordance with the test process project L.P.C-Oct. 89. The values of various measurements are consigned in [Table 2]; each value is the average of three measurements.

Table 2. Mechanical characteristics of sand concrete.

stresses	*Age (days)*				
	03	*07*	*14*	*28*	*90*
Compressive strength (MPa)	*11*	*17*	*21,5*	*23,6*	*28,8*
Tensile strength (MPa)	*1,24*	*1,97*	*2,24*	*2,36*	*2,53*
E (MPa)	*17000*	*19700*	*-*	*23000*	*23000*

2.3 Principle of Formulation

The sand concrete, unlike the mortars, uses a cement factor close to the ordinary concretes (300 to 400 Kg/m3). What distinguishes the sand concrete from the ordinary one resides primarily in the use of aggregates of low diameter ($\phi \leq 5$ mm), an addition of coarse aggregates is however possible but in a mass ratio G/S lower than 1. The different cement factors were possible because of the filling of sand vacuums by a limestone filler (0/80 µm), this has as a positive consequence in increasing compactness by the creation of a continuous granular extent. The fillers used, in general, are of limestone nature thanks to their great reactivity with the hydrates. The great specific surface obtained by the use of a high fraction of fine particles requires a significant wetting from where the utility of a water reducer, with an aim of increasing the performances and attenuating the differed deformations.

3 STUDY OF CRACKING

3.1 Studies with the SEM

The observations carried out with the **SEM** are represented by the figures 1 to 6 which show that the sand concrete is an amorphous and homogeneous material. The interface paste-aggregate 'Fig.6' does not have a particular texture and the bond is good. We do not notice notable cracks apart small faults visible 'Fig.6' in the vicinity of the interfaces which could result from shocks because the sample analyzed has a volume of 1 cm^3 and is obtained by shock fragmentation of a test-tube. The cracking of traditional concrete is due to gradients of traction related to non uniform drying which is at the origin of hydrous gradients. If our material is little or not fissuring, it implies that the hydrous gradients are negligible, this means that the drying of a test-tube is uniform and this is what we propose to check.

Some aspects of the hardened cement paste

Figure 1. Dense paste rather homogenous (X1200)

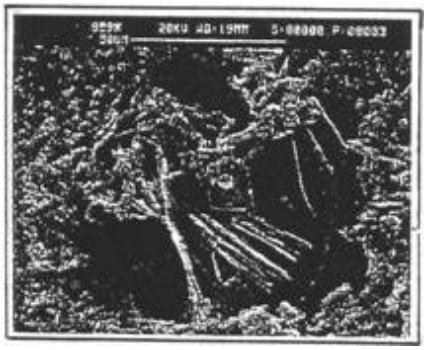

Figure 2. Particular structuring of the hydrated products inside a pore (X 859)

Figure 5. Hydrated products inside a pore (X 156)

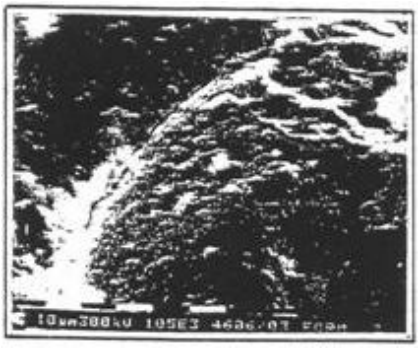

Figure 6. Separation of a tangled up aggregate (Exceptional phenomenon) (X 1050)

3.2 Study of the Kinetics of Drying

A sand concrete test-tube whose faces were made tight thus undergoing a radial drying was analyzed with the bench gamma. The diagram of the study of this test-tube is represented below [Fig.7]. This method, based on the absorption of gamma rays, makes it possible to follow the evolution of the loss of density according to the radius and the age. In this test, the cylindrical test-tube is posed on a plate which can move vertically and is crossed by a collimated beam of gamma rays which one measures the rate of absorption. The position of the test-tube makes it possible to determine, by differences with initial measurements, the variation of the average density of a crown.

The bench used not being equipped with a plate allowing rotation with the test-tube and thus a sweeping of the ring; measurements were made in several points whose average was used as value for the crown. The vertical displacement of the plate authorizes obtaining the distribution of these values along the diameter [Fig 8].

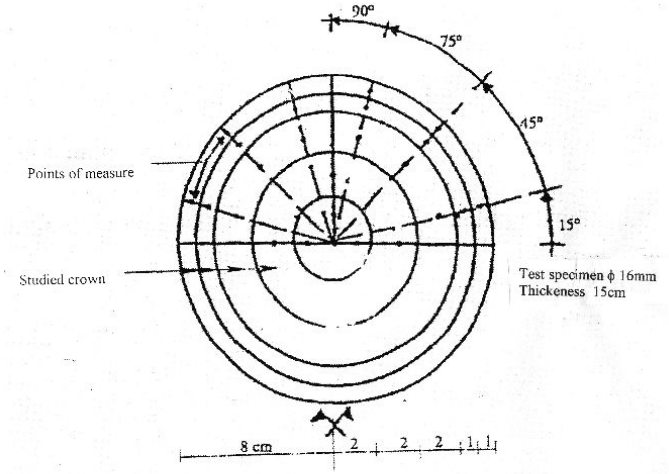

Figure 7. Diagram of the gammametric study

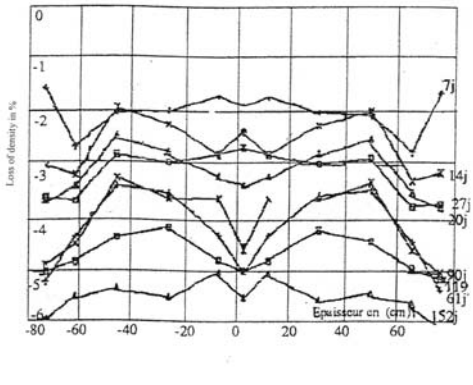

Figure 8. Evolution of the loss of density in function of thickness and age of the sand concrete.

Contrary to the traditional concretes where drying affects only one peripheral crown of a few mm thickness during the first months, the sand concrete test-tube is affected by a drying extremely fast and uniform, indeed the heart undergoes drying from the fifth day after the dismantling, which is operated at 48 hours and the amplitude of variation of density in the heart at the end of 20 days represent more than 80% of that measured at peripheral during the same period. One can think consequently, that the gradients of constraint on the surface are not very significant and density of cracking which results from this is weak. Homogeneity of the sand concrete confirmed by observations with the MEB doesn't explain by itself such behaviour.

The recourse to the porosimetry with mercury prove extremely instructive in similar case, this is why fragments of hardened sand concrete were analyzed. The results obtained being appreciably the same (other evidence of the homogeneity of the concrete), only one of the histograms of the pores is represented [Fig. 9].

The structure of the sand concrete is of monomodal type with a single peak being at the vicinity of 250 A around where are located more than 90% of the pores of the complex. These pores are thus of type "micro", whereas in traditional concrete, hardened cement paste present two peaks.

A first peak corresponds to the pores of small diameters and is located in the space going from 50 to 100 A according to water/cement ratio. The second peak corresponds to the pores of large diameters (600 to 1300 A) of the "macro" type; this last peak l is strongly influenced by water/cement ratio.

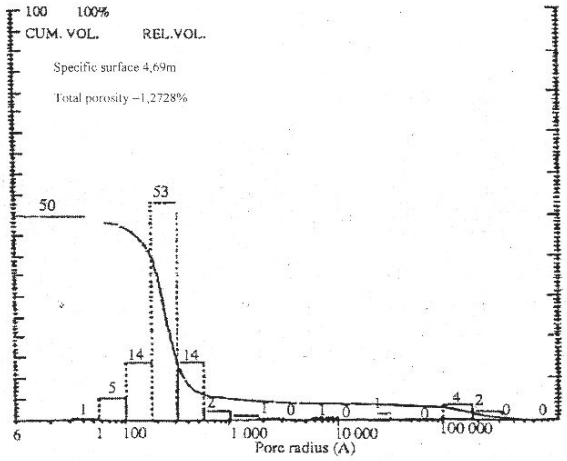

Figure 9. Porosimetry with mercury of the sand concrete.

It is undoubtedly this particular porosimetry of the sand concrete which explains the behaviour with drying. The bimodal structure of the ordinary concrete acts likes a water retention factor in the body of the test-tube, whereas the monomodal structure seems to support on the contrary evaporation. The large pores present in the ordinary concrete act according to us like barrier and are opposed to water evaporation of the micro pores. Such as for example by increasing pressure in the small pores, making any water expulsion difficult. It is not here question of a theory, but of an attempt to explain a phenomenon difficult to interpret, because it is difficult to reason on the scale of infinitely small.

The other explanation would come from the fact that the water of the ordinary concrete pores passes by two successive phases, an accelerated macro diffusion because of the large diameters (peak of the porosimetric curve in the vicinity of 10^3 A) followed by an evaporation of the micro pores clearly more slowed down. This deceleration is to be connected to smallness of pores which have an average diameter of 10^2 A, that is to say 10 times the thickness of one water molecule only, which makes difficult the expulsion of water. Moreover, absorption powers of water in these micro pores must be significant because of the reduced volume of the pores.

In the sand concrete, the main part of the pores (approximately 90%) have an average diameter of 250 A which is 25 times the thickness of the molecule supporting a uniform drying and especially not constrained, from where the fast and plain kinetics forms highlighted previously.

In corollary, according to Benaissa et al. [1992], we advance that the uniformity of drying and the homogeneity of the sand concrete, are the determining factors of the absence of cracks. This state explains, at least partially, the desiccation shrinkage of the sand concrete more significant than that of the ordinary concrete.

Let us note in addition that the weak dispersion of the compressive strengths and measurements of moduli of elasticity, respectively 1.2% and 2.2%, confirms the homogeneous character of the concrete. The moduli of elasticity of the sand concrete are lower than those of the ordinary concrete from where a greater deformability and thus a less cracking.

3. 3 Shrinkage According to the Rate of Drying

The existing linearity between the shrinkage and the rate of drying shows well that the shrinkage is an increasing function of evaporable water. The first measurement being made at 7 days, it is normal to consider that before this age, there is a non nil desiccation shrinkage, which is in addition highlighted by the line (intersection with the axis of the deformations), the other very remarkable information is that the aspect of the line remains rather regular (the experimental points are very close to the line),

whereas one could have expected a break of slope because of possible cracks appearing beyond a certain degree of drying as very precisely stipulated by Abiar [1986] but it is not the case. This regularity translates a likely absence of cracking, while being superimposed on the effect of the evaporation of water, to cause a deformation more slowed down than evaporation, at least in a second phase appearing after the first stage where there is linearity between the variation of the deformation and the rate of drying [Fig 10].

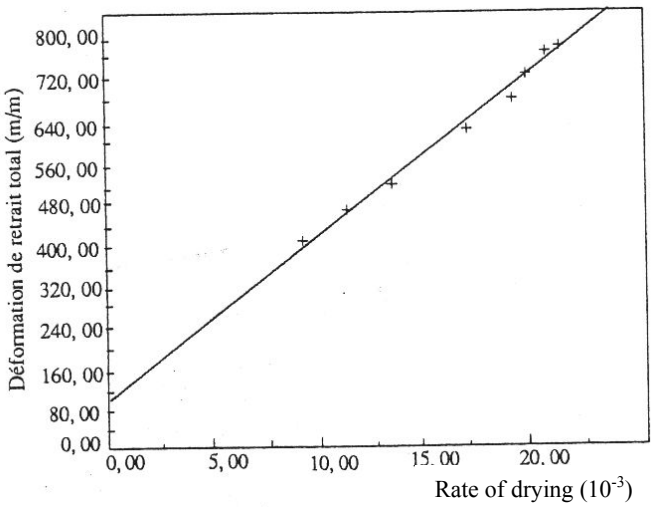

Figure 10. Total shrinkage according to the rate of drying sand concrete

4 CONCLUSIONS

It was shown that the sand concrete is a homogeneous material and of monomodal structure whereas the ordinary concrete is of bimodal type. The fine porosimetry of the sand concrete is at the origin of the nature of the drying which is uniform contrary to the traditional concrete where it is not uniform. This particular kinetics of the desiccation of the sand concrete, explains the not fissuring character of the material. The absence of large inclusions in the matrix is an additional factor which attenuates the risk of cracking.

This not fissuring character, opens to the sand concrete great hopes of use in very varied fields in particular in sub work thanks to its very fine granularity and thus an energy of installation much less expensive than traditional concretes. The use of this material in projected form is to be considered in the rehabilitation of the worn water collectors

Flexural Behavior of Steel-Concrete Composite Girders Strengthened via Fiber Reinforced Plastic FRP

Abdul Qader Melhem [1]

T 11

ABSTRACT

Many of bridge and building elements are in the need of continuous maintenance, repair, and strengthening because of the severe environmental conditions and heavy unpredicted moving loads. This paper elucidates in details theoretically and experimentally how to broaden the structural capacities of steel-concrete composite girders implementing fiber reinforced polymers FRP materials and high strength concrete HSC. Theoretical formulas derived and designing equations put forward in order to improve flexural capacities of steel-concrete composite girder models. Failure modes of those composite models will be discussed also. The experimental composite models are employed to verify the accuracy of the theoretical results. The first model is the steel beam alone, the second model is the steel-concrete composite model assembles of reinforced concrete slab connected by means of studs to the top of steel beam while the third composite model is the second composite model but fabricated with FRP plate to the bottom surface of the steel beam. The simple composite models have the same span length, steel beam section, yield and ultimate strength of steel beam and FRP thickness. High strength concrete has been utilized to improve durability. The models had been exposed to two concentrated loads increased gradually up to failure.

1 INTRODUCTION

With increasing harsh environmental conditions (creep, cracking, de-lamination, wear, and/or effects of foreign object damage …etc) along with unpredictable live loads on highway bridges and other vital structures, there is growing tendency to boost up the structural capacity of the composite components rather than replacing them according to the cost-effective standard. In recent years, there has been a renewed emphasis on improving durability and increasing service life of structures. The value of the concrete is defined in terms of maturity, permeability, air-void structure quantification, sulfate resistance, chloride penetration, strength, and in situ performance [David and Meyerhof 1958].

Strengthening of existing steel-concrete composite structures is becoming a major concern for the industries due to age, steady increase in the applied loads, environmental effects, lack of adequate maintenance … etc. The advent of fiber reinforced polymers FRP has been explored as new materials for strengthening of existing structures. These innovative materials are characterized by their high strength to weight ratio and environmental and fatigue sturdiness. It has been employed successfully in the reinforced concrete structures at least for the last thirty years, but until recently has been utilized momentarily in the composite structures. In fact, the FRP plates, laminates or sheets can be epoxy bonded to the tension face of the composite members to enhance their strength and stiffness.

An earlier study conducted, at the University of South Florida, using CFRP in the repair of steel-concrete composite bridges [Sen and Liby 1994]. Other researchers have investigated the possibility of strengthening steel beams with CFRP plates [Mertz and Gillespie 1996]. The effectiveness of using FRP to increase the stiffness of steel–concrete composite beams also has been demonstrated experimentally [Tavakkolizadeh and Saadatmanesh 2003 and Al-Saidy et al 2004]. Using of externally bonded high modulus carbon fibre reinforced polymer (HM CFRP) materials to strengthen steel bridges and structures has been proposed along with guidelines and installation techniques based on the best practice reported in the literature and the extensive practical experience in bonding of composite materials [Schnerch et al 2007].

2 BASIC ASSUMPTIONS AND OBJECTIVES

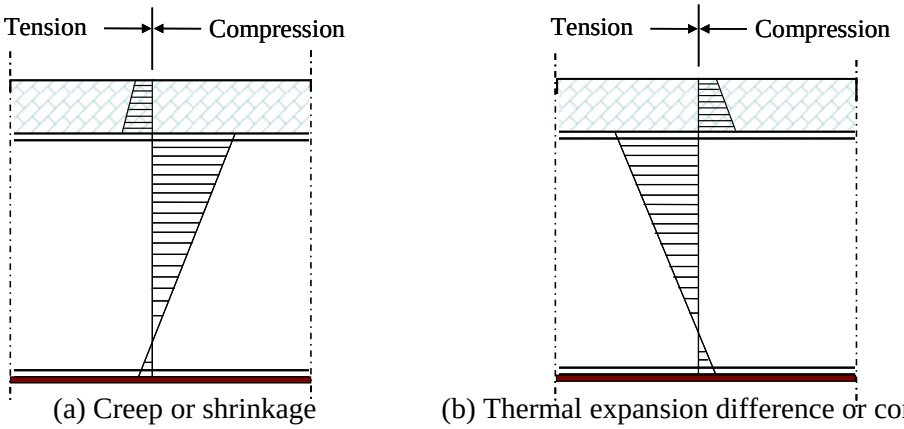
The impending failure manners for a steel-concrete composite beam strengthened with FRP materials are: rupture of the FRP plate, de-bonding of the FRP plate, and crushing of the compression concrete due to loading , environmental conditions or both. There are other failure modes such as, buckling of the compression flange and shear failure of the web. To prevent de-bonding of the FRP plate, it is important to give a ruling for the actual state of stress near the end of the plate. The main objectives of this research are:

- To strengthen previously damaged or distressed steel-concrete composite members making use of FRP plates.
- To build up a procedure that could be used for strengthening of existing steel-concrete composite members, using FRP plates, subjected to up-normal loads or to severe atmospheric conditions.
- To design steel-concrete composite members making use of FRP plates for architectural purpose, such as: reducing the height, weight, etc.

3 STRESSES OWING TO ENVIRONENTAL CIRCUMSTANCES

These stresses are by reason of creep, shrinkage, relative temperature differences, difference between thermal expansion of concrete and steel, and concrete growth. During a sudden rise in temperature, the steel beam and probably the FRP become warmer than that the connected concrete slab because of quicker temperature stabilization of steel. This kind of temperature differential creates an additional strain of $1x(10)^{-4}$ which should be considered in the design. The net combination effect of creep, shrinkage, and temperature differential between cold concrete and warmer steel is shown in Fig.

1.a.The effect of difference between thermal expansion of concrete and steel is shown in Fig. 1.b. Concrete growth causes stresses in composite section similar to that produced by differences in thermal expansion coefficients of steel and concrete. Concrete growth may be due to physical causes such as; freezing-thawing, wetting-drying, heating-cooling, etc. The chemical cause are due to certain cement-aggregate combinations.



(a) Creep or shrinkage (b) Thermal expansion difference or concrete growth

Figure 1. Stresses due to Environmental conditions.

4 FULL PLASTIC BENDING

When the applied moment becomes greater than that moment which generates first yield of farthest fibers, portions of the composite section will keep hold of a constant yield stress, at strains which go beyond the elastic limit. Progressive straining and yielding of the material will then take place until complete plasticization of the section. At this bound no additional moment can be developed, thus a full plastic moment is reached. At this stage, the plastic neutral axis may be located in the concrete slab, steel top flange, or steel web.

The failure load with shoring is almost the same as that developed when no shoring is used. This is because of redistribution of stresses in the steel beam, which has little effect on the final plastic moment capacity of the beam. The amount of longitudinal shear which must be taken in to account should include that produced by the dead loads (if shoring is used), live loads, creep, shrinkage, temperature difference, and any difference between the thermal coefficients of expansion of slab and steel beam. From previous numerous tests, it has been shown that if shear connectors are properly designed, composite beam failure is due to only ultimate compressive stress in the concrete slab or full plasticity in the steel beam, or both combination.

4.1 Neutral Axis in the Concrete Slab (Fig. 2a):

If: $0.85\, f_c^{'} A_c > A_s F_y + A_{frp}\, f_{y,frp}$, the plastic neutral axis is located within the concrete slab. The plastic neutral axis location and ultimate moment are given by these equations:

$$a_{T1} = \frac{A_s F_y + A_{frp}\, f_{y,frp}}{0.85\, f_c^{'} b_e} \qquad (1)$$

$$M_u = 0.85\, f_c^{'} b_e\, a_{T1} [d + t_c - d_T - 0.5\, a_{T1}] + T_{frp}\, (d_T + 0.5\, t_{frp}) \qquad (2)$$

Where,

$T_s = A_s F_y$, $T_{frp} = A_{frp}\, f_{,frp}$

$$d_T = (1/A_s)[A_{bf}\, (0.5 t_{bf}) + A_w\, (t_{bf} + \frac{d_w}{2}) + A_{tf}\, (t_{bf} + d_w + \frac{t_{tf}}{2})]$$

When the section is symmetric: $d_T = d/2$

A_s = Area of steel section = (A_{bf} + A_w + A_{tf})

A_{frp} = b_{frp} t_{frp} = Area of FRP plate

F_y = Yield stress limit of steel beam, f_{frp} = Ultimate tensile strength of the FRP material

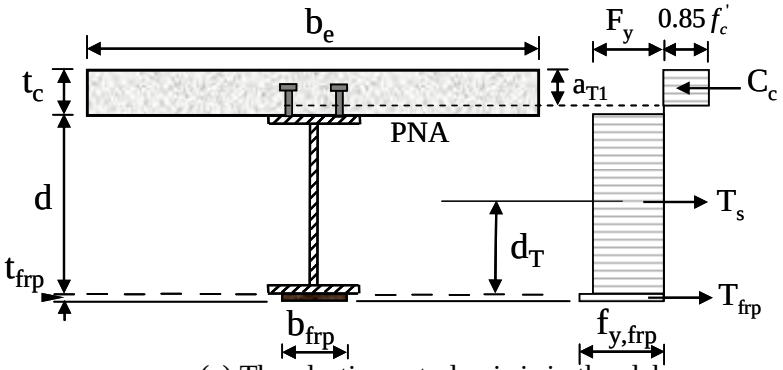
Other terms are shown in Fig. 2

4.3 Neutral Axis in the Steel Section (Fig. 2b, 2c**):**

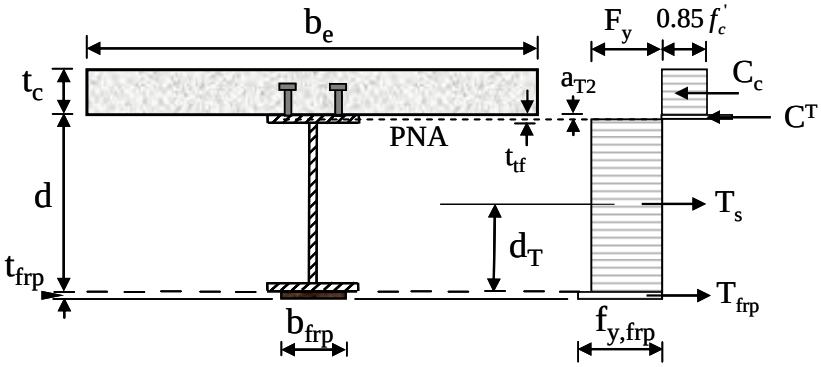
If: $0.85\, f_c^{'} A_c < F_y A_s + A_{frp} f_{y,frp}$, the plastic neutral axis is located in the steel section.

1. If: $F_y A_{tf} > C^T$, the plastic neutral axis is in the top flange of the steel section.

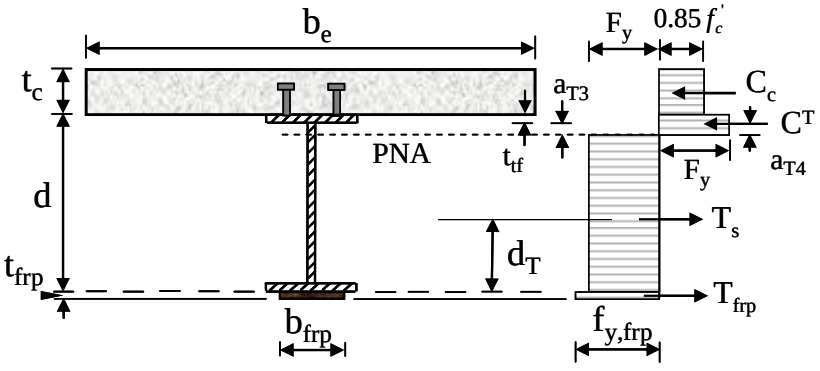
Where,



(a) The plastic neutral axis is in the slab.



(b) The plastic neutral axis is in the top steel flange.



(c) The plastic neutral axis is in the web of steel section.

Figure 2. Plastic analysis of steel-concrete composite model.

$$C^T = 0.5\, [(F_y A_s + A_{frp} f_{y,frp}) - 0.85\, f_c^{'} A_c] \qquad (3)$$

The location of neutral axis and ultimate bending moment are given by these equations:

$$a_{T2} = \frac{C^T}{F_y\, b_{tf}} \tag{4}$$

$$M_u = 0.85\, f_c^{'} b_e\, t_c\, [d + 0.5t_c - d_T] + C^T(d - d_T - 0.5\, a_{T2}) + T_{frp}\, (d_T + 0.5\, t_{frp}) \tag{5}$$

$$d_T = (1/A_{s1})[A_{bf}\, (0.5t_{bf}) + A_w\, (t_{bf} + \frac{d_w}{2}) + b_{tf}\, (t_{tf} - a_{T2})\, (t_{bf} + d_w + \frac{t_{tf} - a_{T2}}{2})]$$

$$A_{s1} = A_{bf} + A_w + b_{tf}\, (t_{tf} - a_{T2})$$

2. If: $F_y\, A_{tf} < C^T$, the plastic neutral axis is in the web of the steel section.

The location of neutral axis and ultimate bending moment are given by these equations:

$$a_{T3} = \frac{C^T - A_{tf} F_y}{F_y\, t_w} \tag{6}$$

$$M_u = 0.85\, f_c^{'} b_e\, t_c\, [d + 0.5t_c - d_T] + C^T[d - (t_{tf} + a_{T3}) + a_{T4} - d_T] + T_{frp}\, (d_T + 0.5\, t_{frp}) \tag{7}$$

$$d_T = (1/A_{s2})[A_{bf}\, (0.5t_{bf}) + t_w\, (d_w - a_{T3})\, (t_{bf} + \frac{d_w - a_{T3}}{2})]$$

$$A_{s2} = A_{bf} + t_w\, (d_w - a_{T3})$$

5 SPECIMEN DETAILS

A steel-concrete composite girder model has been reproduced and reworked again in more specifics [Sen, et al, 2001] using high strength concrete (HSC) to boost up the durability. This is another way to heighten service life through designing, specifying, and building structures using (HSC). The American Concrete Institute has previously defined (HSC) as concrete with a compressive strength greater than 41 MPa (6000 Psi).

The aim of the test is to evaluate the viability of using FRP plates for improving the strength of steel-concrete composite girder models. Table 1 present material properties of the models. Figure 3 shows cross section of the model. The simple model was subjected to two concentrated loads as been show. The loads were applied through two 710 mm transverse stiffened spreader beams welded to a 1220 mm long longitudinal stiffened beam. The loads were two uniform transverse line loads spaced 1220 mm apart, transferred equally to the two spreader beams.

Table 1. Properties of Materials.

Concrete		*Steel*		*FRP*	
Compressive Strength, MPa	43.6	Yield strength, Mpa	370	Tensile Strength, MPa	1840
Elastic Modulus, MPa	13800	Elastic Modulus, Mpa	198300	Elastic Modulus, MPa	114000
Peak strain	0.00197	Poisson's ratio	0.31	Failure Strain	1.6 %
Failure strain	0.00380			Poisson's ratio	0.34

The cross section consists of a 710 mm reinforced concrete slab width, 114 mm thickness attached to a W 8 x 24 steel section via 36 stud shear connectors. The studs were spaced at; @ 127.6 mm for the shear spans and @ 254 mm for the distance between concentrated loads. The FRP plate length was 3650 mm, bonded to the bottom steel surface using epoxy adhesive. Table 1 presents mechanical properties of the model materials. The first phase of the experimental program was testing W 8 x 24 steel section under two concentrating loads. The second phase of the experimental program was the steel-concrete composite girder model had been loaded beyond yield stress limit of its bottom tension flange, which is 0.55 F_y , according to the AASHTO Bridge Specifications.

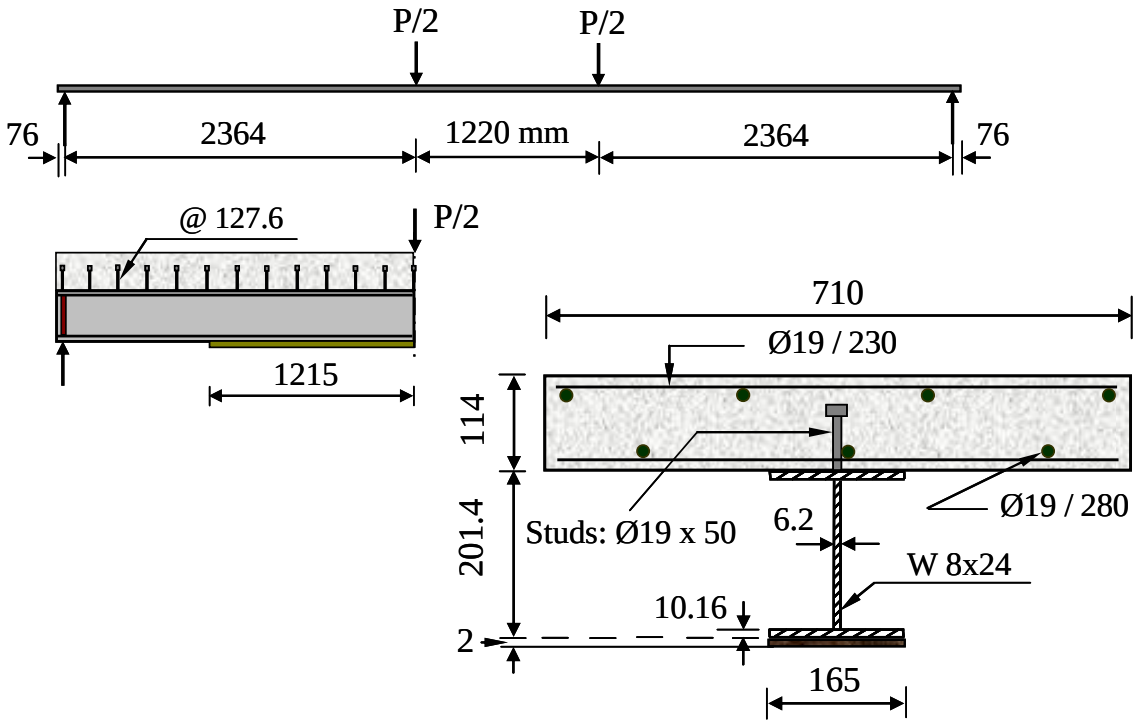


Figure 3. The experimental composite girder model.

As a result of this loading, higher than yield stress limit of tension flange, there was permanent deformation prior to strengthening by means of FRP plate. The third phase of the experimental program was the deformed steel-concrete composite girder model had been strengthened with 2 mm thick, 165 mm width and 3650 mm length epoxy adhesive. After the adhesive cured for 48 h, the ends of FRP plate were bolted to resist the peeling stresses. The same loading scheme had been used for testing the repaired model. The test was stopped when no extra load could be applied and the deflection exceeded the 100 mm limit. No adhesive failure had been observed. Table 2 presents elastic model properties. These properties have been calculated using AASHTO Bridge Specifications.

Table 2. Elastic properties of the sections.

Beam	y_{bot} *(mm)*	y_{top} *(mm)*	I_{com} (cm^4)	S_{bot} (cm^3)	S_{top} (cm^3)
Composite beam	216.8	98.6	13177.11	607.77	1336.28
Composite beam with FRP	216.5	101.0	14072.48	650.15	1393.73

The deflection at midspan is calculated by this equation:

$$\Delta_{L/2} = \frac{(P/2)}{6EI_{tr}}\left(\frac{a}{L}\right)(L^3)\left[\frac{3}{4}-\left(\frac{a}{L}\right)^2\right] \approx \frac{1}{51}\frac{PL^3}{EI_{tr}} \qquad (8)$$

The strains at the top and bottom of the steel-concrete composite section are given by these equations:

$$\varepsilon_c = \frac{P\,a\,y_{top}}{2EI_{tr}} \text{ and } \varepsilon_s = \frac{P\,a\,y_{bot}}{2EI_{tr}} \qquad (9)$$

Where,

L = Span length between supports, equal to 5948 mm

a = Shear span, the distance between support and first load which is equal to 2364 mm

a/L = Shear span ratio is equal to 0.3974

E = Modulus of elasticity of the homogeneous section

I_{tr} = Moment of inertia of composite section

P = Applied load

y_{top} and y_{bot} = Distances from neutral axis to the top and bottom of the steel-concrete composite section

Table 3 presents summary of the theoretical and experimental studies. Figure 4 shows three load-displacement curves; the top one is for the composite girder strengthened with FRP plate, the middle is for the composite girder without FRP plate and the lower curve is for the steel section alone.

Table 3. Summery of outcomes.

Beam	a_{T1} *(mm)*	P_{elast} *(KN)*		P_{ult} *(KN)*	
		Thoe.	*Exp..*	*Thoe.*	*Exp.*
Composite beam	53.8	125	130	225	249
Composite beam with FRP	87.3	131	150	325	271

These curves outline the phases of the experimental program. The curve for repaired or strengthened composite beam is gaining more strength in the post – yield region as been shown. The simulating service damage load for un-strengthened composite beam was 186 KN, while the ultimate load for strengthened composite beam was 271, a strength gain of 46 %. On the other hand, the predicted ultimate load for unstrengthened composite beam was 249 KN while the ultimate load for strengthened composite beam 271 KN, a strength gain of 8.8 %. This low value is attributed to the fact that the FRP plate has a lower elastic modulus than that of steel; 198300 MPa versus 114000 MPa. So, the stresses in FRP plate were less than those stresses in the bottom steel flange prior to yielding.

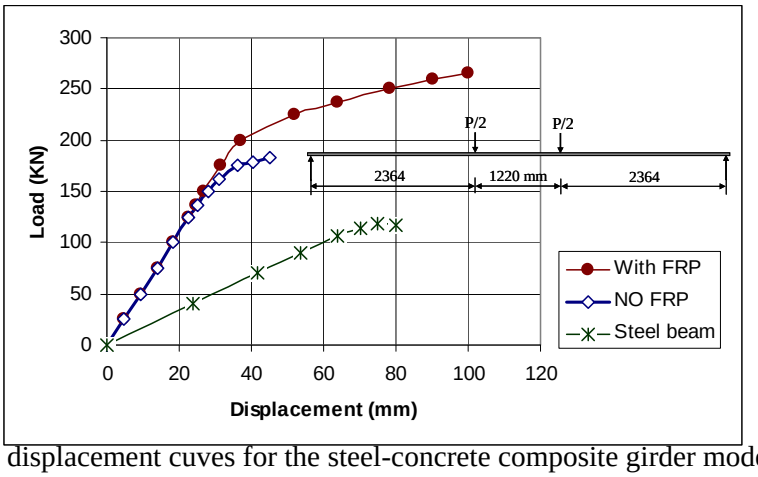

Figure 4. Load displacement cuves for the steel-concrete composite girder models.

6 DESIGNING EQUATIONS

Designing equations have focused on the case where the neutral axis is within the slab **(**Fig. 2a**)**. The Majority of steel-concrete composite girders full under this category. The designing equations may be summarized as followings (Eq. 1 and Eq. 2):

$$q_{frp}^2 + 2\left[q_s - \frac{d}{t_c} - 1\right] q_{frp} + 2\left\{\left[0.5q_s - \left(\frac{d - d_T}{t_c}\right) - 1\right] q_s + \frac{M_u}{0.85 f_c' b_e t_c^2}\right\} = 0 \qquad (10)$$

$$q_{frp} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Where: a = 1 , b = $2\left[q_s - \frac{d}{t_c} - 1\right]$, c = $2\left\{\left[0.5\, q_s - \frac{d - d_T}{t_c} - 1\right] q_s + \frac{M_u}{0.85 f_c' b_e t_c^2}\right\}$

$$q_{frp} = \frac{A_{frp}}{A_c} \frac{f_{frp}}{0.85 f_c'} \text{ and } q_s = \frac{A_s}{A_c} \frac{F_y}{0.85 f_c'}$$

7 CONCLUSIONS

- The presence of FRP plate increases the stiffness of the steel-concrete composite model provided that adequate anchorage of the FRP plate to the bottom steel flange. Therefore, the composite beams strengthened with FRP plates using HSC can be utilized effectively in durability practice.

- A ductile failure mechanism comes about for the repaired or strengthened composite model with FRP reinforcement accompanied with considerable deformation, provided that shear connectors are properly designed against heavier loads and environmental conditions.

- The deformed or distressed sections can be strengthened successfully via FRP plates a substantial strength gain was attained.

- In addition to increases in ultimate load, the elastic region of the un-strengthened composite beam was significantly extended in the repaired composite beam. This provides a valuable marginal safety factor.

- The designed equations can be employed for selection of the area fraction of FRP plate needed to upgrade existing bridges superstructures, provided that ultimate bending moment is available.

Corrosion Detection of Embedded Steel in Concrete

Mohammad Ismail [1]
Rosly Abdul Rahman [1]
Erica Dina [1]

T 11

ABSTRACT

Corrosion of reinforcement is a worldwide problem. It can occur either by carbonation or chloride attack. If the electrochemical process of corrosion can be detected at an earlier stage, some preventive measures can be arranged. The aim of this research is to look at the possibility of using modified fibre optic sensor to detect and monitor the corrosion process of reinforcing steel. The corrosion process was monitored by an unclad plastic optical fibre sensor which is attached to the steel bar. A fibre optic silicon pin detector was used with light source to detect the spectrum of the light. The light spectrum change in intensity due to corrosion product developed on the bar surface becomes thicker as the corrosion progressed. Three types of samples (concrete prisms) with steel bars inserted at the centre have been prepared for this research. One sample was immersed in 10% Sodium Chloride (NaCl) solution and another in 40% NaCl to speed up the corrosion process. Reference sample was immersed in distilled water. The data of corrosion process was collected for a period of 45 days. Replicate samples were prepared and subjected to similar exposure conditions, but the corrosion progress was monitored using half cell kit. The result shows that the potential value of the control sample outgoing light from the optical fibre was about constant at 10500 mV. However for sample immersed in solutions containing 10% and 40% NaCl, the potential value reduced to less than 6000 mV. The intensity value decreases slowly with the progress of corrosion. Similar pattern were also observed by half cell measurements.

1 INTRODUCTION

Corrosion of reinforcement is a worldwide problem that affects durability and integrity of reinforced concrete structures. Corrosion of reinforcement primarily occurs because of carbonation process which reduces the alkalinity of concrete or due to chloride ions which attack the passive layer on the reinforcement [Broomfield 1997, Elsener *et al*. 1999]. Repairing deteriorated reinforced concrete structures at an advanced stage is very costly and time consuming. It is more advantageous if corrosion can be detected at an earlier stage so that some preventive measures can be carried out. The fibre optic sensors monitoring technology were developed to describe the unique marriage of materials in structural engineering. Although this structurally integrated sensing system could monitor the state of a structure's stability and durability but in order to improve the quality control of these structures, it is necessary to develop a good sensor that has the capability to continuously identify the actual changes in the activities leading to corrosion, both at fresh and hardened states.

Fibre optic sensors have demonstrated the ability to take some of the key structural evaluation and performance measurements as described by [Huston and Fuhr 1995]. Fibre optic sensors are similar to electrical sensors in that the fibre optic sensors use light as both the sensing and information transduction medium. However, while electrical sensors operate by modifying the voltage, current, frequency, or phase of an electrical signal the fibre optic sensors operate by modifying the intensity, fast frequency (wavelength), slow frequency (time-modulated intensity), polarisation, phase, and coherence [Huston *et al*. 1999].

The applications of fibre optic sensors in engineering components and systems have been tested in several laboratories and installed in different structures. The laboratory results have been quite promising, showing potentials for further improvements [Eric 1995 and Siaw *et al*. 2002]. The majority of the field installations are currently of the study or demonstration type. Mendez *et al*. [1990] first suggested the use of embedded fibre optic sensors to measure physical properties in concrete. They found that the alkaline nature of concrete could damage the silicon in glass, but the damage can be avoided by jacketing the glass fibre with plastic buffers.

Huston and Fuhr [1992] and [Fuhr *et al*.1993] also used fibre optic sensors in reinforced concrete. Their studies involved embedding optical fibres of various types inside small reinforced concrete cubes (100 mm x 100 mm x 100 mm). The initial tests focused on whether or not optical fibres could survive the concrete environment and curing process. Escobar *et al*. [1992] used bonded fibre optic strain gauges on concrete beams. Maher and Nawy [1993] reported the successful use of fibre optic bragg grating strain gauges in laboratory concrete beam test. The use of fibre optic sensor to determine the physical properties of concrete such as cracking, stress-strain, and temperature has been well developed by [Huston and Fuhr 1995]. This paper highlighted a development of sensor that can monitor corrosion process by modifying a fibre optic.

2 MATERIALS AND TEST PROCEDURES

The properties of specimens used in this experiment are; 1:2:4 concrete prism size 50 mm x 50 mm x 100 mm. 0.6 water/cement (W/C) ratio, and 2% NaCl by weight of cement added to the mix. A 6 mm diameter mild steel rod, cleaned with sandpaper was immersed in nitric acid until the steel is silvery in colour. Fibre optic was cut into pieces of 300 mm length. About 40 mm at the middle of the fibre was unclad. The unclad plastic optical fibre was finally tied to the steel rod and embedded in the concrete prism as shown in Fig. 1.

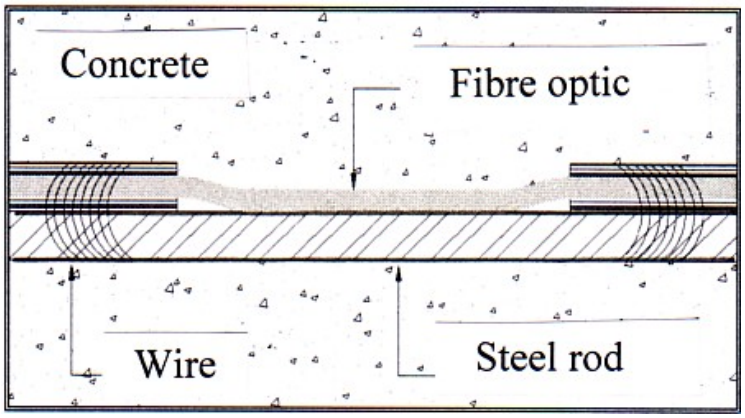

Figure 1. Fibre optic sensor attached to reinforcement.

The glass rod was used to protect the plastic optical fibre from the NaCl solution. The prisms were then immersed in the NaCl solution to speed up the corrosion process. The samples are as shown in Fig. 2.

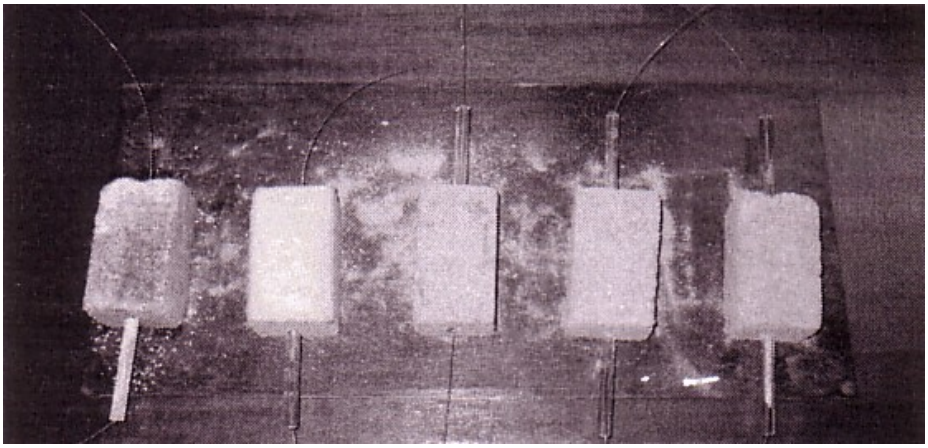

Figure 2. Samples of reinforced concrete prisms.

A specimen was immersed to each of the 10% and 40% NaCl solutions. A HeNe laser was later used to ensure that the cladding was properly removed. The experimental setup is shown in Fig. 3.

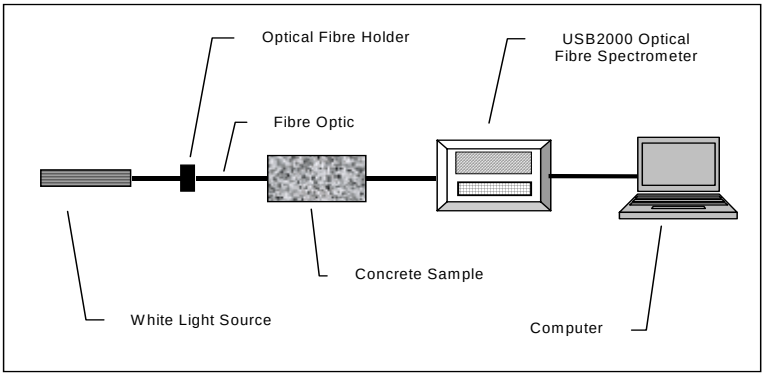

Figure 3. The illustration of experimental setup.

The intensity of the outgoing white light was recorded using Silicon pin detector and the spectra obtained before and during the corrosion process were also recorded.

When corrosion of the reinforcement occurred, it is reflected by transmission of light through the unclad portion of the plastic optical fibre. The light signals from the fibre were then recorded at intervals of 24 hours. This process continued for a period of 45 days.

3 RESULTS AND DISCUSSION

Figure 4 shows the corrosion curve recorded by the unclad plastic optical fibre corrosion sensor of the controlled sample (sample A). The reinforcing steel was not corroded after 45 days. The curve shows that the output voltage is always stable throughout the 45-day period. The voltage for non-corroded reinforcement steel rod fluctuated between 9500 and 10500 mV. Similar observation was also recorded from half cell measurement where the potential stable was around -100 mV. There was no pattern to suggest the occurrence of corrosion.

Observations on sample B which was immersed in 10% NaCl solution for 45 days are shown in Fig. 5. From the figure, the output voltage starts to decrease after day-20. The voltage then drops slowly from 10337 mV to 6110 mV on day-45. The reduction in the output voltage was believed to be attributed to the accumulation and change in colour on the surface of the reinforcing steel. This corrosion product disturbed the light travel along the fibre hence the reduction in the voltage. This observation is also recorded from the half cell results, where the reading drops from -105 mV to -201 mV on day-45. This is an important observation on reinforcement corrosion.

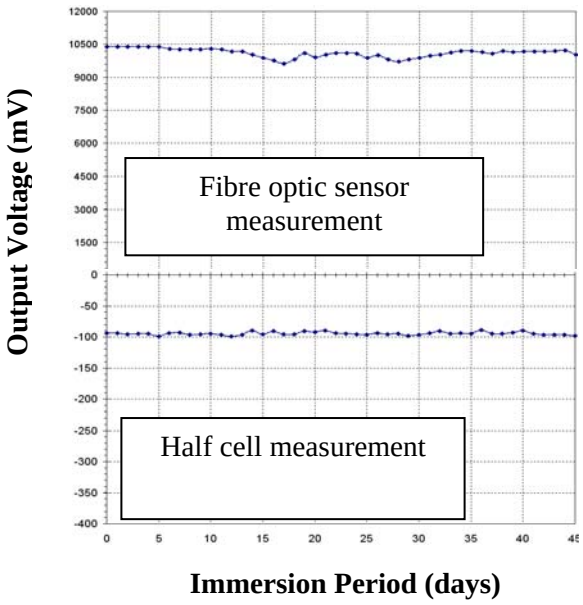

Figure 4. Curve of output voltage Vs Exposure period for controlled sample.

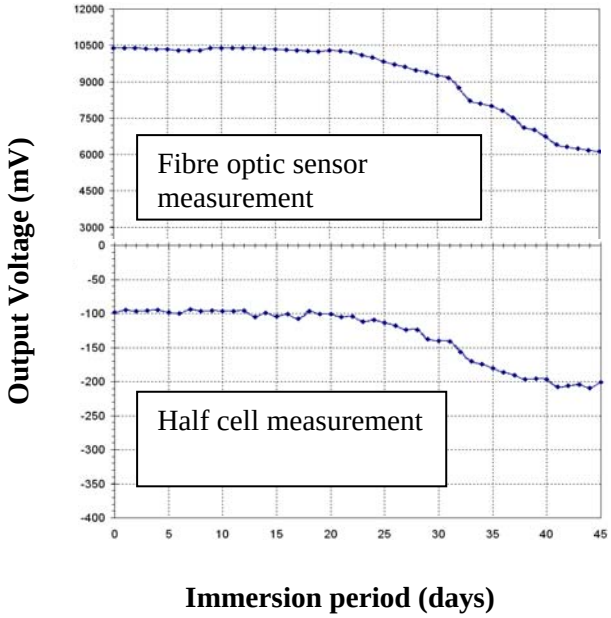

Figure 5. Curve of output voltage Vs exposure period for sample immersed in 10% NaCl.

Figure 6 shows the curve of voltage output due to sample C that was immersed in 40% NaCl solution for 45 days. The voltage curve of this sample drops slowly up to day-20. After day-20 the drop was quite rapid.

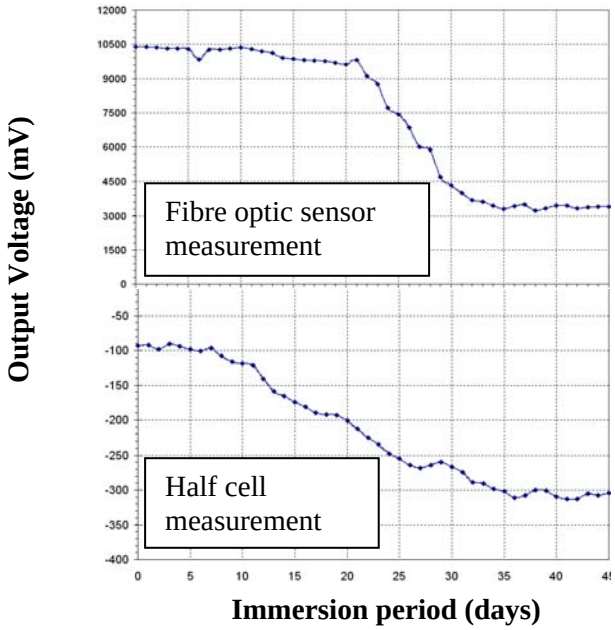

Figure 6. Curve of output voltage Vs exposure period for sample immersed in 40% NaCl.

The pattern showed by the voltage curves proved that, the unclad plastic optical fibre corrosion sensor was capable of observing early corrosion process. This finding is similar to what was found by [Siaw *et al*. 2002] who work on Y-shape fibre bundle and also by [Mohammad *et al*. 2005] in observing corrosion process of reinforcing bar. From the above observation, the application of optical fibre for monitoring the process of corrosion in concrete is very reasonable and promising. Photos of the condition of reinforcement in the three samples after the experiment are shown in Figs. 7, 8 and 9.

Figure 7. Condition of reinforcement in controlled sample after 45 days exposure period.

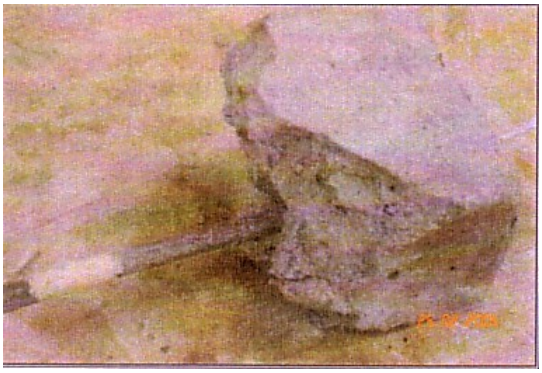

Figure 8. Condition of reinforcement in 10% NaCl solution after 45 days exposure period.

Figure 9. Condition of reinforcement in 40% NaCl solution after 45 days exposure period.

4 CONCLUSIONS

From this study, it is observed that the application of optical fibre sensor to monitor the corrosion process of reinforced concrete structures was encouraging. The changes of white light spectrum intensity tell us about the corrosion intensity of reinforcing steel in concrete.

The following conclusions may be drawn:

i. The unclad plastic optical fibre corrosion sensor can be used as a corrosion monitoring sensor by attaching it to the reinforcement surface.
ii. This type of investigation is very appropriate because the plastic optical fibre can be attached directly to the reinforcement surface.
iii. The transmitted optical power going through the plastic optical fibre decreases dramatically with the severity of corrosion in reinforced concrete.

T 11

ABSTRACT

Various fibers (i.e. polypropylene, steel, etc.) were added to concrete with the purpose of reducing its deterioration rate due to fire. From experimental studies, it was understood that high strength concrete frequently causes explosive spalling under high temperature environment, compared with normal strength concrete.

In order to prevent explosive spalling on high strength concrete, addition of organic fiber was found to be able to provide a good effect. However, on the other hand, concrete structure with organic fiber encountered significant degradation after high temperature heating. Therefore, improvement by hybrid fiber including organic fiber and steel fiber was suggested.

In this research, material testing of the fiber reinforced high strength concrete and the test regarding fracture energy of these types of concrete was performed. In addition, the tensile softening curve was back-calculated with the poly-liner approximation method.

Physical properties and fracture energy were evaluated under a heating stage (i.e. hot test) as well as a cooling stage (i.e. residual test). The experimental results verified the tenacity effect by the hybrid fiber on high strength concrete under high temperature environment.

1 INTRODUCTION

Recently, long tunnels are constructed with high strength concrete and have become an important means of traffic infrastructure worldwide. But, damage due to fire accident inside the tunnel occurs in some cases. As a consequence of the damage for the fire in the tunnel, concrete strength decreases. In terms of high strength concrete, there is a characteristic deterioration due to the explosive spalling phenomenon. With respect to structural collapse mechanism, this will cause secondary damage that must be considered as an important problem. In addition to a recent tunnel structure, secondary tunnel linings are often uninstalled due to the aspect of economical efficiency. With this trend increasing, improvement in fire resistance of primary concrete tunnel linings is required. However, research that deals with fracture behavior of high strength concrete under high temperature condition, comparing to normal strength concrete is still limited [C.V. Nielsen *et al*.2003]. Topics on this issue are still open to be investigated. Therefore, detailed examination regarding fire resistance of high strength concrete is needed worldwide.

In this research, polypropylene (PP) fiber is utilized to prevent the explosive spalling [S.L. Suhaendi *et al*.[2006]], while steel fiber is expected to retain the remaining strength of the concrete. Deterioration behavior of fiber reinforced high strength concrete (FRHSC) exposed to high temperature is examined from the viewpoint of fracture mechanics. This experimental study compares fire resistance of two kinds of FRHSC that utilized various fibers inside HSC mixture. Evaluation of fracture toughness is back-calculated using the poly-liner approximation method [Y. Kitsutaka, 1997].

2 EXPERIMENTAL PROGRAM

2.1 Fibers, Materials, Specimens, and Experimental Conditions

Mix proportion of concrete is shown in Table 1. All series of concrete were casted using ordinary Portland cement, river sand, and crushed stone. Specific gravity of river sand is 2.70, and specific gravity of crushed stone is 2.65 (maximum nominal size of 20 mm). Some parameters of mix proportion were kept constant: W/C = 0.3, sand to aggregate ratio (s/a) = 50%, and water content = 170 kg/m^3. A polycarboxylate-based superplasticizer, air entraining agent, and bubble cutter agent were used to attain desired workability and air content of fresh concrete. Specimens were mixed using a double-axes mixer. All specimens were prisms of 100×100×400mm.

Table 1. Mixture Proportion.

Series	W/C (%)	s/a (%)	Fiber volume (%)			W (kg/m^3)	Air (%)	SP[*1] (%×c)	AE[*2] (%×c)	BC[*3] (%×c)
			Polypro-pylene	Steel (S13)	Steel (30)					
Plain	30	50	-	-	-	170	6	0.8	0.012	-
PP			0.1	-	-			1.2	0.006	0.001
HY1			0.1	-	0.5			1.35	0.008	0.001
HY2			0.1	0.1	0.4			1.4	0.008	0.001

[*1]SP:super plasticizer [*2]AE: air entraining agent [*3]BC: bubble cutter

Polypropylene and two-steel fibers having 18 , 160 and 600-micron effective diameter were used in this experimental study. All of fibers came in bundles that were well dispersed inside the concrete mixture. Properties of fibers are shown in Table 2.

After casting, the specimens were demoulded after 24 hours, and then cured under lime-saturated water at temperature of 20±2℃ for 28 days. The notch with a thickness of 5 mm and a depth of 30

mm was made in the center section of all specimens making use of concrete cutter. Some specimens were heated using electric furnace and heating device. Both heating rates were set at 10℃/min with the maximum temperature kept at 200, 400, and 600℃ for 2 hours. In the case of residual test, heated specimens were let to cool inside the furnace until its temperature coincided with room temperature to prevent cracks upon cooling.

Table 2. Properties of Fibers.

	Polypropylene	Steel (S13)	Steel (S30)
Diameter (mm)	0.018	0.16	0.6
Length (mm)	6	13	30
Shape	Filament	Straight	Indent
Density (gr/cm^3)	0.9	7.8	7.8
T_{melt} (℃)	160-170	1370	1370
$T_{vaporize}$ (℃)	341	-	-

2.2 Experimental Device and Evaluation Method of Fracture Energy

With a designated loading span of 300 mm, the fracture energy test was executed under load control using a servo jack testing machine. The beam specimen was arranged on some rollers under both fulcrums to let it move freely in horizontal direction.

In the case of fracture energy test, loading rate was set at 0.1 mm/min. The fracture energy test was conducted in accordance with a JCI (Japan Concrete Institute) test method [JCI-S-002-2003]. During the fracture energy test, load (P), crack mouth opening displacement (CMOD), and load point displacement (LPD) were measured. The loading device and measurement points layout are shown in Figure 1.

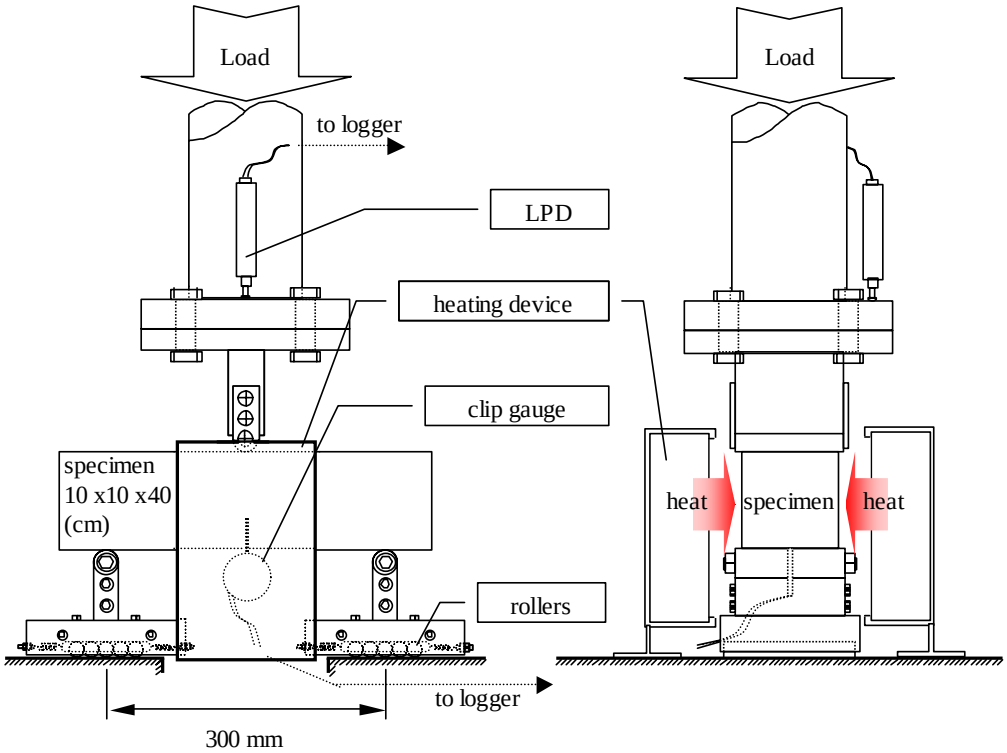

Figure 1. The Fracture Toughness Test Equipment (with Heating Device of Hot Test).

Fracture energy of specimen was calculated as follows:

$$G_F = \left(0.75W_0 + W_1\right)/A_{lig}$$

$$W_1 = 0.75\left(S/L \cdot m_1 + 2m_2\right)g \cdot CMOD_c$$

(1)

where;

G_F :Fracture energy (N/mm)

W_0 :Area under Load-CMOD curve before specimen breaking (N·mm)

W_1 :Weight of the specimen and the work from loading jig forms (N·mm)

A_{lig} :Area of ligament (b·h)

m_1 :Weight of specimen (kg)

S :Loading span (mm)

m_2 :Weight of jig appearing in a specimen (kg)

$CMOD_c$: (mm)

3 RESULTS AND DISCUSSION

3.1 Bending Strength under Hot Test and Residual Test

Bending strength was evaluated both under the heating stage (hot test) and cooling stage (residual test). Bending strength ratio with relation to heating temperatures is shown in Figure 2 and Figure 3.

It is found that inclusion of fiber into concrete will guarantee the residual bending strength, as shown in Figure 2. In addition, in the case of residual test, increase in strength can be noticed at 200. This phenomenon is widly recognized as “dry strength (Austrocknungsfestigkeit)” of Czernin [W. Czernin 1977]. On the other hand, in the case of hot test, the bending strength ratio shows quite different trend, as shown in Figure 3. The bending strength ratio decreases quickly at 200℃ and then stays almost constant up to 600.

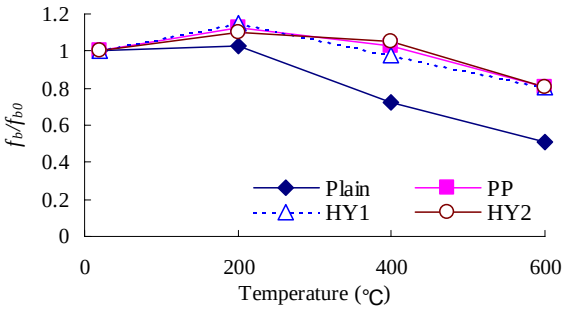

Figure 2. Bending Strength Ratio (Residual Test).

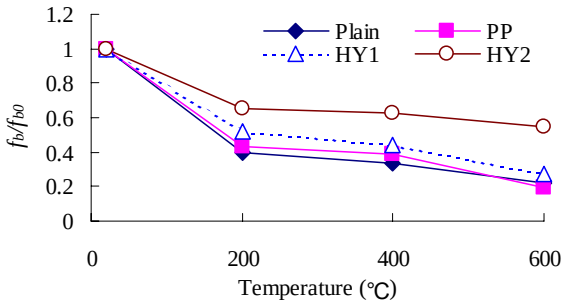

Figure 3. Bending Strength Ratio (Hot Test).

3.2 Fracture Toughness Test Results (Load - CMOD Curve)

Load - CMOD curve is given in Figure 4 (residual test) and Figure 5 (hot test) showing one representative result from the experimental tests. The maximum load decreases with increasing heating temperature.

From Figure 4 and Figure 5, it was verified that CMOD at maximum load becomes larger with relation to the increase in heating temperature. With the increase in heating temperature, stiffness decreases, as shown in both Figures. In each heating temperature of both tests, the load decrease of Plain and PP is considerable after the peak. However, not breaking either after the peak is due to steel fiber reinforcement. Especially, HY2 verified that continues to support the large load, in comparison with Plain and PP.

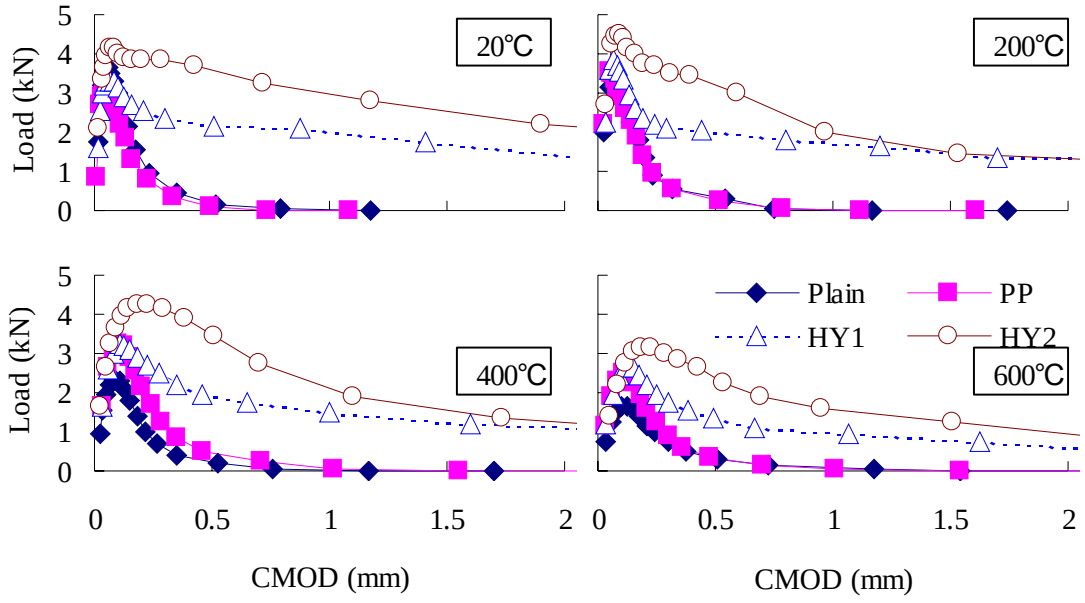

Figure 4. Load–CMOD Curve at 20℃, 200℃, 400℃, and 600℃ (Residual Test).

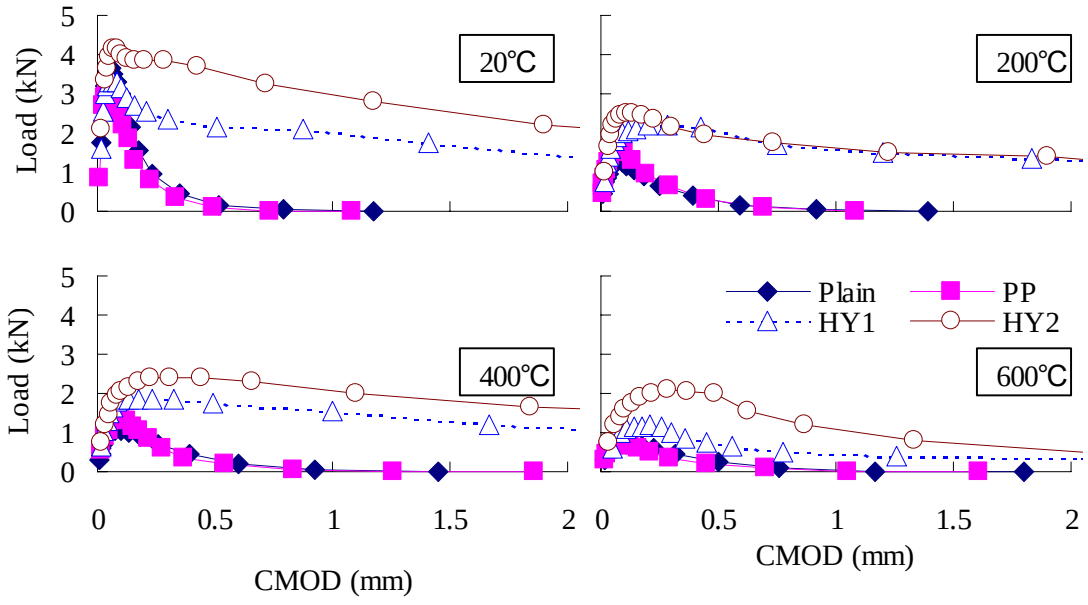

Figure 5. Load–CMOD Curve at 20℃, 200℃, 400℃, and 600℃ (Hot Test).

On the other hand, it is found that the strength decrease of PP under high temperature is small in comparison with that of Plain. Plain and PP destructive behavior almost same. With the polypropylene fiber of 6mm length, it has not contributed to the pulling out efficiency of the fiber before and after heating.

In both tests, the specimens including steel fibers didn't show rapid descending behavior after maximum load. Previous tendency becomes high with the increase in heating temperature. However, in the case of hot test, sudden decrease after maximum load is not observed. The reason of this finding should be investigated further.

3.3 Fracture Toughness Test Results (Fracture Energy)

Fracture energy was calculated from Formula (1). The relationship between fracture energy and heating temperatures is shown in Figure 6. As shown in the figure, large difference of fracture energy between the Plain/PP series and the HY series was observed. As for the fracture toughness of the HY series, it was found that the fracture energy decreased with the increase in heating temperature.

Especially, when it is exposed to high temperature above 200℃, fracture energy of concrete decreases suddenly and converted to fail in a brittle manner. This phenomenon is thought to be affected by the fiber due to the fact that under hot environment polypropylene fiber melts and disappears.

For both tests, it could be found that the fracture energy of concrete that includes steel fiber exceeds the one of Plain and PP series at any heating temperature. Therefore, it was confirmed that the mixture of the steel fiber improves fracture toughness. But, this result should be verified for other mixture proportions.

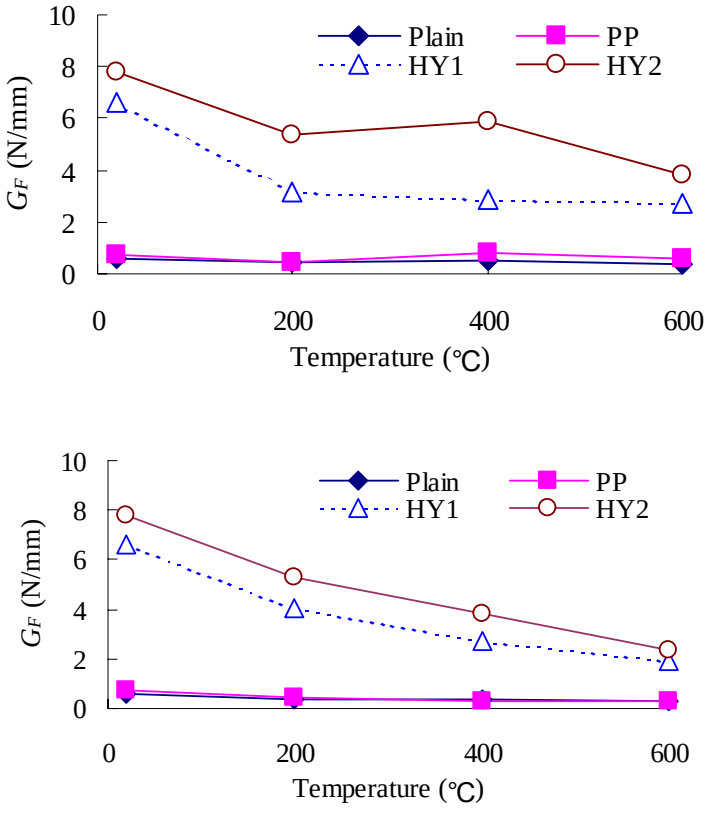

Figure 6. Relatives Fracture Energy Under Residual Test (upper) and Hot Test (bottom).

4 CONCLUSIONS

Quite remarkable difference was observed from the strength quality of HFRHSC due to heating test method, hot test and residual test. Especially, at the time of hot heating above 200℃, sudden decrease of maximum load was verified in the case of hot test. But, the mechanism of deterioration behavior for each mix proportion was not excessively verified. Therefore, bending the concrete with hybrid fiber reinforcement that has large initial strength is found to be effective.

For specimens including steel fiber, the maximum load does not drop suddenly in hot test. It was verified from the Load-CMOD curve that it only caused gradual decrease.

As for mixing the steel fiber which combines long and short fibers into the concrete (HY2), the effect is larger than single use (HY1).

In hot test, hybrid fiber reinforcement in high strength concrete mixture is very effective to prevent brittle fracture. It is verified that this type of reinforcement is very effective with the favor of fracture energy test.

MICROSTRUCTURAL ASSESSMENT OF THE INTERFACIAL TRANSITION ZONE IN GRANITIC CONCRETE

Azimah Hussin [1]
Colin Poole [2]
Robert Fowell [3]

T11

ABSTRACT

The exploitation of granitic aggregate in concrete fabrication is quite common in the construction industry throughout the world. The vast majority of studies have agreed that the mechanical performance of the concrete is strongly related with the characteristics of the aggregates. Thus, the characteristics of aggregates are also one of important variables affecting the concrete microstructure including the development of interfacial transition zone (ITZ). As the weakest link, the ITZ is also well known as the medium in which the transmission of stresses between aggregate and the matrix occurs. However in granitic concrete, most previous experiments have claimed that the siliceous aggregate is chemically inert and plays very little role in the occurrence of the ITZ in concrete. A significant amount of research is now being undertaken in evaluating the effects of granitic aggregate in the development of the ITZ microstructure. This study describes possible differences in the microstructural nature of the ITZ in concrete containing three different types of granitic aggregate. The ITZ microstructure has been investigated in a petrographic manner with the application of backscattered SEM analysis.

1 INTRODUCTION

Modern concrete is a three phase, complex composite material consisting of aggregate particles and cement linked together by an interfacial transition zone (ITZ). Amongst these three phases, the ITZ is known to be the weakest link, influencing both the mechanical properties and the durability of the concrete [Scrivener and Pratt, 1986; Struble, 1988; and Stankowski et al., 1990]. Durability and strength are two major properties that establish the performance of a good concrete. Without these, the concrete is more susceptible to premature failure. Since the ITZ was first identified as one of the factors associated with strength and durability [Thomas and Floyd, 1963] its characterisation has been a crucial parameter in concrete technology. Many researchers have conducted various microstructure tests to evaluate variations in the ITZ. One of the first was Jacques Farran, the pioneer researcher who observed the behaviour of the aggregate-cement paste interface [Scrivener et al., 1988]. He suggested that this aggregate-cement interfacial zone exhibits specific changes in mineralogy and microstructure. Later work by Mindness and Young [1981] confirmed the ITZ as a zone of weakness, both in terms of mechanical properties and durability.

Aggregate occupies 75-80% of the volume of concrete and can, therefore, be considered to have a significant influence on the performance of the ITZ system [Mindness and Young, 1981]. Although rock aggregate is a basic geological product, there is an enormous array of coarse aggregates available for use in concrete making. As a consequence, the most viable sources for a particular use of concrete must have specific characteristics which are often dependent upon the fundamental features of the parent rock or the operations used in their production. This means that the understanding of aggregate characteristics requires a profound knowledge of the rock properties and the variation in these properties. In fact, research shows that coarse aggregate plays a considerable role in determining the strength, stability, workability and durability of concrete [Jamkar and Rao, 2004].
Since the late 1990s, the discussion on aggregate function in the ITZ of concrete has been given greater priority. Among the influential authors on the subject are Tasong et al. [1998], Irvine [1999] and Elsharief et al. [2003]. Their works have examined the development of the ITZ from the viewpoint of the crushed aggregate properties and their findings have provided evidence that aggregates are not inert, as previously supposed. Their results reveal that aggregates are, in fact, chemically active and the interfacial bond strength is controlled by factors such as aggregate structure, aggregate strength and the chemical interaction with cement. In fact, it is now believed that the traditional mineralogical and geochemical behaviour of aggregate sources is responsible for the wide variation of the ITZ in concrete.
The objective of this paper is to present the effects of granitic aggregate in the development of the ITZ microstructure. The methodology and test results of the investigation into the microstructural nature of the ITZ in concrete containing three different types of granitic aggregate are presented and discussed.

2 EXPERIMENTAL INVESTIGATIONS

Three sources of crushed granitic aggregate were used as normal weight coarse aggregate in this study. These three sources consisted of;

i) Shap granite from the Lake District,UK.
ii) Mountsorrel granite from Leicestershire,UK.
iii) Johor granite from Johor, Malaysia

Normal strength concrete specimens (28day nominal strength of 40MPa) with a water binder ratio of 0.5 were prepared using the above granitic aggregate. Polished thin sections of each concrete have been used to obtain results on the microstructure features of the ITZ. Briefly, thin section were sliced from bulk

concrete by low-speed precise diamond-bladed saws using non-aqueous lubricants and all the sections were coated with platinum-paladium film.
The investigations described in this section attempt to address the influence of granitic aggregate type on the microstructure of the ITZ from the normal strength concrete. This study has investigated the characteristics of the ITZ microstructure in a petrographic manner, but as the normal polarizing microscope is unsuitable for this, so investigations proceeded with the application of SEM techniques.
Using SEM observations, the study has attempted to best describe any possible differences in the nature of the ITZ. Analysis was carried on polished sections and the backscattered mode of SEM (Phillips XL 30 environmental scanning electron microscope) analysis was performed randomly on each selected aggregate. The images were taken at x200 and x500 magnification and over 60 images of different ITZs and curing ages were analysed to differentiate the composition. Higher magnifications were used to view the specific morphology occurring in the ITZ.

3 RESULTS AND DISCUSSION

Throughout the BSE imaging analysis, the ITZ specimens containing different type of granitic aggregate displayed considerable heterogeneity in their microstructure. Figure 1 illustrates a typical microstructure found in most analysed images (in this case, one day old Johor granite ITZ). The common constituents in this region are comparatively easy to distinguish, as they show significant microstructural differences.
In all of the present ITZ sections examined, the polymineralic nature appears as its original microstructure outline. The main deposition phase is quite distinct. CH has already been well developed and has a light grey colour appearance, while the dark grey C-S-H is mainly deposited around the aggregate. Other constituents include anhydrous cement grains, pores with dark spot marks and other minor hydration products of needle shaped ettringite(AFt).

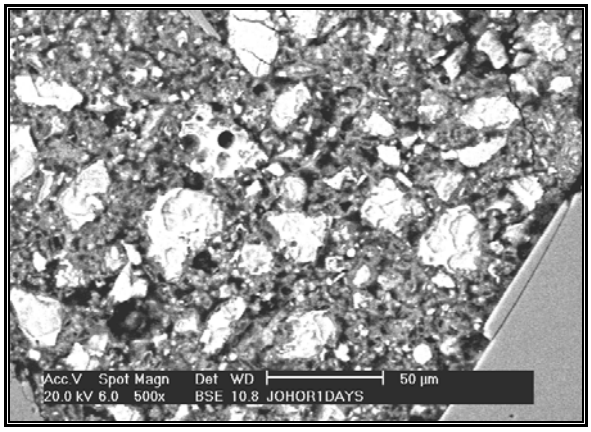

Figure 1. Typical BSE image of the ITZ prepared from one day old concrete containing Johor granite.

After 1 day curing period, the microstructure of the ITZ in each sample (shown in Figure 2) showed a lower degree of hydration and significantly showed a “sheaf of wheat” morphology. Unhydrated cement grains and porosity are common features seen in most samples and masses of CH were also observed throughout the ITZ. In all granitic specimens, higher magnification helped to identify well crystallised CH grains (Figure 3).

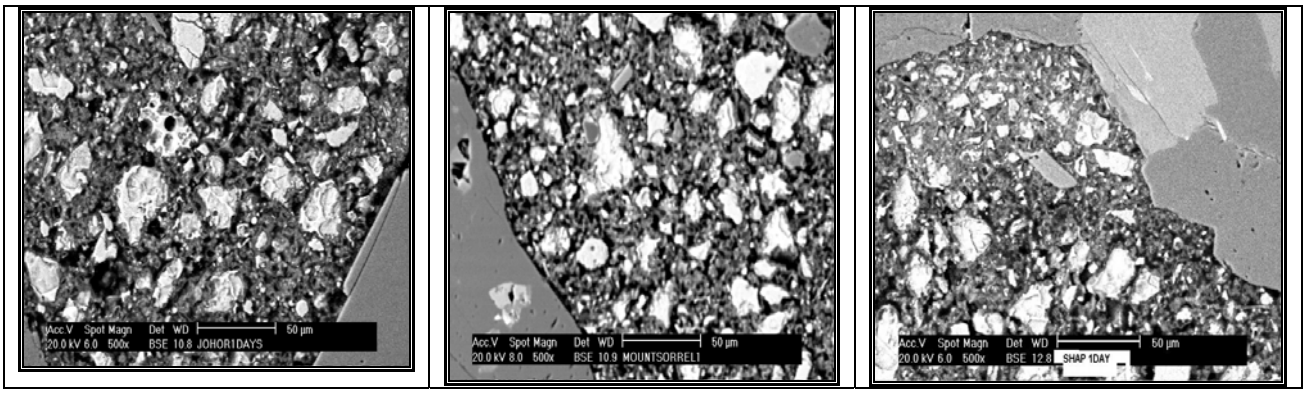

Figure 2. General microstructure of the ITZ and bulk phase of concrete for different types of aggregates after 1 day curing period.

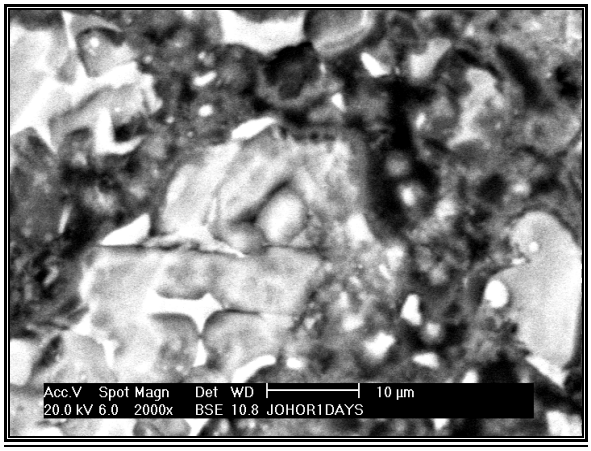

Figure 3. Higher magnification of BSE image for the ITZ of Johor granite concrete after 24 hours curing period. C-S-H is still badly crystallized, but calcium hydroxide show well developed hexagonal plates.

However, it was not possible to indentify any ettringite crystals in any of the samples. These results agree with the suggestion by Scrivener and Taylor [1993], that at this early stage of hydration, ettringite is still embedded within the C-S-H product. The "sheaf of wheat" morphology in ITZ refers to a structure which tends to branch in a radial fashion. According to Zampini et al. [1997] the "sheaf of wheat" morphology is an early formed C-S-H product but structurally similar to CH. These morphology resulting from the reaction of the silica species and the calcium ions. BSE images studies reveal that this kind of morphology is very obvious in granitic ITZ. Apparently, the more numerous 'sheaf of wheat" morphology in the granitic specimens in this study may have related to Wiliamson [1968] statement: the silicate rich particles provides and facilitates the nucleation of C-S-H with branching morphology.

With the progress of hydration continued to 28days, the ITZ became denser and abundant C-S-H was growing. Figure 4 illustrates the general microstructure of the ITZ for each aggregate type after the completion of 28 days curing. At longer age, the porosity has been greatly reduced and the ITZ becomes more amorphous. Although the hydration process was not yet completed, these observation indicate that the ITZ microstructure of each sample, especially with granitic aggregates, appear denser and less porous after 28 days and the acceleration effect of the curing period on the microstructure is more apparent, with hydrated grains such as AFt, CH and C-S-H being well formed in the ITZ region.

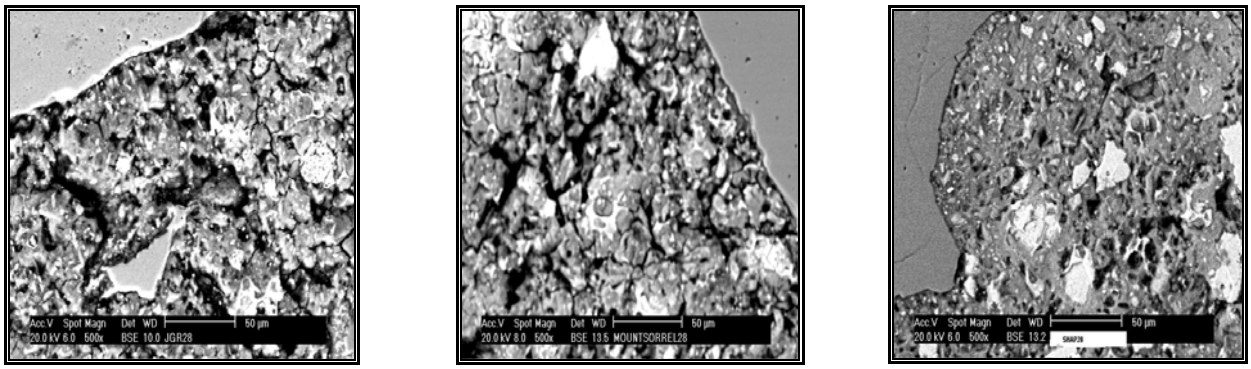

Figure 4. BSE images of the ITZ and bulk phase of concrete prepared from different types of granitic aggregates after 28 days curing period.

SEM observation suggests that the granitic ITZs appear to have, in general, lower porosity and a finer pore structure. The observations also reveal that among the three types of concretes prepared, the Johor granite concrete had the densest appearance. Although a number of 10µm or larger size pores were present in the ITZ, the total volume of pores was obviously much lower than in the other samples. Hardly any granular-like hydrates, and flake-like crystals could be found. The EDAX pattern of the hydrates indicates that it consisted mainly of C-S-H. All of those observations support the assumption that the ITZ microstructure is affected by the mechanism of formation [Scrivener and Pratt, 1996]. For instance, in the fresh granitic concrete, a water film normally will form around the aggregates due to wetting and bleeding effects. Poon et al, [2004]. observed that the local W/C ratio at the ITZ can be twice than that in the bulk paste. As hydration progresses, the water-filled space near the aggregate is gradually replaced by an increasing amount of hydrates.

In the granitic samples, it is probable that there was denser packing of cement particles adjacent to the aggregates, due to the role of the aggregate grain composition. This situation agrees with the hypothesis given by Livingston et al. [1999] and Richard et al. [1999]. They pointed out that the proportions of each type of mineral present in the aggregate produced variations in interface development. In this study, all three types of granitic aggregate had a large proportion of feldspar, including Ca-rich plagioclase and Na-rich albite.

A relatively dense ITZ was obtained in the Shap granite concrete (see Figure 5). The mechanism here could be that the granitic aggregate had a low initial moisture content which lowered the initial W/C ratio in the ITZ at the early hydration stage. Newly formed hydrates then gradually filled the region, and these processes effectively improved the interfacial bond between aggregate and cement.

Furthermore, the variations in hydrate concentration in the ITZ for each specimen in this study appear to support previous work by Maso [1980] and Breton et al. [1993]. In all ITZ specimens three distinct zones could be identified:

- the region located at adjacent to aggregates surface (within 0-15µm), which is rich with CH.
- the region situated between 15-50µm which contained less CH but more C-S-H,
- the region >50µm, which has a similar appearance to normal strength concrete and, in this study, is therefore considered as the bulk phase.

The microstructure of the bulk phase (the region>50µm) in every specimen is generally compact and tends to be more amorphous than crystallized. Based on EDAX analysis, this phase was essentially

composed of more C-S-H. Pores and entrapped air voids were also visible in most samples with a size range of 10-100µm. As well as C-S-H, some massive crystals of CH were also observed in the bulk phase.

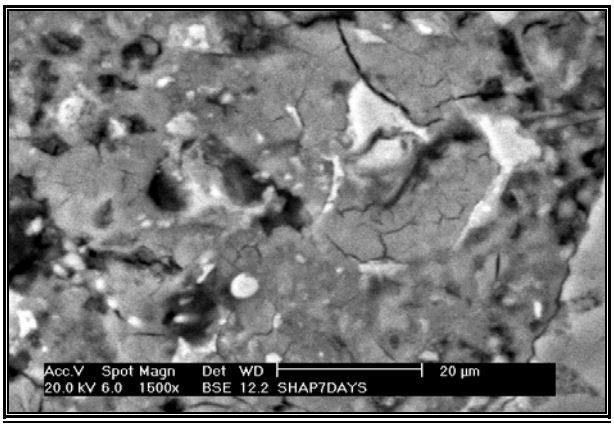

Figure 5: View of higher magnification of the ITZ of Shap granite. The dense looking textural appearance is a result of the growth of hydrate crystal.

4 CONCLUDING REMARKS

Based on observations, the following conclusions can be drawn:

- Normal strength concretes made with crushed granitic aggregates display variation in ITZ properties with excellent behavior
- After 1 day curing, many of the unhydrated cement particles and a few of the products of initial hydration, such as C-S-H and CH, exist in the area about 0-20µm from the edge of the aggregate, with C-S-H appearing as a mesh shape.
- After 28 days curing, more hydration product develops.
- In the range 0-50µm of the ITZ, the porosity changes as the curing age increases. After 1 day, the area of the pores is at its highest, and the pores are distributed uniformly in a large lump. After 28days, more hydration product exists and fills most of the pores, thus the pores are reduced and a denser structure results
- Microstructural observations clearly show that there is an increased frequency of porous patches in the ITZ. This frequency increases towards the interface.

T 11

ABSTRACT

Pervious concrete has large continuous voids of 20-30 % by volume, and has some particular properties (i.e. high-permeability, purification, vegetation, etc). Pervious concrete is attractive as new environmental material and has begun to be applied for the river bank protection and road pavement in Japan. The object of this study is to investigate the frost resistance of pervious concrete as environmental materials. This investigation attempts to address this concern by comparing 3 kinds of specified freezing and thawing tests methods (ASTM C 666 procedure A, B methods and RILEM CIF). RILEM CIF test is different from ASTM C 666 method in water absorption, rate of cooling, length of freezing and thawing period, and number of freezing and thawing cycles. Test result of ASTM C 666 procedure A method, which is widely used for evaluating the frost resistance of concrete, showed extremely low durability of pervious concrete. Because of the low strength and the high porosity due to large void structure, frost resistance of pervious concrete seems to be lower than that of conventional concrete. However, result of RILEM CIF test showed adequate frost resistance. From these test results, it is found that difference of freezing and thawing test has influence on the evaluation of frost resistance. In addition, this study has conducted in situ exposure test for 5 years. Some pervious concrete blocks have been applied for river bank protection of Hokkaido Naie river in Japan, which resembles 70-80 cycles of freezing and thawing action annualy. Frost damage of these blocks by ultrasonic velocity measurement were evalutated to be in a slight degree. From these tests, a total of 350-400 cycles of natural freezing and thawing action showed a similar damage trend as RILEM CIF test and a significant difference with ASTM C 666 procedure A method is observed.

1 INTRODUCTION

In recent years, necessity of the environmental materials for sustanable development is increasing over the world, and pervious concrete has been proposed to be used as such material. The characteristic of pervious concrete has a large continuous void strcure, which accounts for about 20-30 % of the whole volume. Pervious concrete can have a high permeability (about 1.0 cm/sec) and is generally applied for road pavement. This type of concrete, which has large void structure, came from "No-Fines Concrete". According to Malhotra, No-fines concrete had been used in Europe and the United Kingdom since 1930s for building of single story and multistory. In recent Japan, this type of concrete is sometimes called as "Porous concrete", and has begun to gain attention as a promising environmental material. The idea is that the large continuous void structure can give pervious concrete the ability of high permeability, purification, and vegetation. Pervious concrete has begun to be applied for the protection of river dam and further to road pavement.

It is necessary to confirm the frost resistance when pervious concrete is used in cold region. Many reports investigated the environmental functions of pervious concrete [JSCE, 2002]. However, there are few reports of the frost resistance. Frost resistance of pervious concrete has been investigated by several freezing and thawing tests method [M. Sugiyama, 2002 ; Obi and Taguchi, 2004]. The results were not clearly in agreement with in situ exposure condition. Therefore frost resistance of pervious concrete should be evaluated by an specified freezing and thawing test methods. This study attempts to address this concerns by comparing the test result of RILEM CIF test method ("RILEM Recommendation TC176-IDC"), and that of ASTM C666 procedure A and procedure B methods ("Standard Test Method for Resistance of Concrete to Rapid Freezing and Thawing").

It is necessary to conduct in situ exposure test as well as some laboratry tests. This investigation compared the result of in situ exposure test at Hokkaido Naie River in Japan with that of laboratory freezing and thawing tests.

The results of this study provide additional evidence to support the need in obtaining a viable freezing and thawing method and applicable to pervious concrete as environmental material.

2 MATERIALS AND MIXTURE PROPORTION

The mixture proportion in this study is shown in Table 1. The test specimen consisted of 3 types. Design values for the void ratio is set to 20%. Water cement ratio are set to about 23.5 % and 24 %. The matrix constituents of pervious concrete consisted of ordinarily portland cement (C), fine aggregate (S), coarse aggregate (G6 or G7), tap water (W) and some chemical admixtures. Particle size of G6 is 5-13 mm with specific gravity of 2.63. Particle size of G7 of 2.5-5 mm with specific gravity is 2.62. For NR6, a high viscosity agent was added. All specimen contained air-entraining and high-range water-reducing admixture (SP).

Table1. Mixture proportion.

	Void	W/C	Unit content (kg/m^3)						
	(%)	(%)	W	C	S	G6	G7	Ad	SP
NR6	20	24	99	413		1550		8.3	3.1
PG6	20	23.5	80	340	106	1503			3.4
PG7	20	23.5	80	340	172		1431		3.4

3 EXPERIMENTAL PROCEDURES

3.1 Freezing and Thawing Test

The frost resistance of pervious concrete was determined using the specifications of ASTM C 666 procedure A method and procedure B method ("Standard Test Method for Resistance of Concrete to Rapid Freezing and Thawing"), and RILEM CIF test ("RILEM Recommendation TC176-IDC"). Some of important details of three procedures are given in Table 2. As shown in this table, ASTM C 666 is a more severe testing method than CIF test in relation to rate of cooling, length of freezing and thawing period, and number of cycles. A brief description of each test method is provided in the next paragraphs.

Table 2. Test details of ASTM C 666 and RILEM CIF tests methods.

	ASTM C 666 test (procedure A)	ASTM C 666 test (procedure B)	RILEM CIF test
Number of cycles (test period)	300 6 cycles/day (50 days)	300 6 cycles/day (50 days)	56 2 cycles/day (28 days)
Freezing period Lowest temperature	2.75 hr -17.8 C	2.75 hr -17.8 C	7 hr -20 C
Cooling rate	14.4 deg C/hr	14.4 deg C/hr	10 deg C/hr
Thawing period Highest temperature	1 hr 4.4 C	1 hr 4.4 C	5 hr 20 C
Water absorption condition	Entire surfaces	Entire surfaces (only thawing phase)	Only 1 test surface
Evaluation method	Fundamental transverse frequency	Fundamental transverse frequency	Ultrasonic pulse velocity

3.1.1. ASTM C 666 Tests (Procedure A and Procedure B)

Specimens were presoaked in water for 24 hr before starting of freezing and thawing test. For Procedure A, each specimen is completely surrounded by not less than 1 mm nor more than 3 mm of water at all times while it is being subjected to freezing and thawing cycles. For Procedure B, each specimen is completely surrounded by air during the freezing phase of the cycle and by water during the thawing phase. Freezing and thawing test continued on each specimen until it has been subjected to 300 cycles or until it is impossible to measure fundamental transverse frequency. In this test methods, relative dynamic modulus of elasticity is used to evaluate frost damage.

3.1.2 RILEM CIF Test

Specimens were placed in the test containers on 10 mm high spacers with the tested surface underneath. Subsequently, the test liquid was filled into the container to a height of 15 mm. Pre-saturation of test liquid by capillary suction was conducted for 7 days at a temperature of 20 deg C before starting freezing and thawing test. During capillary suction, the liquid level was checked and adjusted. To evaluate frost damage, ultrasonic pulse velocity (UPV) was measured. The transducers were mounted on the sides of the container so that the transit path axis should be parallel and 35mm from the test surface.

3.2 In Situ Exposure Test

Pervious concrete blocks for river protection were exposed at Hokkaido Naie-river in Japan, which has severe environment of freezing and thawing action. The freezing and thawing cycles of this site is about 70 - 80 cycles in a year. The blocks were similar mixture of NR6 in Table 1. To evaluate frost damage, ultrasonic pulse velocity had been measured for 5 years. Consequently a total of 350-400 freezing and thawing cycles were considered to be occured during the investigartion.

4 RESULT AND DISCUSSION

4.1 Frost Resistance with ASTM C 666 Test Procedure A Method

Relative dynamic modulus of elasticity conducted by ASTM C666 procedure A method is shown in Figure 1. As shown in this figure, relative dynamic modulus of elasticity of PG6 and PG7 decreased to about 50 % and 80 % with the same freezing and thawing cycles. Relative dynamic modulus of elasticity of NR6 decreased sharply and specimens of NR6 failed before 30 freezing and thawing cycles. From these results, pervious concrete failed at early freezing and thawing cycles. It showed extremely low durability of pervious concrete with regards to ASTM C666 procedure A method. Because of the low strength and the high porosity, the frost resistance of pervious concrete seems to be lower than that of conventional concrete. In other words, this type of test method seems to bring the pervious concrete in significant disadvantage.

The frost resistance of NR6 was lower than that of PG6 and PG7. One of major differences between NR6 and PG6 is without/with fine aggregate. This indicated that addition of fine aggregate improves the frost resistance. As can be seen on PG7 and PG6 in this figure, the resistance to freezing and thawing improved with a decrease in the particle size of coarse aggregate. Figure 2 shows the typical fracture patterns of NR6 conducted by ASTM C666 procedure A method. The failure of specimen could be attributed to the formation and rapid propagation of large cracks. These cracks originated from stress of ice formation that occured in large continuous voids (greater than 1 mm in diameter). As particle size of coarse aggregate is large, large continuous void size grows larger. Therefore frost resistance of PG6 and NR6 were lower than that of PG7.

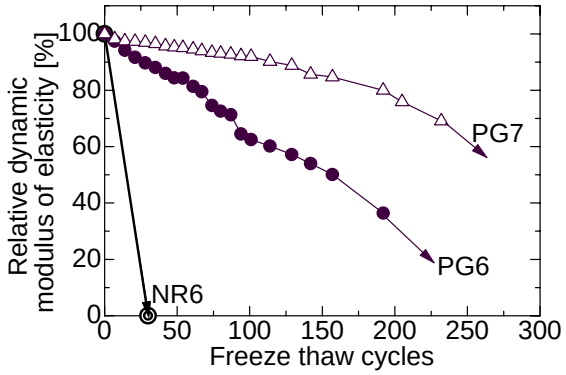

Figure 1. Relative dynamic modulus of elasticity (ASTM C666 procedure A).

Figure 2. Typical fracture patterns after ASTM C666 test procedure A (NR6).

4.2 Frost Resistance with ASTM C 666 Test Procedure B Method

Figure 3 shows relative dynamic modulus of elasticity under ASTM C666 procedure B method. As shown in this figure, relative dynamic modulus of elasticity decreased to about 80 % gradually with additional cycles of freezing and thawing. Comparing with procedure A method, the influence of different particle size and usage of fine aggregate can not be confirmed. Most specimens showed similar decreasing tendency.

Figure 4 shows typical fracture patterns of NR6 by ASTM C666 procedure B. The corner of specimen dropped out with fracture patterns shown in Figure 4, making impossible to measure the fundamental transverse frequency. This phenomenon originated from frost damage of a slight cement paste matrix of pervious concrete. As micro crack developed in cement paste matrix, more water could enter the specimens and freeze, thus further accelerating the rate of crack propagation and eventually leading to spalling and crumbling on the corner of specimen.

4.3 Frost Resistance by RILEM CIF Test

Relative ultrasonic pulse velocity under RILEM CIF test is shown in Figure 5. The result of RILEM CIF test was different from that of ASTM C 666 procedure A and B methods. Relative ultrasonic pulse velocity remained on the same level with additional cycles of freezing and thawing. Therefore deterioration at all specimens of this study was evaluated as a slight frost damage.

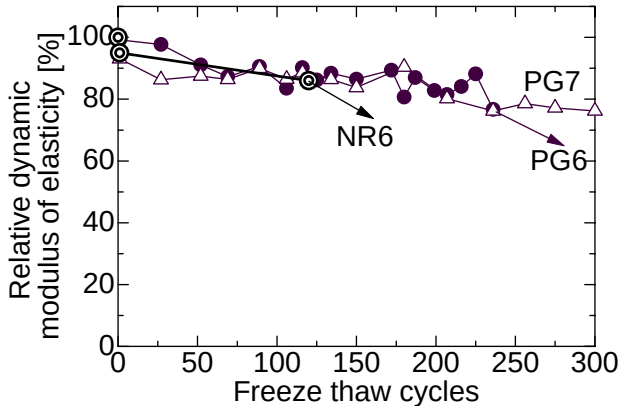

Figure 3. Relative dynamic modulus of elasticity (ASTM C666 procedure B).

Figure 4. Typical fracture patterns after ASTM C666 test procedure B (NR6).

Figure 6 shows a typical fracture patterns after RILEM CIF. In addition, after finishing freezing and thawing test (56 cycles), a little scaling of cement paste without coarse aggregate was found,.and deterioration on tested surface was a slight degree.

The main objective of this investigation is to compare ASTM C 666 procedure A method, procedure B method and RILEM CIF test. Frost resistance of pervious concrete seems to be lower than that of conventional concrete. From the result of ASTM C 666 procedure A method in this study, frost resistance of pervious concrete was evaluated to have a low durability with agrees well with previous research. However, results of RILEM CIF test showed pervious concrete has adequate frost resistance without causing severe scaling and spalling. From these results, the difference of freezing and thawing tests influenced the evaluation of frost resistance on pervious concrete.

4.4 In Situ Exposure Test

Figure 7 presents the change of relative ultrasonic pulse velocity in Naie River blocks for 5 years. Total of 6 blocks (No 1, 2, 3, 9, 13, 24) were measured. As shown in this figure, the ultrasonic pulse velocity for 5 years showed almost a constant valve. The relative ultrasonic pulse velocity of all blocks showed higher than 90 %. These results was found to be that there is no significant frost damage. In addition, the blocks surface seemed to show no deterioration, without spalling nor large crack.

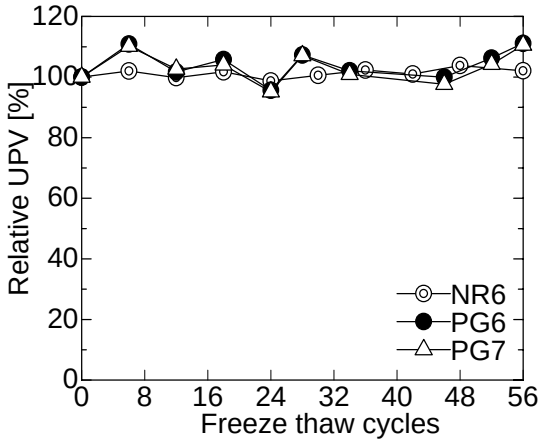

Figure 5. Relative ultrasonic pulse velocity under RILEM CIF

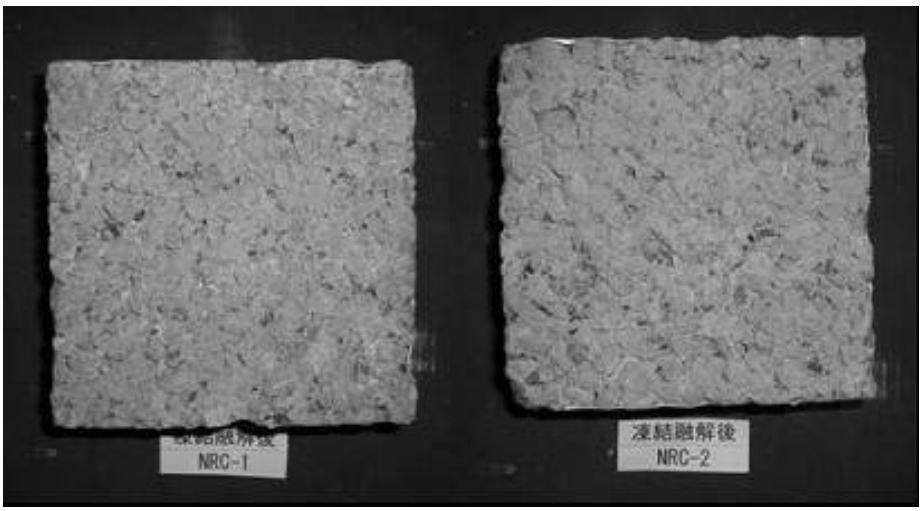

Figure 6. Typical fracture patterns after RILEM CIF (NR6)

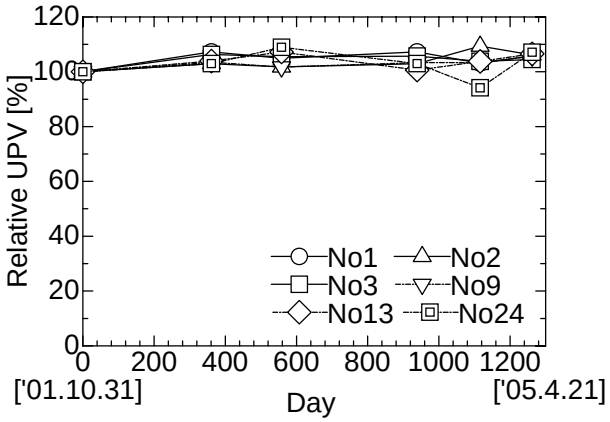

Figure 7 Relative ultrasonic pulse velocity in Naie River blocks.

As already mentioned, more than 70 cycles of freezing and thawing per year were affected to the concrete in situ exposure test. This indicates that more than 350 cycles of freezing and thawing action during the whole 5 years doesn't correlate with the result of ASTM C 666 procedure A method but it shows better correlation with the one of procedure B method and RILEM CIF test.

5 CONCLUSION

Based on the results of shis study, the following conclusions can be drawn:

1. By ASTM C666 procedure A method, relative dynamic modulus of elasticity decreased rapidly and the failure of specimen was attributed to the formation and rapid propagation of large crack. These cracks originated from stress of ice formation which occured in large continuous voids. Frost resistance of pervious concrete may be improved by using small particle size (G7) and fine aggregate in this investigation.

2. By ASTM C666 procedure B method, relative dynamic modulus of elasticity decreased to about 80 % gradually with additional freezing and thawing cycles. This phenomenon originated from frost damage of a slight cement paste matrix of pervious concrete in rapid freezing and thawing actions. The severe fracture patterns observed on ASTM C666 procedure A method did not occured.

3. By RILEM CIF, all specimens showed no clear declination of relative ultrasonic velocity. After freezing and thawing test, surface damage with large cracks was not found. Similar specimens tested in the rapid freezing and thawing environment of ASTM C 666 displayed a far greater degree of frost damage. This phenomenon seemed to originate from the cooling rate and large void strcture which is a characteristic of pervious conrete.

4. The result of in situ exposure test showed little frost damage for five years. The change in relative ultrasonic velocity indicated that freezing and thawing action of in situ exposure test didn't correlate with that of ASTM C 666 procedure A method, but showed better correlation with procedure B method and RILEM CIF test. Total of 350-400 cycles of natural freezing and thawing action showed a similar trend as RILEM CIF test but a significant difference with ASTM C 666 procedure A method.

5. The resistance of pervious concrete to freezing and thawing seems to be considered to be lower than conventional concrete. It is because porous concrete has continuous void structure into which water can permeate during freezing and thawing. However, it is found that the pervious concrete has adequate frost resistance by results of RILEM CIF and in situ exposure test.

T 11

ABSTRACT

Macro-Defect Free (MDF) Cements, which are cement-polymer composites, have been developed by Birchall et al at the early 1980's in order to increase the strength of cement based materials. MDF cements can be produced by adding small amounts of polymer and water into the cement. In addition, high shear and hot press should be applied to the mixture during production in order to get high flexural strengths. Achievement of very high flexural strengths is the most important advantage of this material and more than 200 MPa flexural strengths can be easily obtained while ordinary cement paste has only 5-10 MPa flexural strength. The highest strengths are obtained by using calcium alumina cements (CAC) and polyvinyl alcohol acetate (PVAc) copolymers. In spite of their excellent flexural strengths, MDF cements have serious durability problems under the effect of water. In this study, durability problems of MDF cements were investigated. In the first part of the study, the effect of hydrolysis degree of PVAc on MDF cements was investigated. The influence of alumina cement type on MDF properties is the subject of second part. Biaxial flexural strength tests were applied on the specimens after storing in both dry and humid conditions. Purpose of these tests was finding the most suitable PVAc and CAC type with respect to both mechanical and durability properties.

1 INTRODUCTION

Macro-Defect Free (MDF) cements, which are cement-polymer composites, had been developed and patented by Birchall et al. [1982, 1983] in London in order to increase the strength of cement based materials by decreasing large voids. Birchall et all produced a new composite material by adding a small amount of polymer and water into the cement. This composite has very high flexural strengths and it is the most important feature of this material. The MDF cement specimens produced by Birchall et. al. had reached 177 MPa of flexural strength while some other researchers [Russell 1991, Desai 1990 ve Desai 1992] achieved around 300 MPa flexural strengths, which are nearly equal to the strength of steels and it was a very important breakthrough when compared with ordinary cement paste which has only 5-10 MPa flexural strength.

MDF cements can be prepared by using cement, polymer and water. Birchall et al. used 60-70 % cement, 1-15 % polymer and less than 25 % water at the production of MDF cements. A proper water soluble polymer is necessary for the production of MDF cements. However, some researchers [Pushpalal et al. 1987] have proposed alcohol soluble polymers for this purpose in recent years. A calendering machine has been used in order to decrease large voids by applying shear forces like in rubber industry, after mixing the ingredients in a planetary mixer. Cement, PVAc and water blended in a planetary mixer until obtaining a crumble mix. Then, this mixture passed through between steel roller mills repeatedly until obtaining it in a sheet form. This sheet is cut into desired dimensions and pressed under moderate temperature and pressure.

Birchall et all attributed the high flexural strengths to the elimination of macro voids during the production process and named this material as macro defect free cement but further studies [Rodger 1985, Popoola 1991] showed that it is not the only reason which causes of such high flexural strengths. Crosslinking reactions between polymer and cement, and also the pressing the material after production at moderate temperature and pressure are playing important roles in achievement of high strengths. Reactions of PVA with hydrated calcium alumina cement were described by Rodger et al [Rodger 1985] and they proposed that the behavior of the polymer is more complex than being an inert rheological aid. They studied the evidence of polymer-cement interactions provided by calorimetry, solution chemistry and infrared spectroscopy. When water is added into the cement and partially hydrolyzed polyvinyl acetate mixture, the rising pH causes the hydrolysis of the acetate groups, leaving polyvinyl alcohol in solution with acetate ions, which subsequently react with calcium ions to form calcium acetate. Then, the metal ions in the solution crosslink with the polyvinyl alcohol chains; which makes the polymer matrix rubbery and thus allows the physical processing to continue as the cement-polymer mix attains a plasticine like consistency. The polymer will also coordinate with metal ions on the surface of the cement grains producing a cohesive matrix which links the anhydrous particles. This reaction scheme can be seen on Fig. 1.

Although, this composite has very high flexural strength it has a very important disadvantage. Their flexural strength decreases when they are stored in water and this water sensitivity is the main problem for using this material in commercial applications. Therefore most of the researches about MDF cements are focused on their water sensitivity. Some researchers [Russell 1991, Desai 1992, Atkinson and Walsh 1986, Lewis and Boyer 1995, Pushpalal et al. 1997, Mojumdar et al. 2004, Chowhurry 2004] made some improvements, but none of them seems acceptable enough for this purpose.

Different cement and polymer types were tested for the production of MDF cements. According to Santos [1997] and Sinclair [1985] MDF cements, produced with ordinary portland cement and polyacrylamide, are less sensitive against water comparing with the calcium alumina cement (CAC)-polyvinyl alcohol-acetate (PVAc) MDF systems; however, the highest flexural strengths were always obtained with CAC-PVAc copolymers. Therefore, researches about MDF cements mostly concentrated on CAC-PVAc systems.

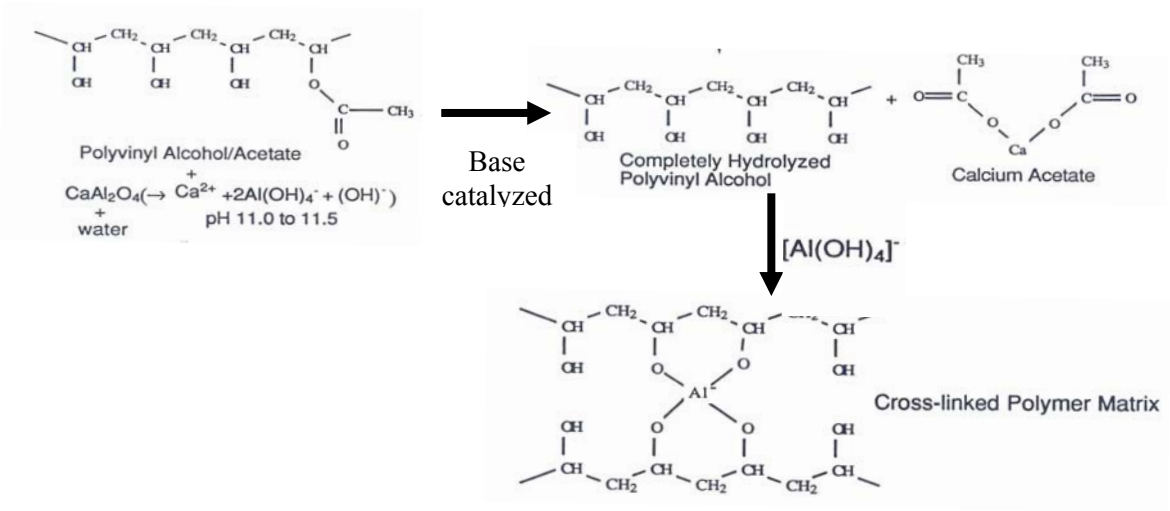

Figure 1. Schematic representation of the CAC with PVA in the presence of water [Desai 1992].

In order to understand the reasons behind the strength loss of MDF cements in contact with water, the properties of polymer and cement and their interaction should be examined. Durability problems of macro defect free cements were investigated in 2 different steps in this study. In first step, PVAc polymers with different hydrolysis degrees were used at the production of MDF cements. In second step, the type of alumina cements used were changed. Thus, effect of hydrolysis degrees of PVAc copolymers and the type of Alumina cements on the durability of MDF cements were investigated. Purpose of this study is finding the most suitable PVAc and alumina cement type for the production of MDF cements.

2 EXPERIMENTAL STUDY

2.1 Materials

2.1.1 Polyvinyl alcohol acetate (PVAc)

Polyvinyl acetate can be produced by the polymerization processes of monomer vinyl acetate, which is reacted with NaOH and methanol in order to obtain polyvinyl alcohol, but this reaction should be controlled and when it is terminated some acetate groups may remain on the polymer. Then, the copolymer of poly (vinyl alcohol) and poly (vinyl acetate), called poly (vinyl alcohol-*co*-vinyl acetate), is the most widely used polymer at the production of MDF, and shows different characteristics, such as alcohol groups are hydrophilic while acetate groups are hydrophobic. So when the copolymer is put in water, it turns into a ball. The alcohol repeated units are on the outer side of this ball, while the acetate groups are on the inner side of the ball [http://pslc.ws].

Table 1. Effect of degree of polymerization (DP) and degree of hydrolysis (DH) on the properties of PVAc [www.poval.jp].

	Polymerization degree		Hydrolysis degree	
	High 1700-2400	Low 500-600	High 98-99	Low 87-89
Solubility	↓	↑	↓	↑
viscosity of aqueous solution	↑	↓	↑	↓
Film strength	↑	↓	↑	↓
Moisture absorption property	↓	↑	↓	↑

The properties of PVAc are mostly determined by their polymerization and hydrolysis degrees. PVAc, which has high degree of hydrolysis, show less moisture absorption according to Table 1, but a previous attempt [Santos 1997] in order to produce MDF with high hydrolysis degree polymers were unsuccesfull, due to their low solubility at room temperature. However, they can be made more soluble by heating up to 80 ^{0}C (Figure 2).

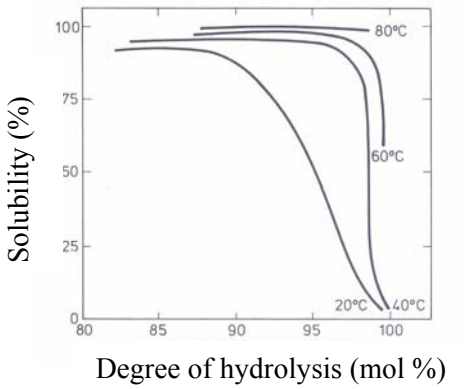

Figure 2. Effect of temperature on the solubility and degree of hydrolysis of PVAc [Finch 1992].

2.1.2 Calcium Alumina Cements (CAC)

Calcium alumina cements (CAC) are mostly preferred to portland cements or other types of cements at the production of MDF, because MDFs produced with CACs have higher flexural strengths than other cement types. It is considered that strong crosslinking reactions take place between Al ions and polymer chains in MDF [Rodger 1985, Popoola 1991, Bonapasta 2000]. Although, mostly the alumina cements which have 70 % Al_2O_3 content were preferred for the production of MDF cements [Birchall et al. 1983, Russell 1991, Desai 1990, Desai, 1992], there is not enough study about investigating the effect of Al_2O_3 content on the moisture sensitivity of MDF cements.

2.2 Production of MDF Cements with Different PVAc's

MDF cements were produced with 7 different type of PVAc in first step. Their hydrolysis degrees were changing between % 79.6 to % 99.1. Properties of PVAc copolymers, which have different degree of hydrolysis can be seen in Table 2. Only N300 type PVAc was fully hydrolyzed while KH17 and GH20R were partially hydrolyzed. Other types were modified with some other groups like carboxyl or acetoacetyl in order to make them more soluble even at room temperature (Table 2).

Table 2. Properties of PVAc's used at the production of MDF.

Product Name	Hydrolysis (mol, %)	pH	Feature
KH17	79.6	5.5	Partially Hydrolyzed
GH 20R	87.1	5.5	Partially Hydrolyzed
Z 320	92.7	4.7	Acetoacetylated
T 330	96.0	7.0	Carboxylated
Z 410	97.9	4.9	Acetoacetylated
N 300	98.4	5.9	Fully Hydrolyzed
Z 100	99.1	5.0	Acetoacetylated

High alumina cement, which has 70 % Al_2O_3 and 29,2 % CaO in composition, was used in this study. Small amounts of water between 11-20 % of cement weight and small amount of glycerol (less than 1 %) were added in to the mixture for plasticizing. MDF specimens were prepared in 3 different ways, and coded as -1, -2 or -3 depending on the method used, as shown in Table 3. These methods can be summarized as follows:

1st method: Conventional production method, optimized by Russell [1991] for PVAc and HAC.
2nd method: Similar with first method. Only difference is preheating the polymer up to 70-90 ^{0}C before adding into the mixture in order to increase the solubility.
3rd method: Similar with first method. Only difference is adding adipyl hydrazide crosslinking agent into to the mixture. Because Z type PVAcs are also known with their high crosslinking capacity when they used with Aldehydes or Amines.

Table 3. Compositions of the mixtures prepared with different PVAcs.

Mixtures	KH17 1	KH17 2	GH20 1	GH20 2	Z320 1	Z320 2	Z320 3	Z410 1	Z410 2	Z410 3	Z100 1	Z100 2	Z100 3
Wat./cem.	0.11	0.11	0.13	0.13	0.15	0.15	0.15	0.20	0.20	0.20	0.15	0.13	0.15
Poly./cem.	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07	0.07

2.3 Production of MDF Cements with Different CACs

In the second step, MDF cements were produced with 4 different types of calcium alumina cements. Their alumina contents were changing between 42 to 79 % and they were coded according to alumina contents. Compositions of cements which were provided by the producer can be seen in Table 4.

Table 4. Compositions of calcium alumina cements used at the production of MDF cements.

Cement Type	Alumina % (Al_2O_3)	Calcium Oxide % (CaO)	Ferric Oxide % (Fe_2O_3)	Silica (SiO_2)
CAC 42	42.29	35.05	14.05	4.52
CAC 49	48.86	34.89	7.16	5.56
CAC 70	70.0	29.2	-	-
CAC 79	78.95	19.57	-	-

PVAc copolymer which has a 79.6 % hydrolysis degree and 5.5 pH ratio was used in all compositions. It was the most widely used PVAc in literature at the production of MDF cement and also it is confirmed that it is the less sensitivite PVAc against water in the previous part of this study. Small amounts of glycerol, which is 10% of PVAc by weight, were also added in to the mixtures. Water/cement ratio was changing between 0.09 and 0.19 while the polymer/cement ratio was kept constant at 0.07. Twenty five different batches were prepared in order to produce MDF cements, which differ in their water contents. These mixtures can be seen in Table 5. Eight circular specimens were cut with diamond saw from each sheet and stored in dessicator or water.

2.4 Biaxial Flexural Strength Tests

All specimens, produced with one of the above methods, separated into two groups. Half of the specimens were stored in desiccator while the other half were in water for 7 days in order to see the effect of water on flexural strength. Then, the biaxial flexural strength test was applied at the ages of 7 days according to ASTM F-394. An Instron model universal testing machine equipped with a 1 kN load cell was used to test the specimens with a cross-head speed of 0.5 mm/min. Dry strength means the flexural strengths of specimens stored in desiccators while wet strength is the strength of specimens stored in water.

2.4.1 Effect of Different PVAcs on the Durability of MDF Cements

MDF cements were successfully produced with 5 of 7 different hydrolyzed PVAcs, except those with fully hydrolyzed PVAc (N300) or carboxylated PVAc (T 330). All mixtures were affected from moisture in different rates between 45 % and 80 % depending on PVAc type. However, the PVAc at the lowest hydrolysis degree (79,6 %) gave the lower strength loss (45 %). Increasing the degree of hydrolysis of PVAc increased the strength loss of MDF specimens, which were stored in water. Preheatiıng the polymer before mixing (specimens coded with -2) sightly increased the flexural

strengths except KH17-2 with respect to conventional production method (coded with -1). All results can be seen in Figure 3.

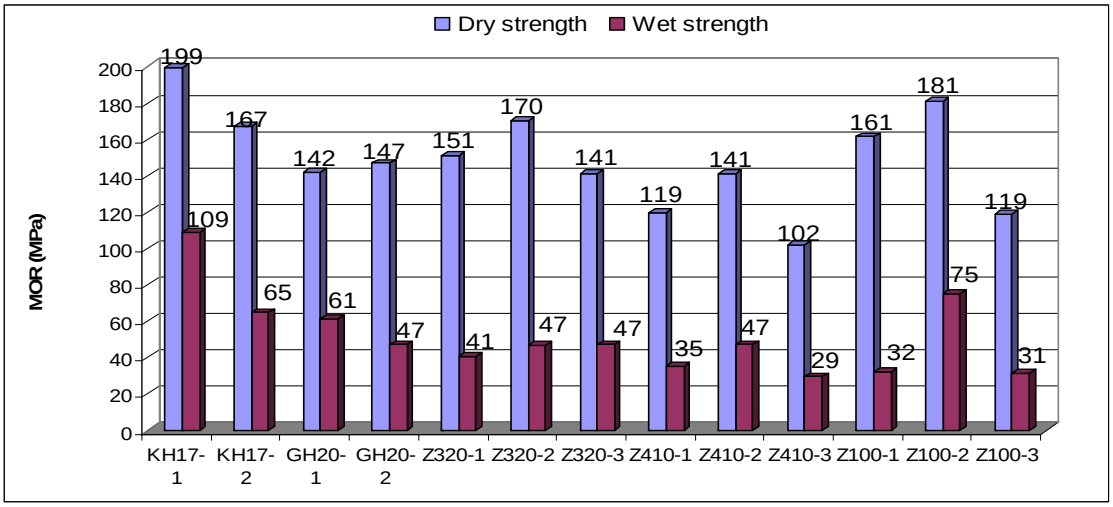

Figure 3. Biaxial flexural strength test results of MDF cements produced with different PVAc's.

2.4.2 Effect of Different Calcium Alumina Cements on the Durability of MDF Cements
MDF cements were successfully produced with all 4 different types of Alumina cements. It was impossible to obtain MDF sheets only with 2 out of 25 batches (49-7 and 79-4) due to the lack of coherence at low w/c ratios. Biaxial flexural strength results and standart deviations as well as coefficient of variations for each batch were calculated and given in Table 5. The highest biaxial flexural strength was obtained as 257 MPa on CAC 70 composite, which was prepared by a cement with 70% Al_2O_3 content and at a water/cement ratio of 0.15. The lowest biaxial flexural strength was 70 MPa and belongs to the CAC 79 composite, which was prepared with 79% Al_2O_3 content cement at water/cement ratio of 0.19. For high level of Al_2O_3 (79%), the production of MDF becomes harder than those with low Al_2O_3 content.

Strength loss is plotted against Al_2O_3 content of alumina cements in Fig. 4. It seems that changing Al_2O_3 content from 42 to 70 % slightly changed the results, but a sharp decrease in strength loss is observed when Al_2O_3 content is 79 %. Composites produced with CAC 79 cement have the smallest flexural strengths and highest strength loss which may be due to the high content of alumina in this cement (79 %). However, all composites produced with all types of alumina cements are sensitive to water and show strength loss after 7 days water storage in varying extents.

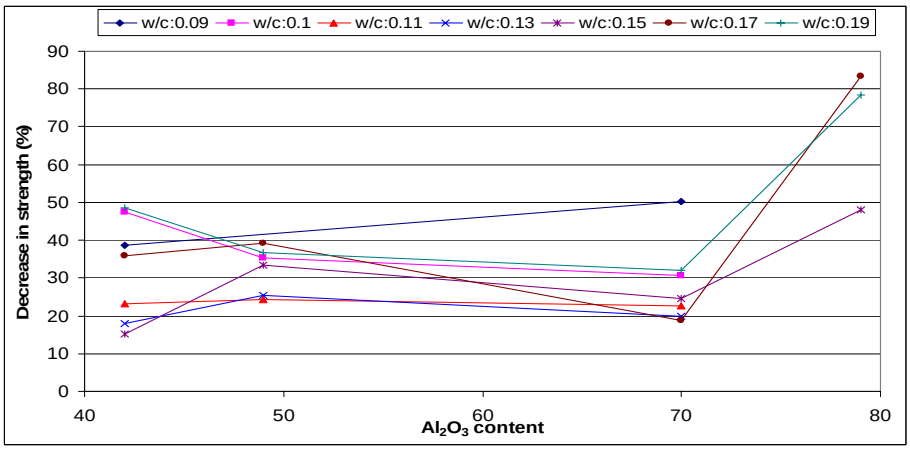

Figure 4. Strength loss versus Al_2O_3 content.

Table 5. Biaxial flexural strength test results of MDF cements produced with different CACs.

Cement type	Mixtures	w/c	Dry Strength (MPa)			Wet Strength (MPa)		
			f_c	σ	V %	f_c	σ	V %
CAC 42	42-1	0.19	169	30	18	87	5	6
CAC 42	42-2	0.17	194	14	7	124	8	7
CAC 42	42-3	0.15	206	18	9	175	25	14
CAC 42	42-4	0.13	220	19	9	180	18	10
CAC 42	42-5	0.11	233	17	7	179	29	17
CAC 42	42-6	0.10	235	25	11	124	27	22
CAC 42	42-7	0.09	206	19	9	126	27	21
CAC 49	49-1	0.19	205	13	6	130	12	9
CAC 49	49-2	0.17	178	8	5	108	6	6
CAC 49	49-3	0.15	213	17	8	142	4	3
CAC 49	49-4	0.13	216	16	7	161	30	18
CAC 49	49-5	0.11	238	12	5	180	46	27

CAC 70	70-7	0.09	174	26	15	87	19	22
CAC 79	79-1	0.19	70	18	26	15	3	22
CAC 79	79-2	0.17	105	6	6	17	6	33
CAC 79	79-3	0.15	85	5	6	44	1	2
CAC 79	79-4	0.13	-	-	-	-	-	-

3 CONCLUSIONS

- MDF cements can be successfully produced with 5 out of 7 different hydrolyzed PVAc's, sometimes with modified procedures.
- MDF cements could not be produced with fully hydrolyzed PVAc or carboxylated PVAc.
- All specimens showed moisture sensitivity. However, the PVAc at the lowest hydrolysis degree (79,6 %) gave the lowest strength loss. Increasing degree of hydrolysis of PVAc's increased the strength loss of MDF specimens which were stored in water.
- Preheating the polymer before mixing (specimens coded with -2) slightly increased the flexural strengths, except KH17-2 with respect to conventional production method (coded with -1)
- MDF cements can be successfully produced with 4 different type of alumina cements.
- Flexural strengths of all specimens decreased between 15 and 83 % after storing in water for 7 days.
- The highest biaxial flexural strength was obtained as 257 MPa on CAC 70 composite, which was prepared by a cement with 70% Al_2O_3 content and at a water/cement ratio of 0.15.
- The lowest biaxial flexural strength was 70 MPa and belongs to the CAC 79 composite which was prepared with 79% Al_2O_3 content cement at water/cement ratio of 0.19.
- It seems that there is an optimum alumina content between 42-70 % for minimum strength loss in water.
- For high level of Al_2O_3 (79%), the production of MDF becomes harder and the level of strength drops while strength loss in water increases comparing with other cements.

ABSTRACT

The aim of this paper is to present a discussion on the assessment of the durability of industrial cement mortars, based on two experimental research works carried out at the Building Physics Laboratory, Faculty of Engineering, University of Porto, Portugal.

The service life prediction of any construction material is not an easy task. The researchers must choose between several different approaches, which one with its advantages and its limitations.

While in real buildings, with in-use conditions, the material or component is subject to changeable actions in an environment where the great majority of the degradation agents is not controllable by man, in laboratory, we can choose to expose the material to artificial and controlled conditions, using chambers of accelerated ageing. The main difficulty of this last type of tests consists in the interpretation of the results, in what concerns their correspondence to real time. Researchers on durability have been discussing this problem since a long time: how to get a valuable correlation between the results of accelerated ageing tests and the one issued from natural exposure? In this paper, a discussion on this subject is presented based on the above mentioned studies, concerning the performance over time of two different types of industrial cement mortars exposed to accelerated ageing tests and also to natural ageing. The main advances and the main difficulties in implementing a service life prediction model will be identified. Finally, suitable strategies are discussed for the future development of this approach.

1 INTRODUCTION

The objective of any service life prediction of a material, system or component integrated into a building is to evaluate its ability to satisfactorily perform its operations throughout the service life of the building or throughout the period considered reasonable for its replacement or repair. The definition of a model of service life prediction and its application are imperative, through this being able to evaluate the reliability of the defined model. The two experimental studies that are presented here use the same model of service life prediction applied to two types of different mortar, but lead to results whose interpretation differs. Therefore, a reflection is presented on the factors that could influence the service life prediction, on the structure of the model and on the possibility of its generalized application.

2 SERVICE LIFE PREDICTION

2.1 Service Life Prediction Model Adopted by LFC - FEUP

Two experimental studies carried out in the Building Physics Laboratory of the Faculty of Engineering of the University of Porto, Portugal were based on the general methodology proposed by ISO 15686-1 standard and lead to the proposal of the model that we are presenting. Tests campaigns were carried out for accelerated ageing and natural ageing stations were simultaneously set up where the materials were exposed to the external environment.

In this way, according to the diagram in figure 1, when in possession of the test results, referring to accelerated ageing and to natural ageing, given that the type of degradation resulting from either one or the other test is seen to be similar, it is possible to interpret these results and develop a model of service life prediction of the products and systems being studied through the establishment of a correlation between the number of cycles of artificial ageing and the real time of natural ageing (Figure 1).

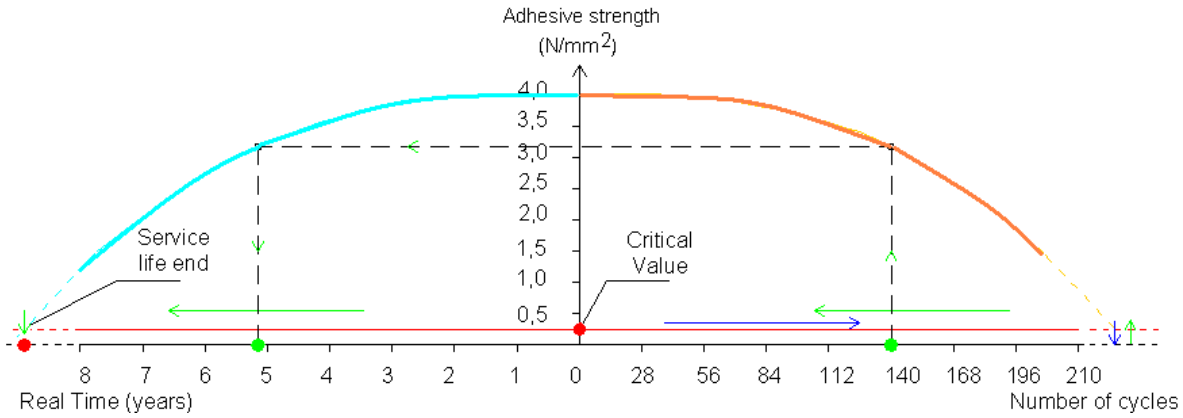

Figure 1. Correlation between the number of accelerated artificial ageing cycles and real time natural exposure – Prediction Model.

Knowing the degradation curve of a given characteristic (as an example, the figure 1 considers the adhesive strength between the mortar and its substrate) it will be possible to establish a correspondence between the number of accelerated artificial ageing cycles and the number of years in real time.

2.2 Critical Analysis of the Difficulties Associated to the Chosen Model

The model presupposes the identification of a degradation curve as a function of time, obtained in accelerated ageing tests. This procurement can be met with several difficulties. Firstly, the most

relevant agents of degradation for the material being studied have to be rigorously identified and the effects of action variation on these agents. For this identification, the performances of the preliminary tests become important. Secondly, performance characteristics to be evaluated must be selected, opting for those that are shown to be critical for durability. This choice is very important and could be based, on the one hand, on the results of the preliminary tests and, on the other hand, on the historical pathologies normally associated with the material to be evaluated. If the identified degradative agents or the selected performance characteristics were not the most adequate, the tests could be shown to be inconclusive and the model would not be able to be applied.

With the adequate performance characteristics chosen and the necessary artificial accelerated ageing tests performed, an other problem could still arise: the results obtained for different stages of ageing do not reveal any definable tendency, making it impossible to draw a degradation curve. In this case, the hypothesis that there are other aspects that are more relevant to ageing of the material or system in study becomes plausible: the agents of degradation being considered may not be very relevant for the variation of the characteristic being tested as it is overall dependent on, for example, the execution, on the interaction between different elements of the construction (interfaces), on the type of in-use conditions, etc. In this case, the application of the model as presented becomes unviable.

It can also be observed that the model assumes the occurrence of a degradation curve that is continuous in time and does not consider the interventions hypothesis along this timeline that restitute or improve a given performance characteristic, which could obviously take place in reality. However, the objective of the model is to obtain a prediction of a reference value for the service life. With this value determined, it will then be possible to take into account the effects of modifying factors related to the various aspects present in the life cycle of each system or material, with these factors being related to the design, the execution, the use, the specific environments to which they will be exposed, maintenance measures, etc.

Regarding the service life prediction starting from a specific number of tests in a natural ageing scheme, it will be as easy as the ease of gauging the deterioration observed and its comparison with the results of the accelerated ageing tests. In this way, for products or systems with a history of applications, it will also be possible to complement the information with a study of its record with respect to pathologies and the repair measures, being able to more easily evaluate the significance of the observed deterioration in the early stages of the experimental installation. In addition to this, the tests on service conditions, performed at construction sites of different ages, could substitute or complement the tests made on the experimental installations of natural ageing, as long as it is possible to retrieve results in a sufficient number to be statistically significant and as long as there is information about the type of products applied, the date of application and the conditions to which they have been subject over the years.

3 EXPERIMENTAL STUDIES

3.1 Brief Description of the Studied Systems

3.1.1 Cementitious Adhesive in Bonded Ceramic Coverings of External Walls

In the first study (Sá, Ana V., 2005), the durability of cementitious adhesive in bonded ceramic coverings is evaluated. This kind of covering has a long tradition in Portuguese construction. It continues, in modern times, to be widely used, both for its aesthetic aspect as well as because an increased durability is expected of it along with a satisfying functional performance. Added to this is the relative ease of cleaning and maintenance.

The system under study is basically composed of three essential elements: the substrate, the bonding material (in this case, the cementitious adhesive) and the ceramic tile. The evaluation of durability of

one of the elements must take into account, by necessity, the durability of the system and the compatibilities between the different elements.

The substrate for the ceramic coverings is defined as a function of the nature of its constituent materials. In the present study, only concrete walls or brick walls covered with extremely hardened mortar were considered. The designation of cementitious adhesive applies to a hydraulic adhesive mortar with a cement base, with aggregates (fine granulometry) and additives that improve water retention, plasticity and adherence.

The ceramic tiles are thin plates made from clay and/or other organic raw materials and are generally utilized as coverings of walls and floors. They are, usually, formed by extrusion or pressing at room temperature but can also be molded by other processes. Next they are dried and finally cooked at a temperature appropriate for obtaining the required characteristics.

3.1.2 One-Coat Rendering Mortar for External Use

In the second study (Quintela, M. A., 2006), the performance of a one-coat rendering mortar made up of an industrial mortar applied at a single layer is evaluated. This type of covering is normally applied by projection and is classified as an impermeable covering, contributing to the overall sealing of the wall and simultaneously carrying out the functions of finishing and decoration, dispensing the need for painting.

3.2 Performance Indicators Evaluated and Criteria for Durability

In the evaluation of the durability of the **adherent ceramic covering system**, the criterion selected for its characterization was the value of the adhesive strength to its substrate. It was considered that this characteristic would be the most important one for the service life prediction of the system. The set critical value was that of 0,3 N/mm^2.

Over a period of time, adhesion tests were performed in order to evaluate the adhesive strength, at different moments of the accelerated ageing process, with the aim of characterizing its influence on the performance of the cementitious adhesive.

Regarding the **one-coat rendering mortar**, in general we can say that in order to effectively contribute to the satisfaction of the functional requirements of the walls, the following characteristics must be maintained: good adhesion to the substrate surface; good waterproofing ability, thereby being unlikely to crack and having low capillarity; increased permeability to water vapor; adequate aesthetic aspect and preservation of its decorative properties through adequate maintenance.

Therefore, given the requirements to meet, the following characteristics were evaluated, also in several different stages of ageing: coefficient of water absorption by capillarity; permeability to liquid water, adhesion to the substrate and aspect characteristics like superficial cracking and coloring. However, in order to compare the results obtained in the two studies and discuss their implications, we present, for this second product, only the results obtained for the value of the adhesive strength. In this case, 0,3 N/mm^2 was considered as the recommended value, with 0,2 N/mm^2 being set as the minimum admissible value.

Of the various mechanisms and agents of degradation responsible for the ageing of the study systems, those of hygrothermic character are considered, namely: variation in temperature; variation in relative humidity; incidence of solar radiation and precipitation. These actions will have a determining role in the ageing of the exterior coverings. Therefore we submitted specimens of the two systems under analysis to accelerated ageing cycles.

The cycles performed in the study of **cementitious adhesive** consist of the exposure of the specimens to extreme conditions of usage, with harsh variations in temperature, relative humidity and radiation in

such a way as to provoke the rapid degradation of the system of covering, figure 2 portrays the cycle utilized.

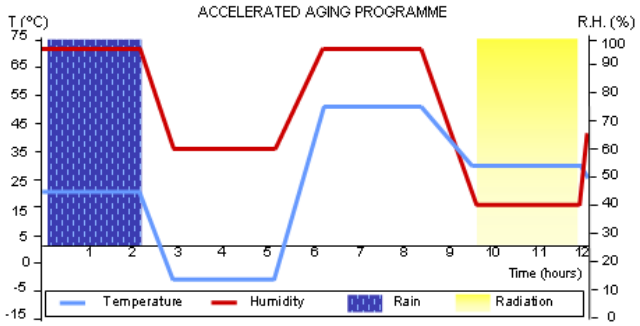

Figure 2. Complete cycle – 12 hours.

In the study of the **one-coat rendering mortar**, brick models covered with this mortar were submitted to three different processes of ageing: the combination of Cycles A; Cycle B and Cycle C. The combination of cycles A corresponds to an adaptation of the process of ageing referenced in the European Standard 1015-21 of 2002 and consists of the association of cycles of heating/freezing and of humidification/freezing, separated by a time of rest in the laboratory atmosphere, Table 1 portrays this combination.

Table 1. Cycles combination A

Cycle A1 heating/freezing				*Standard environment (laboratory environment)*				*Cycle A2 humidification/freezing*		
T	RH	D		T	RH	D		T	RH	D
60ºC	n.c.	8 h						Immersion in water		8 h
20ºC	65 %	½ h	+	20ºC	65 %	48 h	+	20ºC	65 %	½ h
-15ºC	n.c.	15 h						-15ºC	n.c.	15 h
20ºC	65 %	½ h						20ºC	65 %	½ h

T: temperature [ºC]; RH: Relative Humidity [%]; D: duration of the established conditions [h]; n.c.: Relative Humidity non-controlled

The second ageing process, which can be observed in figure 3, consists of the repetition of a cycle (Cycle B) that involves the variation of the conditions of temperature and relative humidity for 24 hours, determined through the analysis of the records of recent years obtained by the meteorology stations of LFC, taking into account, for the definition of the temperature variation, the heating of the surfaces exposed to solar radiation.

Finally, Cycle C consists of the variation of conditions of temperature and relative humidity, associated with the effects of rain (spraying with water) and of solar radiation (Xenon arc lamp), having a duration base of 12 hours. This cycle has the same configuration as the one adopted for the study of cementitious adhesive. These conditions were achieved using a chamber specialized for this type of testing.

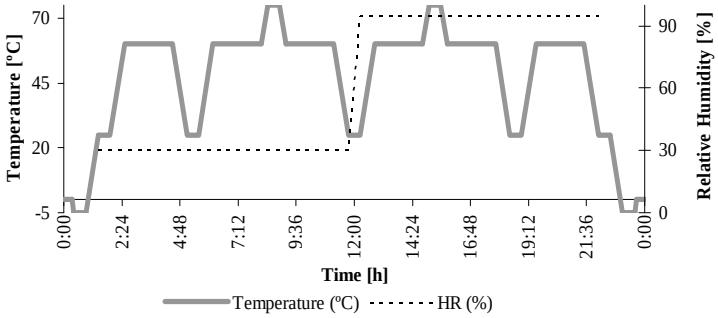

Figure 3. Cycle B.

Simultaneously, stations were set up for **natural ageing** consisting, in the first case, of a wall covered with different ceramic tiles and, in the second case, of a wall covered with different types of one-coat mortar, both exposed to the external environment. Similarly to that performed in the laboratory, adhesion tests were performed on these walls, in order to determine the time period.

3.3 Experimental results

As regards the durability of **cementitious adhesive**, the graphic in figure 4 presents the variation in the adhesive strength as a function of the number of ageing cycles to which the specimens designated as PE0, PE1 and PE3 had been subjected. In these three specimens cementitious adhesive of type C2 [EN 12004] was used along with three different types of ceramic tiles. There is a very clear decreasing tendency and it can be predicted that, independent of the type of ceramic tile used, in the set of tests performed on the specimens with class C2 cementitious adhesive, 140 cycles would be sufficient to drop below the critical adhesive strength value of 0,30 N/mm^2 and thereby reach the service life term of the product.

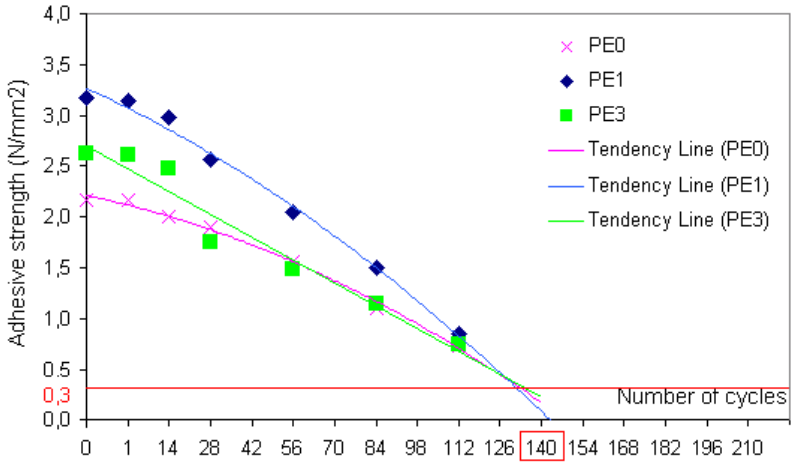

Figure 4. Service life term prediction for C2 cementitious adhesive

Regarding the tests performed on the wall of the natural ageing station, given the little time of exposure that passed by until the performance of the first tests, it was only intended to demonstrate the methodology to follow to establish the correlation between the results obtained from accelerated ageing and those obtained with natural ageing.

As regards the durability of the **one-coat rendering mortar**, figure 5 displays the variation in the adhesive strength of the single layer covering, applied with 1 or 2 cm of thickness, on the brick models submitted to the accelerated ageing cycles.

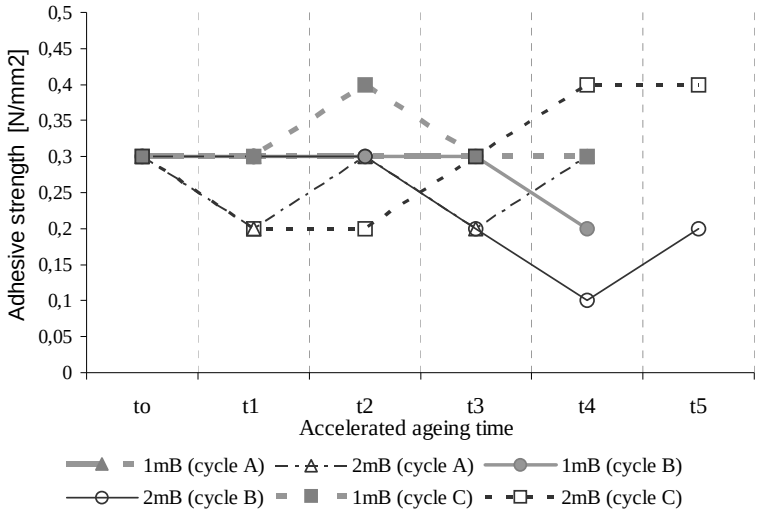

Figure 5. Evolution of the adhesive strength in the models submitted to the three ageing processes. Specimens with 1 cm and 2 cm of covering.

In figure 5 we can observe a random variation in the performance of the one-coat rendering mortar in terms of adhesion to the substrate, being impossible to identify any tendency for any one of the ageing processes. At the natural ageing station, two series of in-situ adhesion tests were performed. Between the first series of tests and the second series of tests a tendency of diminished adhesion to the substrate surface was observed. However, the observed tendency doesn't allow us to come to a conclusion because the time that had passed since the execution of the wall was still too short.

4 CONSIDERATIONS REGARDING THE APPLICABILITY OF THE MODEL IN THE EVALUATION OF MORTAR DURABILITY

4.1 Main Problems

As regards the **cementitious adhesive** applied in a system of adherent ceramic covering, once it is possible to obtain a degradation curve in the accelerated ageing tests, to be able to reliably apply the model, it becomes necessary to only perform the tests in the natural ageing station, for defined time periods (every six months, for example) in order to be able to establish a relationship between the short term tests and the long term tests. However, in this case, it is in the long term testing that we encountered the most difficulties. For products with a reduced application experience or for new products, it becomes more difficult to avoid the necessity of waiting for a relatively long time for the long term tests in the experimental installation, if we intend to quantify its service life period in absolute terms, we do not have performance data for these products in service conditions that serve to gauge the significance of the tests in which they were obtained.

As regards to the cementitious adhesive, it will be possible to collect the performance data for in-service conditions, although total characterization would not always be easy in terms of historical application and utilization. For this case study, we are convinced that in a relatively short time, it will be possible to completely apply a prediction model.

In the case of the **one-coat rendering mortar** the characteristic that was considered to be significant for the definition of its durability, adhesion to the substrate, presented a behavior that significantly varied with time, unable to result in a degradation curve. The evaluation of the situation led us to the conclusion that there are several exogenous factors that significantly affect the performance. In this case, the application conditions are determinant, as well as the roll of the interfaces between layers. This fact made the application of the adopted prediction model unviable in this case.

4.2 Future Strategies

For the development and the future application of the prediction model to different systems and materials, campaigns of accelerated ageing tests must be taken into consideration accompanied by natural ageing tests and the systematic collection of data from existing buildings. For the adopted strategies to be actually efficient, a rigorous identification of the relevant characteristics to be tested (those that are seen to be critical to durability) is very important and also the performance of previous tests for the gauging of the expected variations and for the identification of the most influential agents.

After a service life prediction has been obtained for specified conditions, where we would be able to have the service life as a reference point, it becomes necessary to evaluate the influence of the specific conditions of each real situation. For this, for example, the factorial method proposed in the ISO standard 15686-1 or other equivalent method could be adopted. The method takes into account, for each situation in the project, the conditioning factors of an estimated service life. They are: the intrinsic quality of the material or system; the quality of the design; the quality of the execution; the environmental, interior and exterior characteristics; the type of use and the level of maintenance.

5 CONCLUSION

In this paper, a model of service life prediction of a material or system of construction based on accelerated artificial ageing tests and on natural ageing tests was presented. Its application was discussed and the main difficulties identified.

In general, we can say that the proposed model can be adopted as long as it is possible to identify a degradation curve as a function of time. The dispersion of the results determined by the influence of factors such as the execution characteristics and the role of the interfaces between the layers led to its adoption being unviable.

Carbonation in Concrete with High Fly Ash Content and Hydrated Lime

Juarez Hoppe Filho [1]
Maria Alba Cincotto [2]

T 11

ABSTRACT

Substituting a portion of the cement with fly ash when producing concrete reduces the cost per cubic meter and contributes to sustainable development practices.

Pozzolanic activity is the interaction of fly ash with calcium hydroxide which, forms secondary silicate and aluminate hydrates that reduce the alkalinity of the concrete and the content of portlandite. This causes spreading of the carbonation front, which is undesirable for reinforced concrete. For the purpose of increasing the calcium hydroxide due to the substitution of cement and that consumed by pozzolanic activity, 20% of hydrated lime was added to the concrete and 50% of the high early strength portland cement (HESC) replaced with fly ash.

To achieve compressive strengths of 55 MPa at 91 days, concretes with HESC, HESC + fly ash and HESC + fly ash + hydrated lime were cast with different water/cementitious material ratios. The specimens were then submitted to accelerated carbonation (5% CO_2 and 75% R.H.) for 20 weeks.

The hydrated composition and degree of carbonation were determined by thermogravimetry. The results show that the addition of hydrated lime is efficient in producing a partial reposition of portlandite and accelerates pozzolanic activity. There was identical carbonation in concretes with cement + fly ash, with or without hydrated lime, the spread of the carbonation front was higher in these concretes than the reference concrete.

1 INTRODUCTION

Substituting high early strength cement (HESC) for fly ash, in concrete, changes the microstructure of the hydrated paste, affecting durability. Normally, these modifications improve performance in the hardened state, although, there is an increase in carbonation. [Papadakis 2000, Mira *et al.* 2002].

The pozzolanic activity of fly ash consumes the calcium hydroxide that results from cement hydration, forming hydraulic compounds [Massazza 1998]. The lower portlandite content increases the neutralization rate of the pore solution by carbon dioxide action. As a result, the reduction in alkalinity takes less time to reach the vicinity of the steel, making the reinforced concrete with high fly ash content more susceptible to corrosion [Papadakis 2000].

Sustainable development aims to increase the amount of pozzolan used in clinker substitution [Papadakis 2000, Mira *et al.* 2002], which reduces the portlandite content in hydrate cementitious material [Taylor 1997, Zhang *et al.* 2000, Sakai *et al.* 2005]. Adding hydrated lime minimizes this disadvantage by partially re-establishing the amount of calcium hydroxide.

The hydrated lime in concrete containing fly ash stimulates pozzolanic activity [Mira *et al.* 2002]. The immediate availability of lime in solution increases the precipitation of hydrates in relation to similar concretes, without the addition of lime [Biernacki *et al.* 2001, Saeki & Monteiro 2005].

Carbonation results from the diffusion of carbon dioxide throughout the covercrete, which it dissolves in aqueous pore solution by neutralizing the alkalinity due to ions OH^-, Ca^{+2}, Na^+ and K^+, forming calcium carbonate [Taylor 1997]. The consumption of portlandite decreases the pH-value, inducing a higher solubility of the other hydrated compounds, which partially reestablishes the alkalinity resulting in more carbonation of C-S-H and aluminate phases [Houst & Wittmann 2002, Thiery *et al.* 2007]. To avoid degradation of C-S-H, which is the most responsible for compressive strength, adding hydrated lime to concrete with pozzolan is proposed which, will increase the amount of portlandite available for carbonation.

The carbonation that occurs in concrete with HESC performs differently in relation to concrete containing pozzolan, which consumes portlandite [Thiery *et al*. 2007]. Adding hydrated lime changes the kinetics of the cement's hydration and pozzolanic activity, affecting carbonation [Mira *et al.* 2002]. Therefore, the aim is to evaluate what efficiency a 20% addition in hydrated lime, of the cementitious materials by weight (50% portland cement + 50% fly ash), may have on the accelerated carbonation of concretes which have reached 55 MPa at 91 days.

2 EXPERIMENTAL PROCEDURES

2.1 Materials

High early strength cement (HESC), in accordance with Brazilian standard ABNT NBR 5733 (ASTM C 150), low-calcium fly ash and calcium hydrated lime were used. The specific gravity, measured by helium picnometry, and Blaine/BET specific surface area of each material, are in Table 1.

Table 1. Physical properties of the materials.

Materials	Specific gravity (g/dm^3)	Specific surface area	
		Blaine (m^2/kg)	BET (m^2/g)
Cement (HESC)	**3.02**	**514**	**1.50**
Fly ash	**2.38**	**678**	**3.63**
Hydrated lime	**2.26**	**1597**	**9.40**

The chemical composition of cement (HESC) and low-calcium fly ash determined by X-ray fluorescence is in Table 2:

Table 2. Chemical composition of the materials.

Materials	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	L.O.I.
Cement (HESC)	**17.1%**	**3.7%**	**3.1%**	**64.8%**	**0.7%**	**4.6%**	**4.1%**
Fly ash	**63.6%**	**25.1%**	**2.7%**	**4.0%**	**1.0%**	**0.3%**	**2.0%**

The hydrated lime included 60% calcium hydroxide and 32% calcium carbonate residue of raw material, determined by thermogravimetry using a NETZSCH STA 409 PG. The coarse aggregate consisted of crushed and washed granite using the fraction between 19.0 and 6.3 mm. Quartz sand, washed and sieved in 4.8 mm mesh, served as fine aggregate. The admixture used in this study was a water-reducing MBT Glenium 51, the chemical base of which is modified polycarboxylic ether.

2.2 Concrete Mix Proportion

The mix proportions are in Table 3. The cement used was 50% in mass replaced by low-calcium fly ash. To re-establish the portlandite consumed by pozzolanic activity, 20% hydrated lime (by weight) was added to the cementitious materials (portland cement + fly ash).
To achieve the 55 MPa compressive strength of the 91-day-old reference concrete, concretes containing fly ash must have the water/cementitious material ratio decreased. This leads to an increase in the consumption of binding materials. However, as 50% of the mass is composed of fly ash, there is a reduction in the amount of cement utilized, by weight.

Table 3. Concrete mix proportion.

Abbreviation	w/cm	Portland Cement	Fly Ash	Hydrated Lime	Fine Aggregate	Coarse Aggregate	Water	Admixture
	(kg/kg)	**(kg/m^3)**	**(kg/m^3)**	**(kg/m^3)**	**(kg/m^3)**	**(kg/m^3)**	**(kg/m^3)**	**(kg/m^3)**
HESC	**0.52**	**304**	**---**	**---**	**872**	**1088**	**157.9**	**0.60**
HESC + Fly ash	**0.42**	**189**	**189**	**---**	**758**	**1088**	**158.2**	**1.05**
HESC + Fly ash + Hydrated lime	**0.43**	**179**	**179**	**72**	**743**	**1054**	**152.2**	**2.25**

slump – 85 ± 10 mm

The specimens (ϕ10 x 20 cm) tested for compressive strength cured in the wet chamber at 23ºC ± 2ºC and 95% relative humidity for 91 days.

The samples analyzed for accelerated carbonation were extracted from 15 x 15 x 60 cm beams and cured in the wet chamber at 23ºC ± 2ºC and 95% relative humidity for 28 days, Fig. 1.

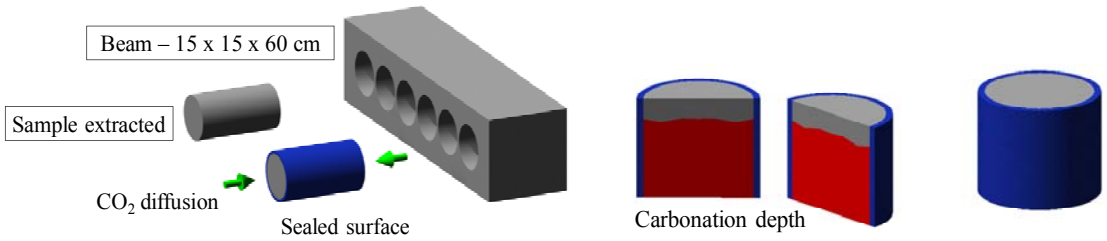

Figure 1. Schematic representation of the samples used in the accelerated carbonation test.

2.3 Accelerated Carbonation Test

The extracted samples (ϕ8 x 15 cm) were pre-conditioned in accordance with RILEM TC-116 PCD [1999] before undergoing the accelerated carbonation test. The pre-conditioning phase occurred for 63

days, until the extracted samples were 91 days-old. Subsequently, the accelerated carbonation test lasted for 20 weeks in a chamber with 5% CO_2 volumetric concentration, 75% relative humidity, and 20ºC ± 1ºC. One sample remained vacuum-sealed to be the non-carbonated reference concrete.
After 4; 8; 12; 16 and 20 weeks, samples were removed from the chamber, split into two halves and the carbonation depth measured by spraying a phenolphthalein solution on the freshly broken concrete surfaces, in accordance with RILEM CPC-18 [1988].

2.4 Chemically Bound Water and Portlandite Content

Preparation of Samples: After the accelerated carbonation test, thin sample slices were taken from the carbonated region of all the concretes. Thin sample slices were also cut from the non-carbonated concretes. From these samples, the coarse aggregate was removed and the mortars submitted to thermogravimetry analysis. These analytical samples were frozen in liquid nitrogen, stored at –30ºC and D-dried.

Thermogravimetry analysis: the dried mortar samples were ground to 150 – 75 □m and the fraction analyzed by thermogravimetry using a NETZSCH STA 409 PG, in a nitrogen atmosphere. The heating rate was 10ºC/minute, applied from 30ºC to 1000ºC. The mass losses were all corrected to non-volatile base [Taylor 1997]. Deconvolution of the calcium carbonate peak (DTG) was determined with the NETZSCH Peak Separation program.

3 TEST RESULTS

3.1 Compressive Strength

Table 4 shows the compressive strength of concretes at 91 days. In the reference concrete, the BET specific surface area available for hydrates precipitation was 1.50m^2/g. This area represents the cement particle surface gradually covered by hydrates. Concrete containing cement + fly ash had 2.56m^2/g. This larger area speeds up the dissolution/precipitation of cement, increasing the degree of hydration by heterogeneous nucleation [Lawrence *et al*. 2003]. The addition of hydrated lime increased the area for crystals growth up to 3.71 m^2/g.

Table 4. Compressive strengths of concretes at 91 days.

Abbreviation	Compressive strenth (MPa)
HESC	**54,7 ± 1,4**
HESC + Fly ash	**54,5 ± 1,6**
HESC + Fly ash + Hydrated lime	**54,9 ± 1,6**

Increases in the compressive strength of concretes with fly ash result mostly from the chemical (pozzolanic activity) and physical effect produced by the extra nucleation sites. The greater degree of cement hydration in concretes containing fly ash, results in Van der Waals forces that are more intensive. In Table 5, concretes with fly ash have lower quantities of chemically bound water as C-S-H and AFt/AFm phases than the reference concrete. Conclusion, the compressive strength of concrete containing fly ash does not depend only on the chemical effects (cement hydration and pozzolanic activity). The physical effect contributes heavily to the compressive strength when pozzolan replaces a portion of the cement.

3.2 Carbonation Depth

Fig. 2 (A) gives the results of carbonation depths, as determined by spraying phenolphthalein solution. The carbonation depth in the reference (HESC) concrete was approximately half of that in concretes with fly ash. When hydrated lime was added, the carbonation depth did not significantly decrease in relation to concrete produced with cement + fly ash, without the addition of lime.

Carbonation is not entirely limited to the areas indicated by the phenolphthalein solution [Chang & Chen 2006, Thiery *et al.* 2007]. Nonetheless, the carbonation coefficient for the area with a pH ≤ 9 may be calculated using the colorimetric test results and used to adequately compare differing concretes.

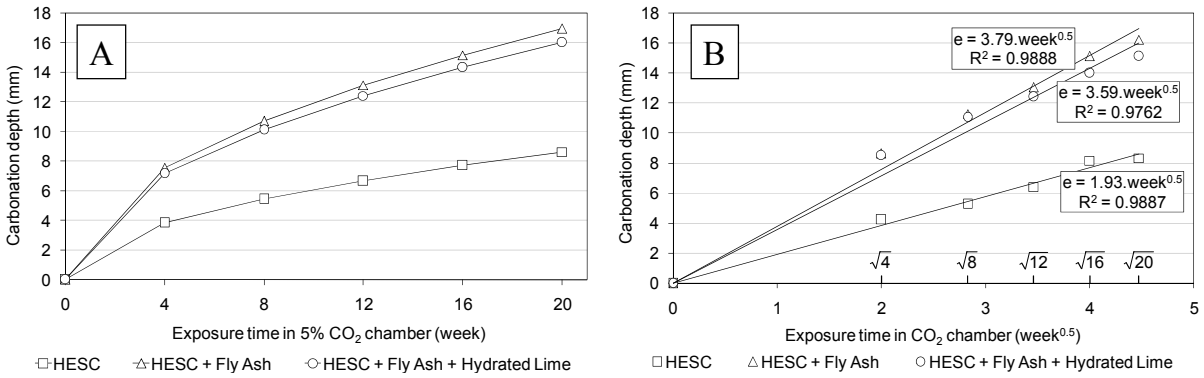

Figure 2. Carbonation depth of concretes in accelerated condition for 20 weeks.

Calculation of the carbonation coefficient was achieved by plotting the carbonation depth against the square root of time, as shown in Fig 2 (B). The angular coefficient of the linear equation represents the carbonation coefficient of the concrete. The reference concrete, with HESC, has a coefficient of 1.9 mm/week$^{0.5}$. The carbonation coefficients of concretes with fly ash, with or without hydrated lime, are very similar, 3.6 mm/week$^{0.5}$ and 3.8 mm/week$^{0.5}$, respectively.

3.3 Chemically bound water and portlandite content

Fig. 3 shows the mass loss (TG) and mass loss rate (DTG) for the reference concrete, carbonated, and non-carbonated. The difference between curves represents the accelerated carbonation effects in hydrates (C-S-H + aluminates + magnesium compounds) and portlandite in relation to the non-carbonated concrete.

Mass loss between 30ºC and 390ºC is due to the decomposition of C-S-H and aluminates (AFt and AFm phases). Calcium hydroxide decomposes between 390ºC and 480ºC and, calcium carbonate above 480ºC.

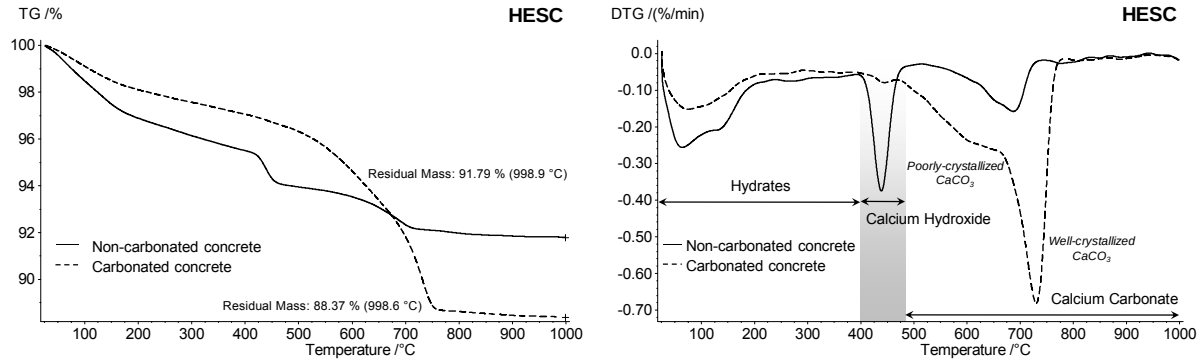

Figure 3. TG/DTG of HESC concrete, carbonated and non-carbonated (20 weeks).

X-ray diffraction (Fig. 4) showed there was some remaining portlandite in the carbonated zone of the reference concrete while in concretes containing fly ash, with or without hydrated lime, there was none. This residual portlandite in the carbonated zone is due to the formation of a $CaCO_3$ coating around the $Ca(OH)_2$ crystals, reducing their solubility in pore solution [Thiery *et al.* 2007]. Vaterite appeared in the reference concrete but not in concretes containing fly ash.

Calcium carbonate formed during accelerated carbonation results in well-crystallized $CaCO_3$ (calcite) and poorly crystallized $CaCO_3$ (vaterite and/or aragonite). In stable form (calcite), the decomposition of crystals occurs at higher temperatures than in meta-stable phases. Fig. 5 displays the mass loss rate (DTG) for all concretes above 480ºC. Deconvolution of DTG curves results in two main reactions of decomposition.

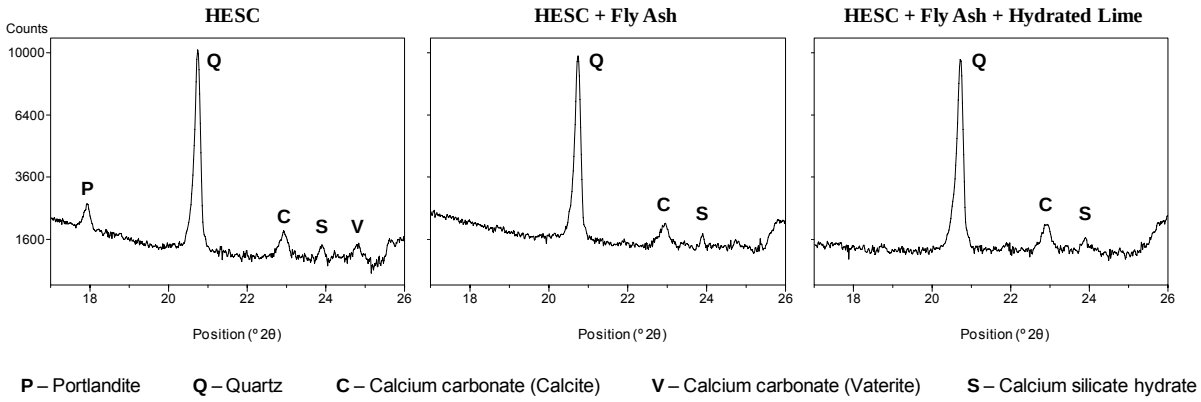

Figure 4. X-ray diffraction of concretes after accelerated carbonation.

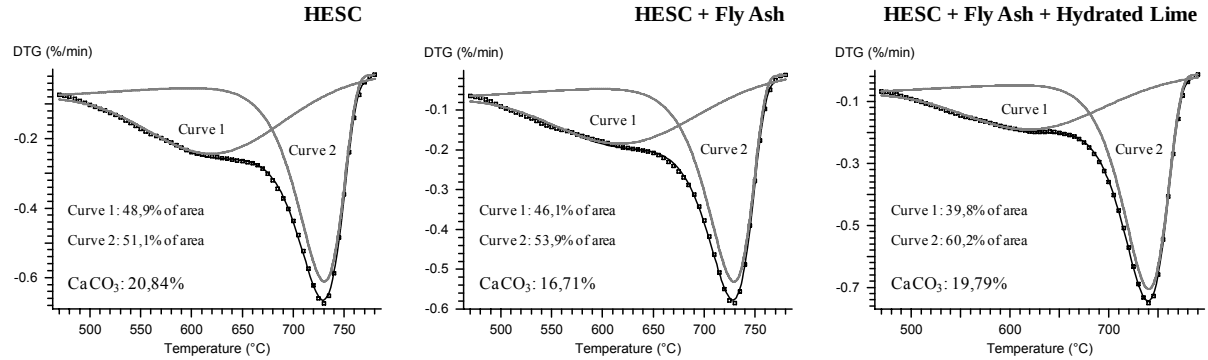

Figure 5. Deconvolution of DTG curves in calcium carbonate decomposition zone.

The first reaction (curve 1) represents vaterite/aragonite and calcite in a less crystalline state of decomposition. Curve 2 indicates well-crystallized calcite decomposition. Each concrete in the study presented these two reactions. However, when hydrated lime was added to concrete with fly ash, the amount of well-crystallized calcite became higher than in the other concretes because lime has well-crystallized calcium carbonate in its composition.

The mass loss data of all carbonated and non-carbonated concretes is in Table 5. The addition of hydrated lime in concrete with cement and fly ash increased the remaining amount of calcium hydroxide. With the addition of hydrated lime, the quantity of portlandite increased to 66% of that found in the reference concrete. Without the addition of hydrated lime, the portlandite content remained at 46%.

In concrete containing cement + fly ash, the total theoretical amount of calcium hydroxide produced was 4.24%, and the remaining portlandite content was 3.12%. Pozzolanic activity consumed 1.12%. With the addition of hydrated lime the theoretical amount rose to 7.65%, the portlandite remaining was 4.48% and the portlandite consumed was 3.17%. Thus, adding hydrated lime speeds up the pozzolanic activity, which consumes greater quantities of portlandite and consequently forms more hydraulic compounds.

Carbonation consumes the portlandite and provokes decomposition of the hydrated compounds to form calcium carbonate. After carbonation, the chemically bound water, in the form of C-S-H and AFt/AFm phases, is lower than in non-carbonated concretes, Table 6.

Table 5. Mass losses, on the same ignited mass, of carbonated and non-carbonated concretes.

Concrete	Chemically bound water (%)	Calcium Hydroxide (%)		Calcium Carbonate (%)		Loss on Ignition (%)
	C-S-H Aluminates	Water	$Ca(OH)_2$*	CO_2	$CaCO_3$#	
HESC – NC (*non-carbonated*)	**4.78**	**1.66**	**6.82**	**2.43**	**5.52**	**8.87**
HESC – C (*carbonated*)	**3.27**	**---**	**---**	**9.18**	**20.84**	**13.1**
HESC + Fly Ash – NC	**2.99**	**0.76**	**3.12**	**2.28**	**5.18**	**6.03**
HESC + Fly Ash – C	**2.45**	**---**	**---**	**7.36**	**16.71**	**10.29**
HESC + Fly Ash + Hydrated Lime – NC	**2.81**	**1.09**	**4.48**	**1.85**	**4.20**	**5.75**
HESC + Fly Ash + Hydrated Lime – C	**2.37**	**---**	**---**	**8.72**	**19.79**	**11.68**

* $Ca(OH)_2$ = % chemically bound water as portlandite x [$Ca(OH)_2$ molecular mass / H_2O molecular mass]
\# $CaCO_3$ = % carbon dioxide x [$CaCO_3$ molecular mass / CO_2 molecular mass]

Table 6 shows the amount of calcium oxide bound as portlandite and calcium carbonate, in non-carbonated concrete, and the amount bound as calcium carbonate in carbonated concrete, using the data in Table 5.

Table 6. Calcium oxide as portlandite and calcite in non-carbonated and carbonated concretes and calcium oxide from hydrates to form calcium carbonate in carbonated concrete.

Concrete	Calcium Hydroxide (%)		Calcium Carbonate (%)		CaO Total (%) (as portlandite and calcium carbonate)	CaO from Hydrates (%)
	$Ca(OH)_2$	CaO*	$CaCO_3$	CaO#		
HESC – NC (*non-carbonated*)	**6.82**	**5.16**	**5.52**	**3.09**	**8.25**	**3.42**
HESC – C (*carbonated*)	**---**	**---**	**20.84**	**11.67**	**11.67**	
HESC + Fly Ash – NC	**3.12**	**2.36**	**5.18**	**2.90**	**5.26**	**4.10**
HESC + Fly Ash – C	**---**	**---**	**16.71**	**9.36**	**9.36**	
HESC + Fly Ash + Hydrated Lime – NC	**4.48**	**3.39**	**4.20**	**2.35**	**5.74**	**5.34**
HESC + Fly Ash + Hydrated Lime – C	**---**	**---**	**19.79**	**11.08**	**11.08**	

* CaO = % calcium hydroxide x [CaO molecular mass / $Ca(OH)_2$ molecular mass]
\# CaO = % calcium carbonate x [CaO molecular mass / $CaCO_3$ molecular mass]

The total amount of calcium oxide calculated from the calcium hydroxide and calcium carbonate in non-carbonated concretes is insufficient to produce the amount of calcium carbonate measured in the carbonated concrete, as shown in Table 6. Therefore, the difference represents the amount of calcium oxide resulting from the decomposition of hydrates (decalcification), which forms calcium carbonate [Kobayashi *et al*. 1994].

The amount of calcium oxide resulting from the decomposition of hydrates and consumed by carbonation reactions was higher in concretes containing fly ash than in the reference concrete. The addition of hydrated lime increases this consumption. Therefore, the lower alkaline reserve in concretes containing fly ash, with or without hydrated lime, results in a higher degradation of the C-S-H and AFt/AFm phases than for the reference concrete, when submitted to the accelerated carbonation test.

4 CONCLUSIONS

This work leads to the following considerations:

The carbonation depth in concrete containing a high amount of fly ash, measured in accelerated test for 20 weeks after 91 days of casting, was approximately two times higher than reference concrete with high early strength cement.

The addition of hydrated lime increases the amount of portlandite remaining in concrete with cement + fly ash. However, the percentage of portlandite is not a determinant factor for slowing down the spread of the alkaline interface in concrete containing high amounts of fly ash when they were cast for the same compressive strength.

Carbonation decreases the amount of chemically bound water in C-S-H and AFt/AFm phases. The decomposition of these compounds, measured by thermogravimetry, was more evident in the reference concrete, with high early strength cement than concrete containing fly ash, with or without hydrated lime.

Effect of Curing Age on the Durability of High-Volume Fly Ash Concrete

Nele De Belie [1]

Kathelijn Cox [1]

T 11

ABSTRACT

High volume fly ash (HVFA) concrete is one of the "green" alternatives developed to reduce the energy consumption and CO_2 emission related to the cement production. The pozzolanic reaction of fly ash is a retarded process compared to the cement hydration. As a result, the strength, microstructure development and consequently also the durability behavior of fly ash mixtures will be strongly influenced by age. After all, durability is, to a large extent, determined by the possibility for aggressive substances to penetrate into the concrete, and the latter is in turn determined by the porosity and transport properties of the concrete.

This paper describes the results of tests on 4 fly ash mixtures, each with a different fly ash replacement level namely 0, 35, 50 and 67%, but with the same water-to-cementitious materials ratio. The experiments were executed at the age of 1, 3 and 6 months. Permeable porosity and gas permeability increased with increasing fly ash content. A reduction in porosity was noticed between 1 and 3 months for the fly ash mixtures due to the pozzolanic reaction. The carbonation depth was considerably higher for the 50 and 67 % fly ash mixtures at all ages compared to the ordinary Portland cement concrete. Carbonation appeared to have a negative effect on gas permeability, especially for the 50 and 67 % mixtures.

1 INTRODUCTION

The production of portland cement consumes a great deal of energy and yearly produces a considerable amount of CO_2. By replacing cement in concrete by fly ash (FA), which is a by-product of the combustion of pulverized coal, the environmental impact of the concrete production can be reduced [Malhotra & Mehta 2005]. Concrete with a fly ash replacement level above 50% is called high-volume fly ash concrete (HVFA concrete). Fly ash is a pozzolanic material which has to be activated by the hydration products coming from the hydration of portland cement. The replacement of a large quantity of cement by fly ash has an important influence on the composition, the microstructure and the properties of fresh and hardened concrete. Therefore the durability characteristics of high-volume fly ash (HVFA) concrete are different from those of ordinary Portland cement (OPC) concrete. In this article, carbonation is investigated, which plays a major role in the resistance of the concrete to corrosion of the embedded steel. Gas permeability – strongly influenced by porosity – is a determining factor in this mechanism and is therefore studied as well. Also the influence of carbonation on porosity and gas permeability is tested.

2 LITERATURE REVIEW

2.1 Permeable Porosity

Potentially harmful substances penetrate into the concrete through connected pores. Factors influencing the permeable or 'open' porosity therefore automatically have an impact on durability. Several authors mention 2 important effects through which a lower porosity could be obtained in HVFA concrete compared to OPC concrete [Malhotra & Mehta 2005, Bilodeau *et al.* 1994, Berry *et al.* 1994, Kosmatka *et al.* 2002]: (1) Fly ash improves concrete workability; therefore a lower water - cementitious materials ratio (W/CM) can be used with increasing fly ash content; (2) due to the pozzolanic reaction, additional hydration products are formed which fill the pores and produce a denser structure. According to Papadakis *et al.* [1992] a higher fly ash replacement level in concrete with a constant W/CM leads to a higher porosity and an increasing percentage of large pores. Khan [2003] performed experiments on concrete with a FA/CM level between 0 and 40 % and W/CM between 0.27 and 0.50. According to Khan fly ash replacement has little influence on the porosity. Only for very low W/CM ratios the porosity decreased with increasing fly ash level.

2.2 Gas Permeability

Gas permeability gives an indication of the difficulty for harmful substances such as CO_2 to penetrate into the concrete. It is strongly related to the open porosity and the distribution of the pores. Abbas *et al.* [1999] mention that the coefficient of gas permeability varies with the pressure gradient because of the change from laminar to molecular flow. They also state that the permeability is strongly dependent on the degree of saturation of the concrete. Moisture in the pores forms a barrier for the gas molecules, as a result of which their penetration is hindered. Because most authors are convinced that a lower porosity is possible in HVFA concrete, also a lower gas permeability should be possible. Tests executed by Kosmatka *et al.* [2002] and McCarthy & Dhir [2005] confirmed this. Following their conclusions on porosity Papadakis *et al.*[1992] found that for a constant W/CM ratio the gas permeability increased with increasing fly ash content, while Khan [2003] concluded the opposite.

2.3 Carbonation

There are two determining factors concerning carbonation [Jiang *et al.* 2000] :

- the lower the gas permeability, the slower the CO_2 diffusion and the lower the carbonation rate.
- the more $Ca(OH)_2$ is available, the more CO_2 molecules can react, which leads to a slower ingress of CO_2. In the pozzolanic reaction of fly ash $Ca(OH)_2$ is consumed. Therefore less carbonatable material is available in HVFA concrete.

Papadakis *et al.* [1992] noticed a higher carbonation depth with increasing fly ash content for concrete with a constant W/CM ratio, because of the higher permeability and lower amount of carbonatable material. Jiang *et al.* [2000] found conflicting results in literature, but generally it seemed that the carbonation depth increased with increasing fly ash content, which was confirmed by their own research (fly ash replacements of 0, 55 and 70 % but decreasing W/CM with increasing fly ash content). They are convinced though that HVFA concrete with appropriate mixture proportions could match the resistance to carbonation of OPC concrete. They experienced that not all fly ash in HVFA concrete had reacted as a result of an insufficient amount of $Ca(OH)_2$. They concluded that the effective W/CM ratio, W/CM*, which takes into account the amount of cementitious materials that effectively can be hydrated, is the most important parameter concerning porosity and that the amount of cement C is the most important one for the amount of carbonatable material. Tange Jepsen *et al.* [2001] found that a 40% fly ash mixture with W/CM = 0.4 carbonates considerable faster than other "green" concrete due to the consumption of $Ca(OH)_2$ in the pozzolanic reaction.

2.4 Influence of Carbonation on Porosity and Gas Permeability

$CaCO_3$ formed in the carbonation process has a very low solvability and therefore will precipitate in the pores as a result of which in general a denser structure will be obtained. The effect of carbonation on the concrete structure is nevertheless not the same for all types of concrete. Ngala & Page [1997] executed tests on OPC concrete and a 30% fly ash concrete with different W/CM ratios to investigate the influence of carbonation on porosity and gas permeability. The total porosity was reduced for all mixtures after they were fully carbonated. The capillary porosity on the other hand seemed to increase slightly for the OPC concrete, but increased significantly (± 140%) for the fly ash concrete. Ngala & Page attribute the reduction in total porosity to filling of the gel pores with $CaCO_3$. The increase in capillary porosity can be explained by the formation of silica gel as a result of the decomposition of CSH gel during CO_2 exposure, causing a "pore size redistribution". The higher increase in capillary porosity for the fly ash concrete compared to the OPC concrete can be explained by the higher amount of CSH gel as a result of the pozzolanic reaction. Ngala & Page also found that carbonation has a large influence on gas permeability, especially for fly ash concrete, where the gas permeability increased with a factor 10.

3 EXPERIMENTAL DETAILS

3.1 Materials

Four different mixtures were made: a reference mixture (REF) with 100% portland cement and three fly ash mixtures (FA) with 35, 50 or 67 % of the portland cement replaced by fly ash. A portland cement CEM I 52.5, complying with EN 197-1 (2000), was used and a class F (according to ASTM standards) fly ash with a low calcium oxide content (1.96%). All mixtures had a total amount of CM (cement + fly ash) of 400 kg/m³ and were made with a W/CM of 0.4. A superplasticizer, based on carboxylic acid, was added to obtain a decent workability and an air entraining agent was used to obtain an air content of about 4% and a good freeze-thaw resistance. The mixture proportions are given in Table 1.

3.2 Experimental Procedures

All durability tests - except gas permeability - were performed at the age of 1, 3 and 6 months; gas permeability was only examined after 3 months of curing. During this period the specimens were stored in a climate chamber with a relative humidity above 90% and temperature around 20 °C.

Table 1. Concrete mixture proportions.

	REF	FA35	FA50	FA67
sand 0/4 [kg/m³]	686.4	667.8	659.8	651.9
aggregate 2/8 [kg/m³]	450.5	437.2	431.9	426.6
aggregate 8/16 [kg/m³]	694.3	678.4	667.8	659.8
CEM I 52.5N [kg/m³]	400	260	200	132
water [kg/m³]	160	160	160	160
fly ash [kg/m³]	0	140	200	268
air entraining agent [ml/m³]	270	350	400	400
superplasticizer [ml/m³]	1080	486	473	342
W/CM [-]	0.4	0.4	0.4	0.4

3.2.1 Permeable Porosity

A vacuum saturation technique, as described in the Belgian standard NBN B05-201 (1976), is used to determine the open porosity. For each mixture 3 cylindrical specimens (diameter = 100 mm, thickness = 50 mm) were taken out of a 150 mm cube. The specimens were dried in a ventilated oven at 45 °C to constant mass, then vacuum saturated and weighed. The procedure was repeated after drying at 105 °C. This allows to get a rough estimation of the capillary and gel porosity of the concrete [Audenaert & De Schutter 2007].

3.2.2 Gas Permeability

An oxygen permeation test was executed as described in RILEM TC 116-PCD [1999]. For each mixture three cylindrical specimens with a diameter of 150 mm and a thickness of 50 mm were taken out of a 400 x 400 x 100 mm slab. After 3 months of curing the specimens were dried at a temperature of 60° C until the mass loss in 24 hours was below 0.1% (approximately 10 days). The gas permeability was measured using a “cembureau” permeameter. Tests were performed under a pressure of 2, 3 and 4 bar. The apparent oxygen permeability coefficient was calculated using equation (1):

$$K = \frac{2.P_a.Q.L.\eta}{A.(P^2 - P_a^2)} \quad (1)$$

where P_a = the atmospheric pressure (Pa), Q = volume flow rate of the fluid (m^3/s), L= thickness of the specimen (m), η = dynamic viscosity of the fluid (for oxygen at 20°C equal to 2.2 x 10^{-5} $N.s/m^2$), A = cross-sectional area of the specimen (m^2), P = absolute inlet pressure (Pa).

3.2.3 Carbonation

For each mixture 4 cubes (100 mm) were cast and placed in a room with 10% CO_2 (20 °C, 60% RH) to obtain an accelerated carbonation. Five of the six surfaces of the cubes were coated to ensure unidirectional CO_2-ingress. At 1, 3, 6, 10, 14, and 18 weeks the carbonation depth was measured on 3 cubes by removing a 10 mm thick slice from the cubes perpendicular to the exposed side and spraying with phenolphthalein. The slices of the remaining cubes (only for 3 months curing period) were used for thermogravimetric analysis (TGA) to estimate the content of $Ca(OH)_2$. The 10 mm near to the exposed surface was removed from the slice, crushed and sieved. The powder was heated in Argon atmosphere to 1100 °C at a rate of 10 °C/min, which leads to the decomposition of $Ca(OH)_2$ around 450 °C. The mass loss caused by $Ca(OH)_2$ decomposition was corrected with the loss of chemically bound water in the interval considered.

3.2.4 Influence of Carbonation on Porosity and Gas Permeability

The samples were made in the same manner as for normal tests. However, before accelerated carbonation they were coated and sealed with plastic in a way that CO_2 could only enter at one side. Tests were performed after 0, 6 and 14 weeks of exposure to 10% CO_2.

4 RESULTS AND DISCUSSION

4.1 Permeable porosity

In Fig. 1 the average values and standard deviations on individual measurements are shown for capillary permeable porosity (CPP) and total permeable porosity (TPP) respectively. The gel porosity (GP) can be calculated as the difference between total and capillary porosity. The initial capillary porosity at 1 month of age increases with increasing fly ash content due to the actual increase in W/C ratio and is approximately equal for FA50 and FA67. The initial gel porosity decreases with increasing fly ash content. The CPP hardly changes for the reference mixture after 1 month of curing. The fly ash mixtures however show a substantial reduction in CPP between 1 and 3 months of curing as a result of pore filling with additional hydration products from the pozzolanic reaction. The reduction is more pronounced for FA50 than it is for FA35, but is lower for FA67 than for FA50. A possible explanation is that the amount of fly ash which reacts is lower for FA67 than for FA50 because of the lower clinker content, resulting in a shortage of $Ca(OH)_2$. Between 3 and 6 months the CPP hardly decreases for all mixtures. In fact, a small increase is noticed for FA67. This can be the result of a starting carbonation (see further). Fig. 1 shows that the TPP decreases between 1 and 3 months for all mixtures, even for the reference. Apparently the further hydration of portland cement in the reference mixture fills the gel pores, but not the capillary pores. For FA50 and FA67 there is an increase in GP, inferior to the decrease in CPP, between 1 and 3 months of age. This illustrates the transformation of capillary pores into gel pores in time, also called pore refinement. Between 3 and 6 months a slight increase in TPP is noticed for FA35 and FA50, while the GP hardly changes. The TPP and GP of FA67 decrease, which is possibly caused by starting carbonation. The results from this research are contradictory to Khan's [2003] but similar to those of Papadakis *et al.* [1992]: an increasing porosity with increasing fly ash replacement for a constant W/CM ratio.

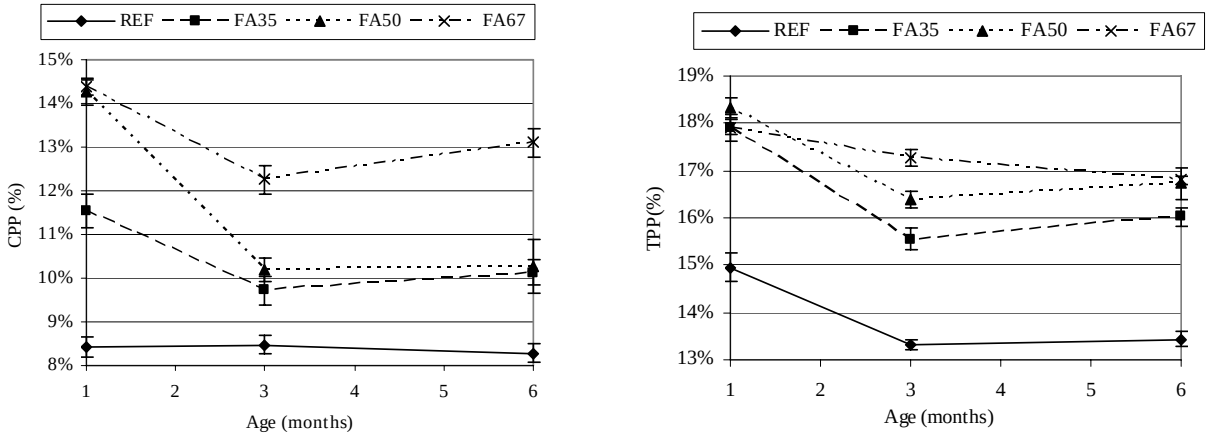

Figure 1. Capillary permeable porosity, CPP (left) and total permeable porosity, TPP (right) at different ages, including standard deviation on individual measurements.

4.2 Gas Permeability

The results of the permeation test at the age of 3 months are shown in Fig. 2. The decrease of K with increasing applied pressure is in accordance with RILEM TC 116-PCD [1999]. The gas permeability at all pressures is lower for FA35 than for REF, in spite of the higher capillary porosity for FA35. Nevertheless, generally the gas permeability seems to increase with increasing capillary porosity. Just as with porosity, the test results for gas permeability are in general contradictory to Khan's [2003] but similar to those of Papadakis *et al.* [1992]: an increasing gas permeability with increasing fly ash replacement for a constant W/CM ratio.

4.3 Carbonation

The carbonation depths after accelerated carbonation tests, starting at 1, 3 and 6 months of age, could be expressed at each age as:

$$x = A\sqrt{t} \quad (2)$$

where x = carbonation depth (mm), A = carbonation coefficient (mm/week$^{0.5}$) and t = time of exposure (weeks). The carbonation coefficients for each mixture are presented in Fig. 2. The more open structure and lower amount of carbonatable material for HVFA concrete has a substantial negative effect on the resistance to carbonation. The carbonation coefficient decreases with increasing age for all fly ash mixtures. This means that the positive effect of the decreasing porosity at later age is more significant than the negative effect of the decreasing amount of $Ca(OH)_2$ because of the ongoing pozzolanic reaction. As with the capillary porosity, the decrease is most pronounced for FA50. The results show that the carbonation coefficient strongly increases between FA50 and FA67, which indicates that it will not be easy to make mixtures with a good resistance to carbonation if more than 50% of the cement is replaced by fly ash.

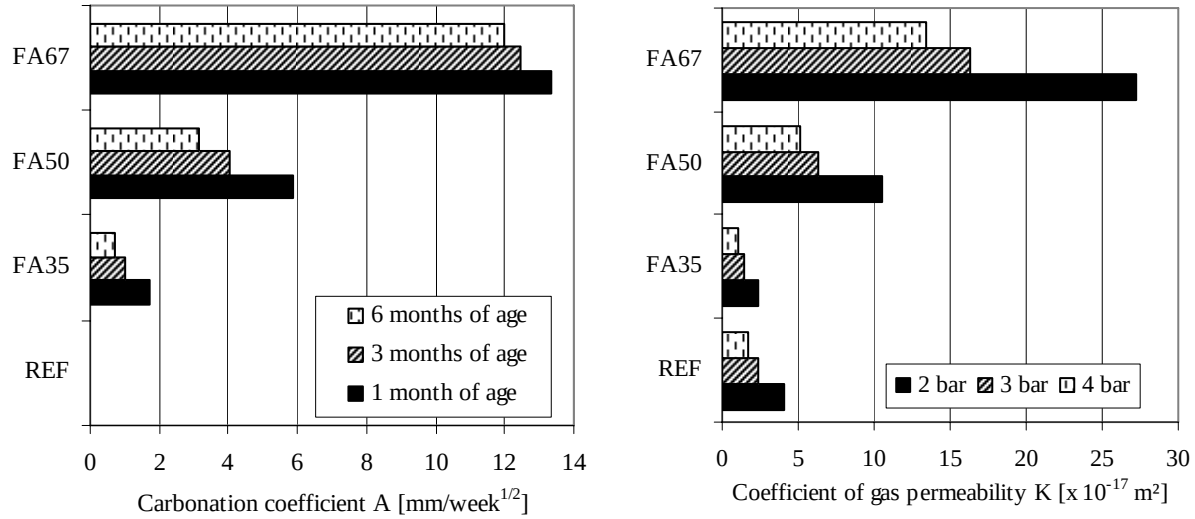

Figure 2. Coefficient of gas permeability K after 3 months of curing for several applied pressures (left) and carbonation coefficient A at different ages (right).

4.4 Thermogravimetric Analysis (TGA)

At all exposure times the amount of $Ca(OH)_2$ decreased with increasing fly ash replacement level, due to the lower amount of portland cement and the consumption of $Ca(OH)_2$ in the pozzolanic reaction. For all mixtures a substantial part of the $Ca(OH)_2$ in the outer concrete zone was consumed in the carbonation process after 1 week of exposure. After 3 weeks all $Ca(OH)_2$ in the outer 10 mm of the 67% mixture had reacted. For FA50 no $Ca(OH)_2$ was left after 10 to 18 weeks. During the test period there was always $Ca(OH)_2$ left in the reference and 35% mixtures.

4.5 Influence of carbonation on porosity and gas permeability

Tests were performed at 0, 6 and 14 weeks of exposure of 3 month old samples to 10% CO_2. Only the samples for FA67 were completely carbonated after 14 weeks, while for REF en FA35 hardly any carbonation could be measured. Therefore it is more correct to speak about influence of exposure to CO_2 than about influence of carbonation on porosity and gas permeability.

4.5.1 Porosity

Fig. 3 presents the results for the CPP and TPP. Despite the fact that for the reference mixture no carbonation could be measured using phenolphthalein (on thin sections carbonation was visible), the capillary porosity decreases significantly after 6 weeks of exposure. For FA35 and FA50 the CPP also decreases because of the exposure to CO_2, while for FA67 there is a slight increase. The TPP remains equal for REF, but decreases for all fly ash mixtures. So globally it can be said that carbonation doesn't seem to have a big negative effect on the porosity of concrete. These results for the reference mixture are contradictory to the ones from Ngala & Page [1997], who say that in (fully carbonated) OPC concrete the total porosity decreases and the capillary porosity stays approximately equal.

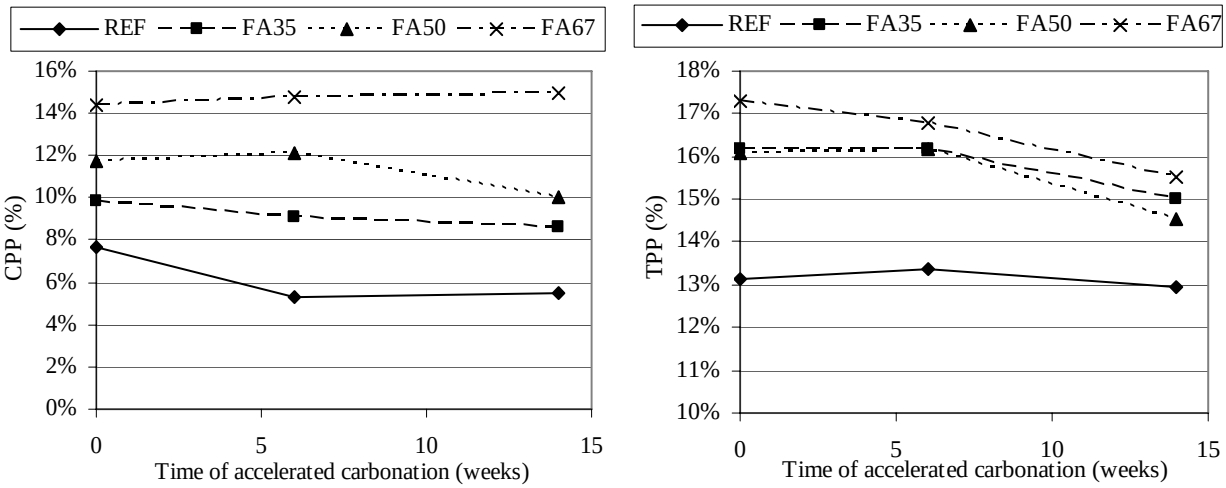

Figure 3. Change in capillary permeable porosity, CPP (left) and total permeable porosity, TPP (right) during accelerated carbonation

4.5.2 Gas permeability

The influence of carbonation on gas permeability is shown in Fig. 4 for an applied pressure of 3 bar. For all mixtures the gas permeability increases with increasing carbonation. For REF and FA35 the increase is limited, but for FA50 and FA67 the gas permeability increases considerably: after 14 weeks of exposure with a factor 2.6 for FA50 and 3.6 for FA67. This will of course have a negative influence on the resistance of the concrete to corrosion. Not only the carbonation rate will increase, but also the penetration of O_2 – necessary for corrosion – will become more easy.

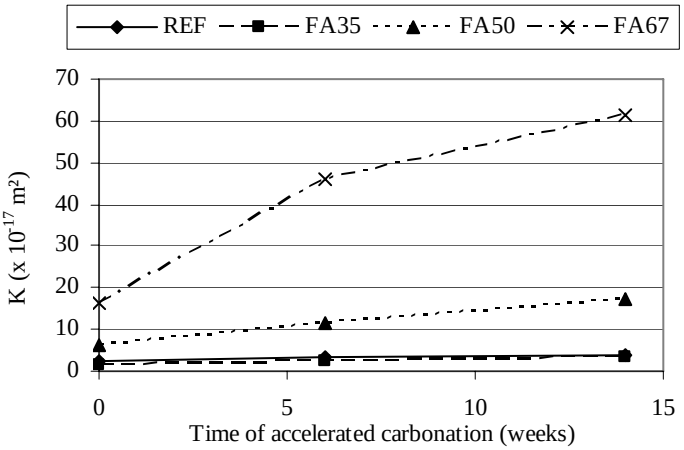

Figure 4. Coefficient of gas permeability K (3 bar) after 0, 6 and 14 weeks of exposure to 10% CO_2

5 CONCLUSIONS

The porosity, gas permeability, carbonation and their interaction were studied in concrete mixtures with different levels of fly ash replacement (up to 67%) and a constant W/CM ratio. The capillary and total permeable porosity increased with increasing fly ash replacement level. A considerable decrease in porosity was noticed for the fly ash mixtures between 1 and 3 months of age as a result of the pozzolanic reaction and the transformation of capillary pores into gel pores. Following the results of capillary porosity, the gas permeability at the age of 3 months increased with increasing fly ash content, but also other factors influenced gas permeability. Since the gas permeability increased and the amount of carbonatable material decreased with increasing fly ash content, the carbonation rate at all ages was much higher in HVFA concrete than in OPC concrete. Thermogravimetric analysis showed that the amount of $Ca(OH)_2$ decreased with increasing fly ash level, and that it was rapidly depleted by accelerated carbonation in FA50 and FA67. Carbonation did not have a negative effect on porosity, while the gas permeability increased significantly for the fly ash mixtures as a result of exposure to CO_2.

Concerning gas permeability and carbonation HVFA concrete (FA50, but certainly FA67), with a W/CM = 0.4 en CM = 400 kg/m³, performed worse compared to OPC concrete with the same W/CM and CM. Therefore the use of reinforced HVFA concrete with these mixture proportions does not seem advisable in practice. Further research on HVFA concrete with lower W/CM ratios, and therefore lower porosities, is needed to improve the durability performance of HVFA concrete.

Analysis of Rebar Cross Sectional Area Loss by Reinforced Concrete Corrosion

Angela Gaio Graeff [1]
Luiz Carlos P. da Silva Filho [2]

T 11

ABSTRACT

One of the most important pathological manifestations which occur in reinforced concrete structures is the rebar corrosion. This deteriorative process is known by its high frequency of incidence and, mainly, by the destructive effect that it causes to structures. Several researches focused on the corrosion initiation phase can be found in the literature. However, restricted knowledge is available on the propagation phase, which is the broad aim of this work: to focus on the analysis of the consequences, in terms of structural properties, due to corrosion incidence on rebar. Among these properties, it is emphasized the loss of cross sectional area, loss of bond between concrete and reinforcement, and cracking due to rust accumulation on the bar length – which can lead to concrete spalling in advanced stages. The loss of cross sectional area can be highly responsible for several consequences on reinforced concrete structures. This property is the one of the key outputs of building design methods and, therefore, variations on its properties during the structure's life-cycle, along with other pathological manifestations that may occur, or yet with the misuse of the building, can put the structure under an unusable status or even cause its failure. This work focuses on the study of rebar cross sectional area loss of reinforced concrete specimens subject to accelerated corrosion process stimulation, at specific levels of deterioration (0, 2, 5 and 10% of weight loss), under chloride action. The specimens were induced to corrosion through the use of constant current and immersion in an isotonic solution of sodium chloride. The losses of cross section were measured by using a 3D image reconstruction with laser. The results show that the loss of bars section under corrosion effect is significant, and these values should be taken in consideration when an assessment of these structures is carried out.

1 INTRODUCTION

Among the pathological manifestations that accelerate the performance loss of reinforced concrete structures, rebars' corrosion is one of the most important, due to its occurrence and damage potential. According to Helene [1993], reinforcement corrosion is known as a destructive interaction with the environment, which leads to damage reaction of chemical or electro-chemical nature, associated or not to deterioration processes (both physical or mechanical).

The reinforcement corrosion modifies some of the basics parameters used in the structural design and its incidence leads to some considerable consequences, for instance: the loss of rebar cross sectional area; the increase of radial tensile forces in the concrete – with subsequent cracking of the cover concrete due to rust along the rebars surface and along the surrounding pore structure of the concrete – eventually leading to spalling of concrete on advanced stages; and the loss of bond between concrete and reinforcement.

All of these effects are relevant, not only from the durability impact perspective, but also from the structural performance point of view. On account of these issues, reinforcement corrosion has received special attention by the scientific community over recent years. However, it has been observed in the literature a great amount of researches about the initiation phase of corrosion, i.e. period on which the structural effects have not yet evidenced [Breit 2001; Vu and Stewart 2000; Li 2003a; Glass *et al.* 2000; Val and Trapper 2006; Morris *et al.* 2002 and 2004; Engelund and Sorensen 1998]. The approaches used in some of these works rely on the simulation of chloride penetration and the advance of carbonation front in concrete elements. In general, these researches aim to determine the moment on which steel depassivates. Both experimental and numerical analysis have been investigated in this area. Nevertheless, only a reduced number of researches are dedicated to study the propagation phase of corrosion [Wang and Liu 2006; Coronelli 2002; Li 2003b and Vu *et al.* 2005].

The initiation phase is the period of time comprised between the time the corrosion first appears on the structure's construction and ends when the steel is depassivated. During this period, the structural damage may not occur, or it can be considered null, on the assumption that the corrosion intensity is very low in this phase: it does not represent a risk to the life-cycle.

The propagation phase attends the period after the steel depassivation is triggered, when corrosion current is established in the rebar, which is considered damaging to the life-cycle. By the time this phase starts, some changes in the steel alloy occur and an amount of expansive iron oxide is formed. This process should be interrupted in order to avoid the structure loss of performance or, in some critical situations, in order to avoid the failure of the building.

This study focused on delivering guidelines to assess the deterioration level of reinforced concrete structures by creating an equivalency between the corrosion level and the loss of cross sectional area of the reinforcement bars through the use of experimental laboratory test. This study also aims to determine the effect of the formation of pitting regions in the bars by using an accurate method to measure the cross sectional areas at 5.0mm spacing along the bar element.

2 LOSS OF REBAR CROSS SECTIONAL AREA

The reinforcement used in the majority of structural elements is a result of accurate and complex designing processes. The key output of a structural design, following the necessary data input, e.g. applied loads, element geometry and the materials properties, is the rebar cross sectional area. Hence, changes on its value may lead to significant impact in the construction stability/serviceability.

The chloride attack is considered one of the most critical pathological manifestations which occur in reinforced concrete structures. When the corrosion is due to this chloride attack, it is expected the

formation of some pitting regions. In these specific pitting points it is possible to evaluate a considerable loss of cross sectional area or even the total failure of certain fragments of the bars.

Some researches found in the literature suggest a linear correlation between the loss of cross sectional area and the corrosion level [Apostolopoulos et al. 2006; Graeff 2007].

3 EXPERIMENTAL PROGRAMME

In order to evaluate the loss of rebar cross sectional area, an experimental analysis was carried out. The method consisted basically in accelerating the corrosion process in reinforced concrete specimens by means of a chloride attack. The experimental program was divided into three stages: the first of them being in regard to the research variables and the materials' characterization; the second, concerning the corrosion acceleration method employed and the third referring to the measurement of cross sectional area loss resulting from the corrosion stimulation.

3.1 Research Variables and Materials

The research variables were established considering the rebar corrosion level, for instance, 0, 2, 5 and 10% of weight loss. The concrete and materials' quality were kept constant, as well as the rebar diameter used (12.5mm). The concrete was produced in laboratory by using a vertical mixer; the quantities showed in the Table 1 were used in order to produce a concrete with a 25MPa of compressive strength.

Table 1. Concrete mixture to produce a 25MPa concrete.

Material	*kg per m^3 of concrete*
Cement	289.95
Sand	840.85
Coarse Aggregate	1043.82
Water	191.37

The cement used to cast the specimens was the High Initial Strength Portland cement. Its composition is formed of 95-100% clinquer and 0-5% limestone and fly ash. The sand is from Jacuí River (Southern Brazil) and its gradation is considered as medium. The origin of the coarse aggregate is basaltic. The gradation curves of both the sand and the coarse aggregate are shown in Fig. 1.

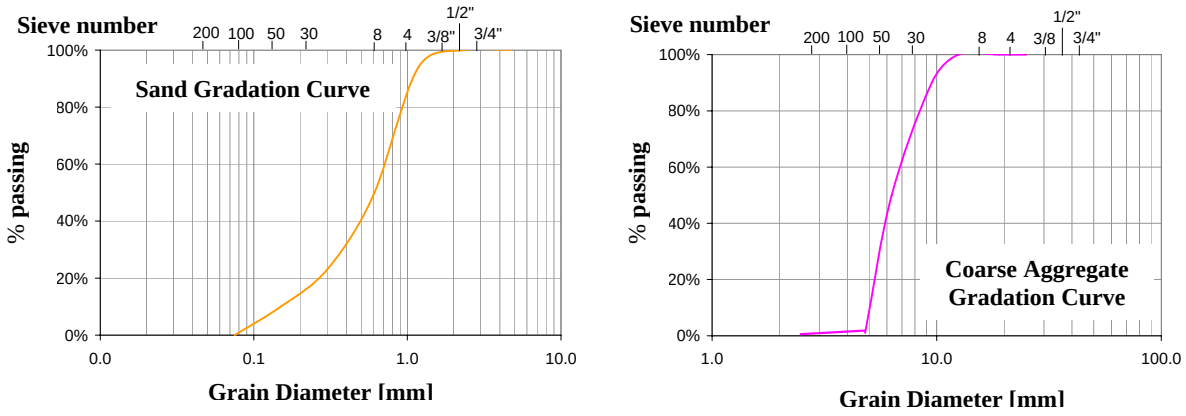

Figure 1. Gradation curves of gravel and coarse aggregate.

Samples sizing 100x100x200mm were cast with one rebar of 12.5mm of diameter and 145mm long placed in the midst of it. The samples were left into the moulds for a period of 24 hours after casting.

After this first 24 hours, the specimens were demoulded and placed in a humid and temperature controlled chamber for a period of 20 days for curing.

3.2 Corrosion acceleration in the samples

An accelerated test modifies the natural environment conditions and, therefore, makes more difficult the establishment of correlations between the test and the environment to which the material would be legitimately exposed to. Hence, it becomes impracticable to estimate the life-cycle of the material in analysis considering the test's periods of time. Nonetheless, accelerated tests can be useful tools to establish comparative analysis. It helps identifying how variations in the materials may affect their behaviour and express long term effects in shorter scales, allowing, for instance, the evaluation of long-term degradation effects caused by corrosion in this research.

The majority of the tests found in the literature are based in electrochemical process to accelerate corrosion in reinforced concrete specimens. A great number of corrosion stimulation and chloride penetration tests are based on the application of constant voltage. In order to decrease the test's duration some test methods use higher values of voltage to accelerate corrosion [e.g. ASTM 1202C 1999]. However, the use of high voltages cause strong heating of the samples due to the elevated passing electric current associated with the resistance decrease of the concrete. Thus, it has been observed in the newest studies a strong preference for using constant electric current to study the propagation phase in lieu of constant voltage.

The method used to accelerate the corrosion is based on exposing concrete samples in a chloride solution (3.5g/l) and applying an electric current in order to stimulate chlorides to migrate from the solution to the rebar, as shown in Fig. 2.

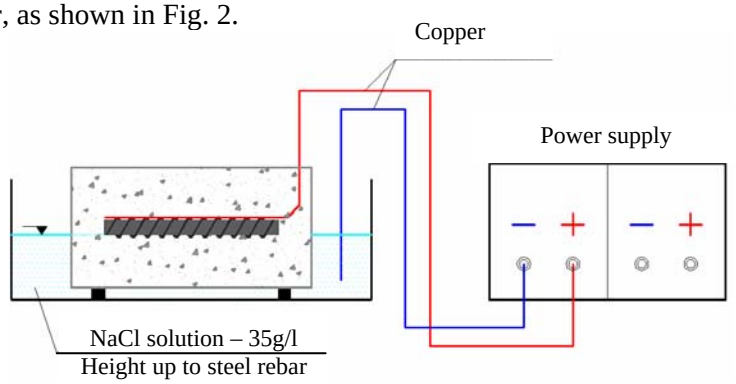

Figure 2. Test layout to accelerate corrosion.

Samples are partially immersed in an isotonic solution of sodium chloride, which was used in a similar concentration to the salt found in the Atlantic Ocean. The solution depth in the chamber was equivalent to the concrete cover thickness: this condition is important to allow the entrance of both the humidity and the oxygen. A copper wire was placed over the rebar, with no electric contact with the steel, prior to the casting of the samples. During the test, the wire was connected in the positive pole of the power supply, while the other copper wire, showed in the previous figure, was connected to the negative pole. The current density applied was 500 A/cm^2.

Faraday's Law was used to predict the period of time required to reach the specific corrosion levels of 2, 5 and 10%. This theory is widely used in the literature, for instance, the work of Fang et al. [2004] and El Maaddawy and Soudki [2003]. One previous calibration was done in order to verify the accuracy of the Faraday's Law. Information about this calibration study can be found elsewhere [Graeff, 2007].

3.3 Measurement of the Loss of Cross Sectional Area

After achieving the desired corrosion level by the acceleration procedures employed, the samples were broken in order to retrieve the rebar placed on its core. The excess of concrete around the rebars was manually removed and the bars were immersed in a solution of 3,5g hexamethylene tetramine diluted in 500ml of hydrochloric acid and 500 ml reagent water according to the procedures of ASTM G1-03 (2003) for a period of 40min time. After this period, the bars were removed from the solution and washed with clean water. Finally, the rebars were placed in the oven for 30min, with an average temperature of 25ºC, in order to completely dry the steel fragments. After the careful cleaning process, the bars were weighted to measure the mass loss and placed inside a three-dimensional scanner which is able to acquire the co-ordinates of the bar surface by applying a laser beam. The bar is rotated at least three times in order to allow the scanner to read the entire surface of the bar. When the scanner is done with the readings, a graphical software is used to render the surface of the bars. After the images have been graphically reconstituted, the measurements of the cross sectional areas in all sections of rebars tested were carried out using the software. In this research, the areas were measured at 5.0mm spacing apart from each other. Two non-corroded bars were placed in the scanner prior to the corrosion induction, in order to get the areas at 0% corrosion level, preventing errors caused by differences in the samples used. Only the samples that yielded corrosion levels of 2 and 5% were measured using this technique. Samples with 10% of corrosion level were not tested before the corrosion acceleration because it was noticed a strong similarity between the results of the two previous scanned bars; hence, it was decided to reduce costs and time on scanning the specimen, with no damage to the analyses.

4 RESULTS

A comparison was carried out between the actual weight losses and the foreseen values determined using the calibration study based on the Faraday's Law previously cited [Graeff, 2007]. This comparison is important in order to prove that the targeted corrosion levels were in fact achieved. The values from this comparison are show in the Table 2.

Table 2. Comparison between the target corrosion level and the calibration study based on the Faraday's Law.

Corrosion level targeted	*Calibration study based on the Faraday Law – actual weight loss*
2%	2.29%
5%	5.03%
10%	10.33%

The following pictures (Fig. 3 and Fig. 4) are the models obtained from the 3D rendering, before and after the corrosion acceleration test. Figure 5 shows the results, in terms of area loss for each analysed section, for the corrosion levels of 2, 5 and 10%, respectively.Table 3 shows the mean of the areas of the total amount of bar sections analysed, with the standard deviation and general percentage of area loss. It can be observed in the graphics on Fig. 5 and on the above table that the cross sectional areas corresponding to the corrosion levels of 2 and 5% did not decrease considerably, and they were also similar in value (around 2.5%). In regard to the corrosion level of 10%, however, a considerable decrease of the cross sectional area has occurred, equivalent to approximately 7.5% (almost more than three times the area loss observed in the 5% of corrosion level).

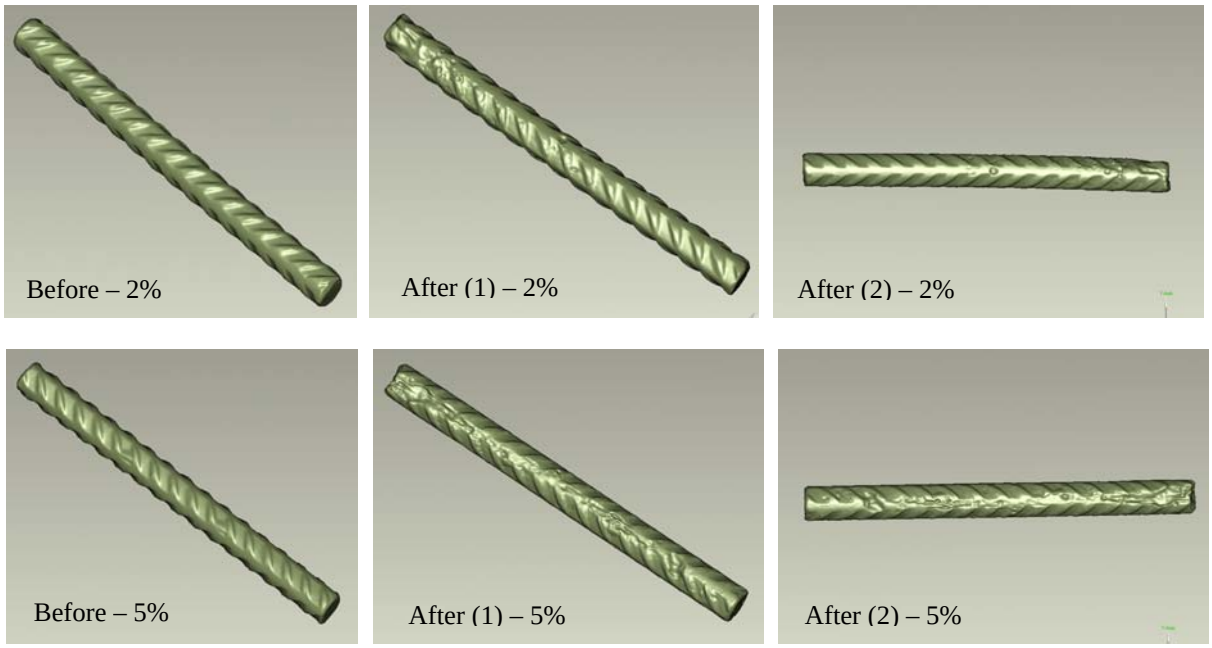

Figure 3. Digital images before and after corrosion acceleration (corrosion levels of 2 and 5%).

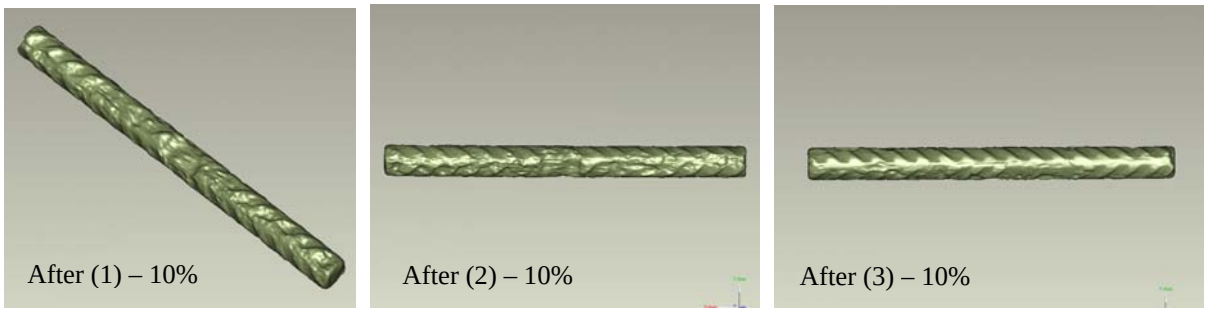

Figure 4. Digital images after corrosion acceleration (corrosion level of 10%).

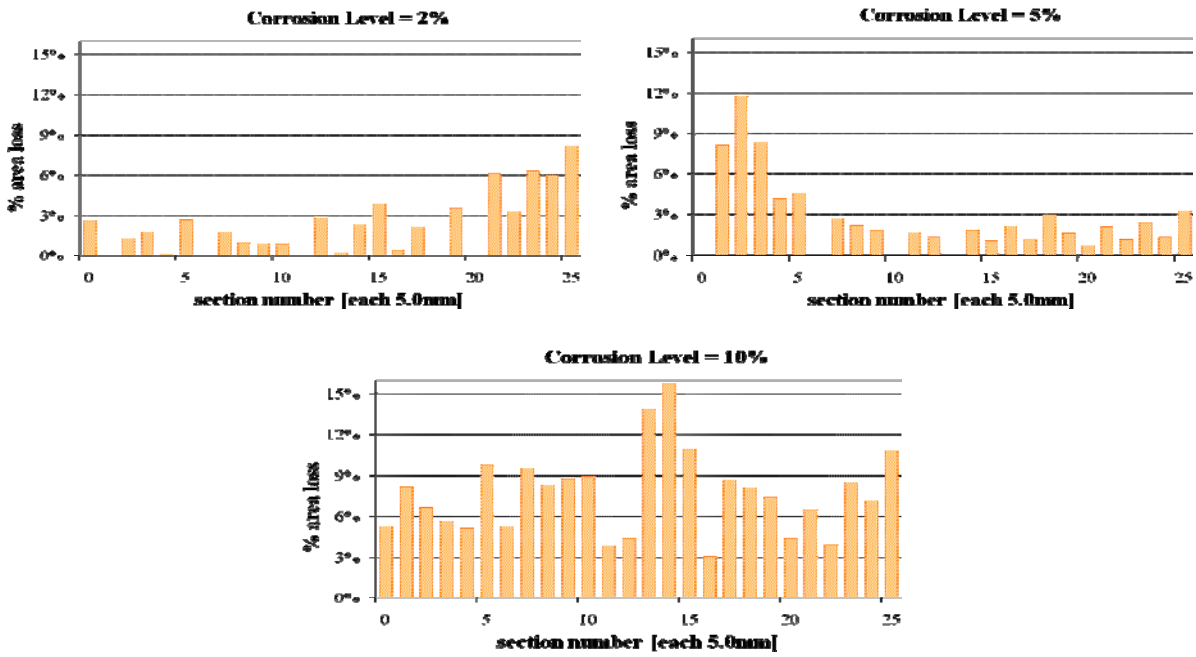

Figure 5. Graphics of the area loss considering each section analysed.

Table 3. General calculus of the cross sectional areas.

Corrosion Level		*Areas mean (mm²)*	*Standard Deviation (mm²)*	*% area loss*
2%	Before	120,64	1,14	2,20
	After	117,98	2,98	
5%	Before	118,75	1,54	2,75
	After	115,49	4,16	
10%	Before	119,66	0,55	7,64
	After	110,52	3,49	

Figure 5 shows that the bars with 2 and 5% of corrosion level presented a larger decrease of area nearer the bar end. In these points, 8% and 12% of area loss were obtained for the corrosion levels of 2 and 5%, respectively. For the corrosion level of 10%, the major values of area loss were concentrated in the middle of the bar length, with a peak of 16% of area loss. These points where the area loss was more intense than the other sections are, probably, a result of the pitting effect, due to chloride attack.

5 CONCLUSIONS

- Although corrosion acceleration test methods are not entirely effective to simulate the real corrosion phenomenon which occur in the environment, the method used in this research seems to be reliable. It appears to adequately simulate the corrosion process, allowing the rust to re-locate in the concrete pores due to its slower speed.
- The measurement of the cross sectional area loss confirmed that corrosion due to chloride attack does not occur uniformly. In some points it is observed values of area loss higher than three times the mean of the area loss of the entire bar. These points are considerably critical and can cause the structure's failure.
- The technique used to measure the rebars' cross sectional area by using the 3D scanner proved to be a very accurate method. It can be considered as a great instrument to measure the effects of the corrosion propagation phase in concrete samples. The results can be used as an important tool to predict the degradation in structures, and in some models of life-cycle.
- An increment of the cross sectional area loss was noticed when the corrosion level is higher.

Durability Of Metakaolin Based Cement Mortar To Chloride Attack Under Wet – Dry And Freeze – Thaw Exposure

Shweta Goyal [1]
Maneek Kumar [2]
B. Bhattachargee [3]

ABSTRACT

This study investigates the effect of metakaolin as replacement of cement on durability of mix to chloride attack when subjected to freezing / thawing and wetting / drying exposure conditions. Two metakaolin replacement levels were considered in the study: 5% and 10% by weight of cement. The effect was investigated at water-to-binder ratios of 0.5. The mortar specimens were cast for each mix and after 7 days of initial water curing period, specimens were immersed in various chloride salts (3% concentration), with or without corrosion inhibitor, for a total period of 42 days. The progressive deterioration was evaluated through visual inspection, relative change in mass and relative strength determinations.

The investigations indicated that metakaolin as replacement of cement increased the chloride resistance of mortar. The various chloride salts have different penetration rates into the given mix, resulting in different degree of damages. Calcium chloride was found to be most destructive under the applied exposure conditions. Also, the compatibility of corrosion inhibitor was found to depend on the type of salt solution to which the specimens were exposed. Among the exposure conditions, freezing – thawing cycles were found to be more detrimental as compared to wetting – drying cycles.

1 INTRODUCTION

Mineral admixture concrete is one of the most significant new material available worldwide for utilization in new construction and in rehabilitation of buildings, highways and bridges. Economics (lower cement requirement) and environmental considerations have a role in the growth of mineral admixture usage. Studies have shown [Bouzoubaa et al 2002; Mazloom et al 2004; Tan & Pu 1998; Ozyildirum & Halstead 1994] that mineral admixtures such as blast furnace slag, fly ash and silica fume enhance the strength and durability of concrete. Recently, there is a growing interest in the use of metakaolin (MK) as a mineral admixture in the concrete industry. It is well known that metakaolin is produced by calcining purified kaoline clay in the temperature range of 700 to 800˚C to derive off the chemically bound water and to destroy the crystalline structure [Ding and Li 2002; Khatib & Wild 1996; Al-Akhras 2007; Lee et al 2005]. The end product of this reaction is nearly 100% reactive pozzolana which actively combines with calcium hydroxide to form C-S-H gel.

Extensive research has been reported in the literature regarding the effect of MK on different properties of concrete [Gruber et al 2001; Boddy et al 2001; Ding & Li 2002; Sabir et al 2001; Wild et al 1996; Khatib & Wild 1998]. However, limited research has been carried out on the effect of MK when the concrete is exposed to deicing chemicals (sodium chloride and calcium chloride) under freeze-thaw and wet-dry exposure conditions. The deicing chemicals increase the concrete damage originating from freeze-thaw due to many reasons. Firstly, deicing chemicals increase the degree of concrete saturation and therefore, keep pores at maximum fluid saturation that leads to the increase in risk of frost damage [Litvin 1976]. It also decreases the freezing point of concrete pore solution, leading to hydraulic pressure. Along with this, the pressure is also generated in between the layers because salt concentration varies with the distance from the concrete surface [Wang et al 2006]. Apart from the above stated physical interactions, the concrete materials also interact chemically with the deicing salts that lead to decomposition of cement hydration products [Heukamp et al 2001]. These chemical reactions become more vulnerable after the formation of cracks formed due to the physical interaction between the deicers and the concrete materials [Mehta & Gerwick 1982]. Looking at the wide range of effects of deicer chemicals of the concrete mix, it becomes imperative to study the effect on MK mixes as well. The purpose of the present investigation is to examine the effect of various deicing solutions and exposure conditions on mortars containing MK. The study is further extended to cover corrosion inhibitors with the deicer salts.

2 EXPERIMENTAL DETAILS

2.1 Materials

ASTM Type I Portland cement was used throughout the investigation. The physical properties and the chemical composition is given in Table 1. The MK used is Metacem of 85-C grade with properties given in Table 1. Locally available river bed sand confirming to Zone III of IS: 383-1970 was used as fine aggregates to make mortar specimens. The specific gravity, absorption and fineness modulus of the aggregates were 2.68, 1.02% and 2.507 respectively.

2.2. Aggressive Chemicals

Four chemical, sodium chloride (NaCl), calcium chloride ($CaCl_2$), sodium chloride with the corrosion inhibitor (NaCl + inhib), calcium chloride with corrosion inhibitor ($CaCl_2$ + inhib) were considered in the present study. The percentage of the salt solution used was 3% and the percentage of corrosion inhibitor was kept at 1%. Triethanolamine was used as corrosion inhibitor.

Table 1. Chemical properties of cement and MK.

Chemical (%)	CaO	SiO_2	Al_2O_3	Fe_2O_3	SO_3 (%)	MgO	K_2O	Na_2O
Cement	61.7	22.4	5.93	4.91	2.28	1.5	0.65	0.122
MK	2.8	55.3	37.1	2.4	-	0.3	0.6	0.25

2.3 Mixtures details

Three different mortar mixes were prepared for water-to-binder ratios of 0.5. For this water-to-binder ratio, cement was partially replaced by 5% and 10% of MK. The binder to sand was kept as 1:3 for all mixes. For each mix, 70.5 mm cubes were cast to study the variation of compressive strength. The specimens were demoulded after 24 hours and then cured in tap water for initial 7 days. After the initial water curing period, the samples were subjected to different chemical, as stated earlier, in plastic containers. For wet-dry (W-D) exposure, samples were immersed in the solution at room temperature for 16 hours followed by 8 hours of air drying. Similarly, for freeze-thaw (F-T) cycles, the specimens were stored in a freezer at -15 ± 1˚C for 16 hours, followed by 8 hours of thawing in large tubs having the same solution at room temperature. Thus, one W-D and one F-T cycle was of 24 hours duration. The tests were conducted at the end of 14, 28 and 42 cycles.

Prior to compressive strength tests, the specimens were visually investigated for any signs of cracking, spalling, delamination etc. Weight change was also monitored throughout the test and compared with the initial weight of the specimen before it was immersed in the salt solution.

3. RESULTS AND DISCUSSIONS

3.1. Strength Results

Figs. 1 to 3 present the compressive strength development of mortar specimens under F-T and W-D exposure conditions, made at water-binder ratios of 0.5 and different percentages of metakaolin. In these graphs, data represented in columns indicate the effect of F-T exposure while line representation is made for W-D exposure. It can be observed that for all mixes, the strength development of the mixes under both W-D and F-T exposure follows similar pattern, however, it is more for W-D exposure than that under F-T exposure condition. Such a small increase in strength can be due to slowing of cement hydration at low temperature. Analyzing F-T exposure condition thoroughly, it can be seen from the Fig. 1 that for control mix, the addition of sodium chloride did not cause great damage in mortar specimens although the increase of strength is lower than the mix exposed to F-T under distilled water. Addition of corrosion inhibitor further reduced the damage caused by the aggressive chloride salt. Attack by calcium chloride is worst. Addition of corrosion inhibitor to calcium chloride could not produce the effect it caused in sodium chloride salt. In this case, addition of corrosion inhibitor delayed the damage but could not diminish it.

Similar to the control mix, the effect of sodium chloride salt is less aggressive than the calcium chloride salt. However, the presence of corrosion inhibitor has a different effect on the specimens containing MK. In this case, the strength educed regardless of the type of salt present.

The strength loss is very high when the corrosion inhibitor is present along with calcium chloride salt. It means that the corrosion inhibitor used in this study is not compatible with MK. It emphasizes the need of a pre-study to check the compatibility of the ingredients with corrosion inhibitors.

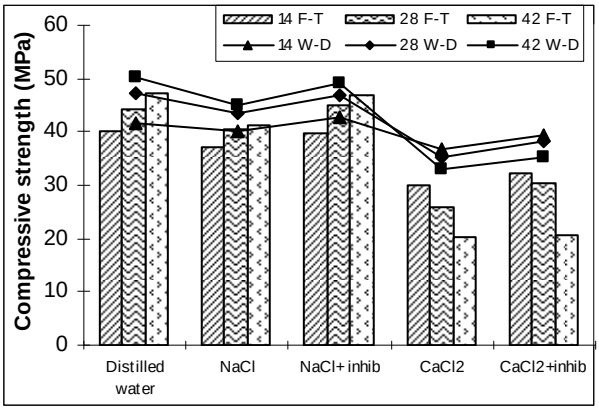

Fig. 1. Compressive strength of the control mix under F-T and W-D cycles.

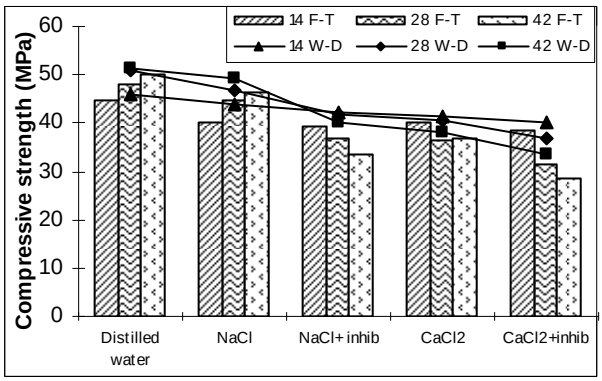

Fig. 2. Compressive strength of mix with 5% metakaolin under F-T and W-D cycles.

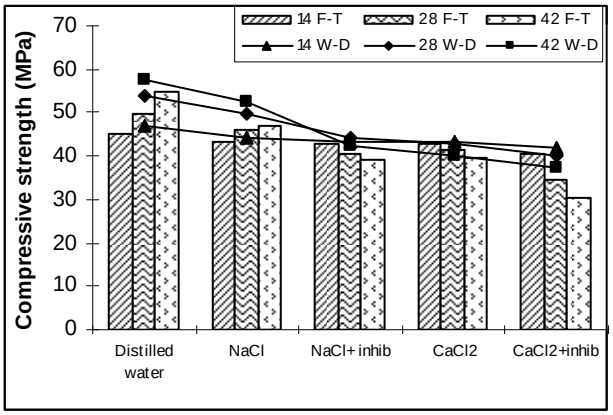

Fig. 3. Compressive strength of mix with 10% metakaolin under F-T and W-D cycles.

3.2 Mass Loss and Scaling

Fig. 4 and 6 shows the mass change of the mortar specimens with percentage replacement of metakaolin varying from 0% to 10%. The mass change data is presented for F-T cycles only, because, it is established in the compressive strength studies that F-T exposure is more aggressive than W-D exposure. Secondly, it

was observed weight change was negligible for W-D exposure. The mass change of the specimens was calculated as follows:

$$\text{Percentage mass change} = \frac{M_2 - M_1}{M_1} \times 100$$

Where M_1 (gm) is the mass of the specimen at 7 days of initial water curing, i.e., before immersion in salt solution and M_2 (gm) is the mass of cleaned specimens after immersion in salt solution. Negative value of percentage mass change will indicate decrease in mass with the number of F-T cycles.

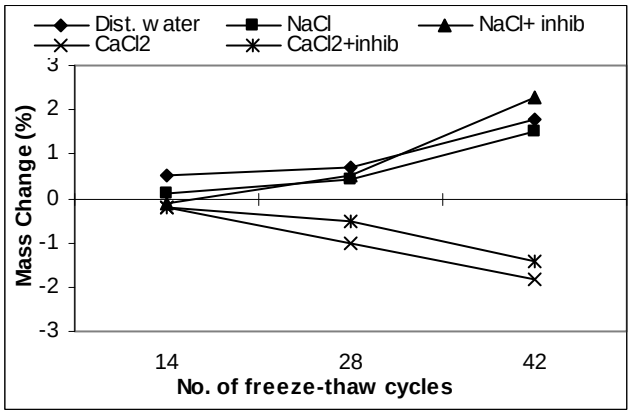

Fig. 4. Mass change of control mix under F-T cycles at 0.5 water-to-binder ratio.

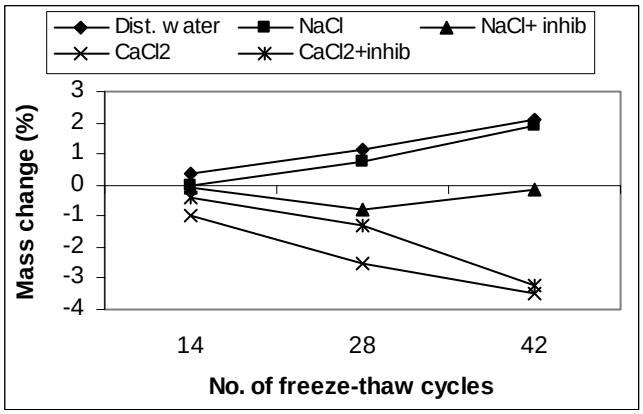

Fig. 5. Mass change of mix with 5% metakaolin under F-T cycles.

It is found that the specimens containing only OPC as binder and exposed to distilled water and NaCl displayed a small amount of mass gain. Mass loss of the specimens with metakaolin and exposed to NaCl started a bit late, i.e. after 28 cycles of freeze-thaw. The specimens exposed to $CaCl_2$, with or without corrosion inhibitor, showed a higher mass loss indicating that $CaCl_2$ salt is more aggressive than NaCl and its aggressivity does not depend on presence or absence of mineral admixture. Also, the initial mass loss of the specimens containing corrosion inhibitor was lesser than when $CaCl_2$ alone is present, however, the final losses are almost the same. This result once again implies that the presence of corrosion inhibitor postpones the damage but does not eradicate it completely.

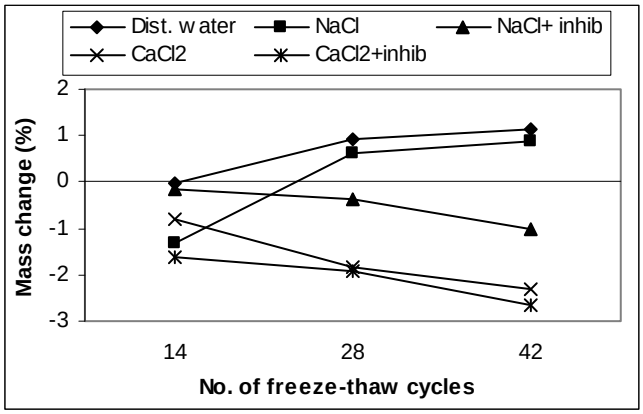

Fig. 6. Mass change of mix with 10% metakaolin under F-T cycles.

Visual investigation indicated that the intensity of damage of the specimens submerged in distilled water and NaCl solution is less and they showed very small scaling damage throughout the test, indicating that these solutions are less aggressive. Samples containing mineral admixture and immersed in NaCl solution containing corrosion inhibitor showed the presence of micro-pores (Fig. 5) at the surface of the specimen that increased with the increase in number of exposure days indicating the loss of material due to stresses developed in alternate freeze-thaw. However, the samples immersed in $CaCl_2$ with or without corrosion inhibitor, demonstrated increased scaling with the increase in freeze-thaw cycles. In this case, the damage is more at the edges and it is traveling to the surfaces indicating the rate of loss will increase with exposure (Fig. 6).

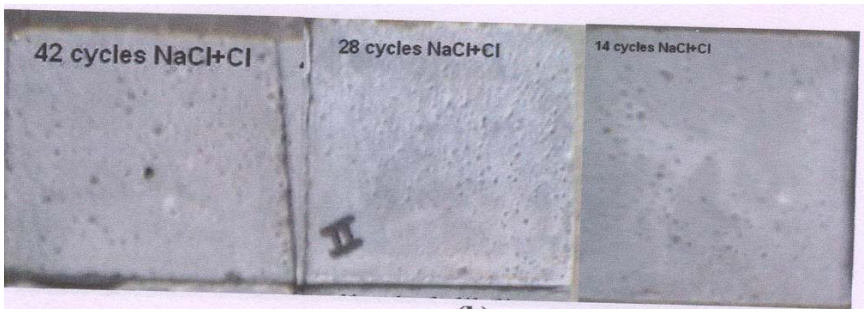

Fig. 5. Cubes containing 10% MK and exposed to NaCl + inhib. under F-T exposure.

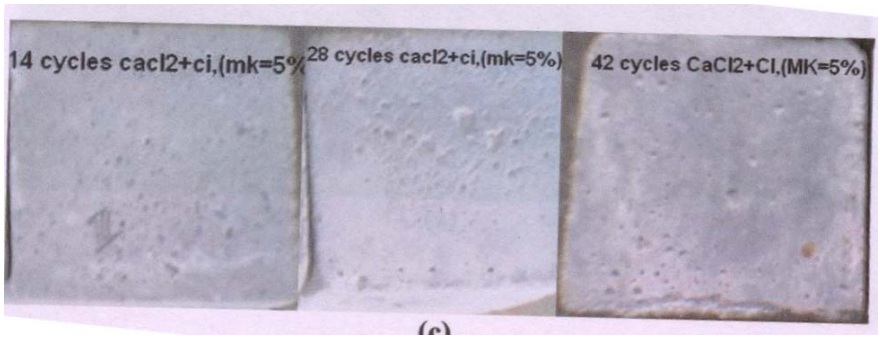

Fig. 6. Cubes containing 5% MK and exposed to $CaCl_2$ + inhib. under F-T exposure.

4 CONCLUSIONS

The following conclusions can be drawn from the present investigation:

1. F-T exposure condition is more aggressive than the W-D exposure condition. The damage of specimens was aggravated under F-T cycles.
2. Among the chemicals studied, $CaCl_2$ solutions, with or without corrosion inhibitor, displayed more severe damage on the specimens in terms of compressive strength loss and weight loss.
3. Metakaolin replacement of cement was found to be effective in improving the resistance against aggressive chemicals under W-D and F-T exposure conditions. However, the performance was dependent on the percentage replacement level.
4. While using corrosion inhibitor with MK, it is essential to check the compatibility of both by conducting small experiment on the strength development pattern.

Alternative Reinforcement for Durable Reinforced Concrete Structures

Marijana Serdar [1]
Irina Stipanović Oslaković [2]
Dubravka Bjegović [3]

T 11

ABSTRACT

The enormous costs and safety issues associated with corrosion of steel in concrete have resulted in the development of a wide range of new technologies and materials to increase the durability of reinforced concrete structures and their repairs. One of these methods is the use of certain types of stainless steel, which are resistant to corrosion in concrete environment even when the concrete is highly contaminated with chlorides, as substitution of part or all reinforcement in concrete. The use of stainless steel as a replacement for carbon steel reinforcement has been limited to vital structures exposed to aggressive environments by concerns over the increase in initial construction costs.

Recent results indicate that some alloy steels under certain conditions behave significantly better than ordinarily used black steel reinforcement. Since the price of alloy steel reinforcement is comparable to the price of normal black steel reinforcement, the idea of using alloy steel as reinforcement is economically justified.

In this paper the experimental program that will be used to evaluate corrosion behaviour of different types of alloy steel when used as reinforcement in concrete is presented. Results of so far performed corrosion testing of different types of alloy steel in alkaline media are presented as well. The aim of the research is to evaluate the influence of chloride ions and carbonation on passivity of alloy steel in alkaline media such as concrete. Corrosion performance and material cost of alloy steel will be compared to black and stainless steel.

1 INTRODUCTION

Nowadays the main responsibility of construction engineers is not only to design and construct structures that are functional, safe and aesthetic but that these structures remain such during their whole service life. Inspections of reinforced concrete structures exposed to aggressive (marine or continental) environment have shown that almost all of them have degraded due to chloride induced corrosion of reinforcement and that corrosion is the main reason for their reduced service life (Bertolini *et al.*, 2004). Maintenance and repair costs constitute a major part of the current spending in infrastructure worldwide and often overhead the costs of structures themselves. The enormous costs and safety issues associated with corrosion of steel in concrete have resulted in the development of a wide range of new technologies and materials to increase the durability of reinforced concrete structures and their repairs. One of these methods is the use of certain types of stainless steel, which are resistant to corrosion in concrete environment even when the concrete is highly contaminated with chlorides, as substitution of part or all reinforcement in concrete (Nürnberger, 1996). The use of stainless steel as a replacement for carbon steel reinforcement has been limited to vital structures exposed to aggressive environments by concerns over the increase in initial construction costs. Recent results indicate that some low alloy steels under certain conditions behave significantly better than ordinarily used black steel reinforcement. Since the price of low alloy steel reinforcement is comparable to the price of normal black steel reinforcement, the idea of using low alloy steel as reinforcement is economically justified. All this is the main scope of working package 3.1 “Validation and application of low-alloyed steel” of the specific targeted research project ARCHES “Assessment and Rehabilitation of Central European Highway Structures” (031272), funded by the European Community under the Sixth Framework Programme, Priority 1.6.2 Sustainable Surface Transport. The aim of this part of the ARCHES project is to validate the application of low alloyed steel in the concrete and finally to produce Guidelines for the use of low-alloyed steel. In this paper detailed experimental program that will be used in this part of the project ARCHES is presented. Experimental program is designed with the aim of evaluating corrosion behaviour of alloy steel in high alkaline media, such as fresh concrete and media with lower alkalinity, such as carbonated concrete with different concentrations of chlorides, simulating aggressive marine environment.

2 STATE OF THE ART

At the beginning of this research the task of the researchers was to evaluate all corrosion resistant types of steel available on the market and to classify them concerning the content of alloying elements. The aim was to find those types of steel that contain lower content of alloying elements, which makes them cheaper than stainless steel, but still have satisfying corrosion behaviour (better resistance than black steel).

Research has shown that corrosion behaviour of different steel types depends on type and quantity of alloying elements and on the nature of the corrosive environment. By the comparison of corrosion behaviour of ordinary (black) steel and low alloy steel it was calculated that low alloy steels corrode almost two times slower than black steel in the first two years of service life and four times slower from sixth till fifteen year of service life. (Shreir *et al.*, 1994). Steel commercially called TOP12 produced by Swiss Steel, is a ferritic stainless steel (X2Cr12, basis 1.4003). TOP12 is manufactured by a new production process, where the material properties are achieved by only two production steps: hot rolling of the billets in several steps to the final product and controlled cooling (Schiegg *et al.*, 2004). This type of steel has a lower content of Nickel and a somewhat higher content of Silicon than austenitic stainless steels and around 12 % of Chromium, which sets it into the category of corrosion resistant steel. Recent research of steel TOP12 shows that its corrosion resistance is significantly better than corrosion resistance of black steel (Hasler *et al.*, 2000). Since the behaviour of TOP12 has not been fully researched in alkaline media such as concrete and its application as reinforcement in concrete has not been validated this type of steel was chosen for testing in present research. Research of the low-Ni type 204Cu stainless steels showed that, in chloride contaminated pore solution, they

have corrosion behaviour very similar to that of traditional austenitic stainless steels. Since Nickel very much contributes to the price of stainless steel, the price of this steel is 35-40% lower than the price of stainless steel (Bautista *et al.*, 2006). Newer research of duplex steel, type 1.4362, show that this type of steel has good corrosion resistance in concrete contaminated with chlorides (Chauveau *et al*., 2007). The price of this steel type is lower than the price of stainless steel grade 316 because of the lower content of nickel and molybdenum. During the project corrosion resistance and price of chosen types of steel will be compared to normal black steel, whose corrosion resistance is very weak (Berke *et al.*, 1990; Bentur *et al.*, 1997) and with stainless steel, whose corrosion resistance is proven in laboratory research (Bertolini *et al.*, 2000; Veleva *et. al*, 2005; Blanco *et al.*, 2006) and on site application (Castro-Borges *et al*., 2007).

3 EXPERIMENTAL PROGRAM

In the first stage of the research accelerated corrosion testing will be performed on electrodes made of chosen types of steel in highly alkaline media (pH 12,5), such as fresh concrete, and middle alkaline media (pH 10), such as carbonated concrete, all with different concentrations of chloride ions. In the second stage of the research electrochemical testing will be performed on concrete "lollipops" with the embedded steel specimens. In the third stage of the research concrete specimens with steel reinforcement will be prepared and placed into salt spray chamber to simulate aggressive marine environment. In the last part of the research a testing field near Croatian seacoast will be established. At this testing field concrete beams reinforced with chosen steel types will be exposed to natural aggressive marine environment and their corrosion behaviour will be evaluated.

3.1 Materials

During this research, corrosion behaviour of six different steel types will be researched: two types of steel with lower content of alloying elements (TOP12 and 204Cu), two grades of duplex steel (1.4362 and 1.4462), two grades of stainless steel (1.4301 (AISI 304) and 1.4306 (AISI 304L)) and black steel B500B. Till now three types of steel have been delivered and tested: TOP12, stainless steel grade 1.4301 (AISI 304) and black steel. Their chemical composition is given in Table 1 and mechanical properties in Table 2.

Table 1. Chemical composition of the researched steel types.

Quality	TOP12	AISI 304	Black steel B500B
C	0,03	0,058	0,190
Mn	1,50	1,460	0,620
S	≤0,015	<0,001	0,022
Cr	10,50/12,50	18,240	0,070
Mo		0,036	<0,020
Ni	0,0,30/1,00	7,930	0,020
N	0,030	0,051	0,005
Fe		71,450	98,910

Table 2. Mechanical properties of researched steel types.

Type	TOP12	AISI 304	Black steel B500B
Yield strength, $R_{p0,2}$ [MPa]	566	882	500
Tensile strength, R_m [MPa]	748	992	540
Stress ratio, $R_m/R_{p0,2}$	1,32	1,12	1,08
Elongation, A_{gt} [%]	8,2	10,3	5,0

3.2 Corrosion Testing of Steel in Pore Solution

Investigation of corrosion behaviour of different steel types will be performed in pore solution with pH value 12,4 (non carbonated concrete), pH 9,5 (carbonated concrete) and pH 10,1 with different concentration of NaCl using anodic linear polarization (LP). Potentiodynamic polarization is performed after one hour submersion in the potential range between -0.2 V and 0,8 V with scan rate 10 mV/s. The aim is to evaluate which concentration of chloride ions will surely cause corrosion initiation of steel, in other words which concentration of chloride ions is for given system the critical one. Measurements will be performed using PAR VMP2 potentiostat / galvanostat with three-electrode arrangement. For electrochemical testing working electrodes were prepared manually (Bjegovic *et al.*, 2007). Small specimens of steel were connected to copper wire that was inside a glass tube. All sides of steel specimen were protected with 5 mm thick epoxy coating, except one unprotected side with area of 0,196 cm^2. After the epoxy coating had firmed, electrodes were mechanically abraded on 400 and 600 grade emery paper, rinsed in distilled water, degreased with ethanol and dried. Counter electrode was carbon rod and reference electrode saturated calomel electrode (SCE). All potentials reported, refer to SCE. Working electrode is shown in Figure 1 a) and three-electrode experiment setup in Figure 1 b).

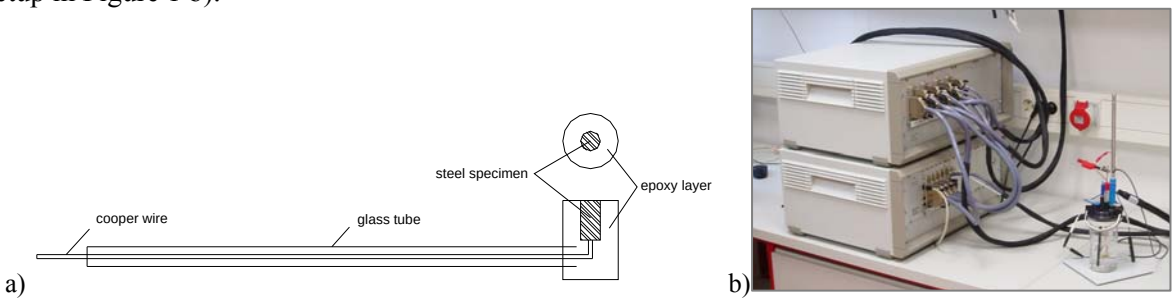

Figure 1. a) Steel specimens for corrosion testing; b) Experiment setup for steel specimens

3.2 Accelerated Corrosion Testing of Steel in Concrete

Investigation of corrosion behaviour of different steel types embedded into smaller concrete specimens ("lollipops") will be performed in 3,5% of NaCl contaminated water using potentiostatic anodic polarization. Anodic potential of 10 V will be applied and change of current in time will be measured. Rapid increase of current is considered to be a sign of corrosion initiation (Stipanovic et al., 2007). Measurements will be performed using PAR VMP2 potentiostat / galvanostat with three-electrode arrangement. Working electrodes were prepared manually. Concrete specimens with embedded steel were prepared in this way: isolated copper wire is connected to 10 cm long steel bars and the connection is protected with layer of water resistant material. These steel specimens are then embedded in 12 cm high and 4 cm thick moulds in which fresh concrete will be poured, Figure 2 a). Concrete specimens prepared this way will be cured for 28 days and then used in accelerated corrosion testing. Counter electrode is carbon rod and reference electrode is saturated calomel electrode (SCE). All potentials reported, refer to SCE. Experiment setup is shown in Figure 2 b).

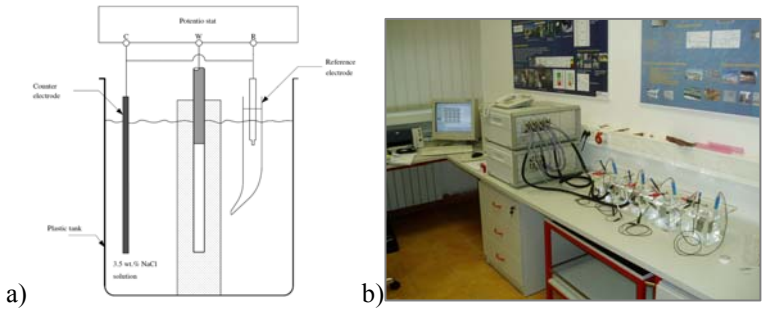

Figure 2. a) Three electrode system for corrosion testing; b) Experiment setup for concrete specimens

3.3. Corrosion Testing of Steel in Concrete Exposed to Artificial Atmosphere

During this part of the project task concrete specimens reinforced with different types of steel rebar will be exposed to artificial marine environment with the use of salt spray chamber, Figure 3. Concrete specimens will be exposed to conditions simulating splashing zone in marine environment: 60 - 100% moisture, temperatures between 35 °C and 50 °C and continuous spraying of 3,5% sodium chloride solution. During the exposure in salt spray chamber half cell potential, corrosion current and concrete resistance measurements will be performed.

a)  b) 

Figure 3. a) Concrete specimens; b) Salt spray chamber

3.4 Corrosion Monitoring of Steel in Concrete Exposed to Marine Atmosphere – Testing Field

In the last part of the task an exposure site will be established in the real marine environment. Testing site is situated near Rijeka in Croatia at the Adriatic coast in very aggressive chloride environment, as it can been seen in Figures 4 a and b. Larger concrete beams reinforced with different types of steel with embedded probes for corrosion monitoring will be exposed to aggressive marine environment. Corrosion behaviour will be monitored with electrical resistant probes embedded in concrete specimens and periodically with the use of galvanostatic pulse instrument (half cell potential, corrosion current and concrete resistance measurements).

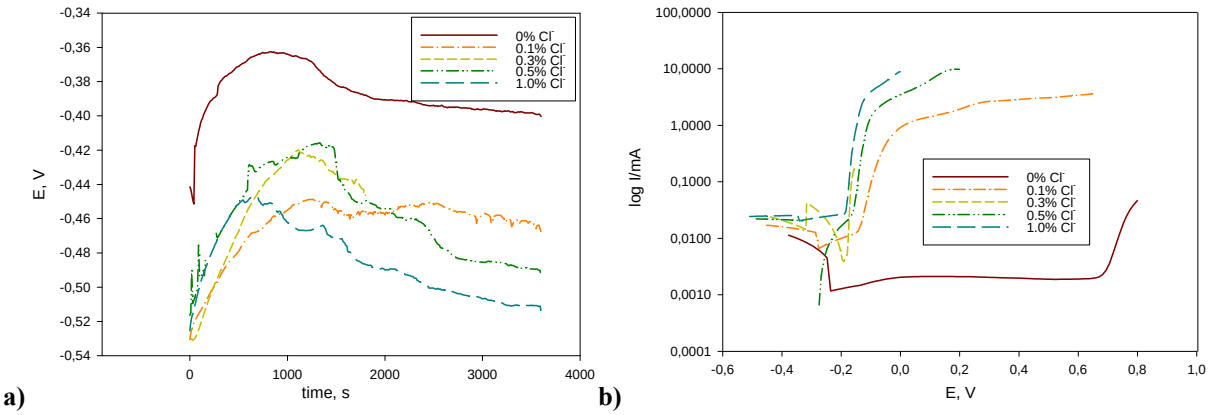
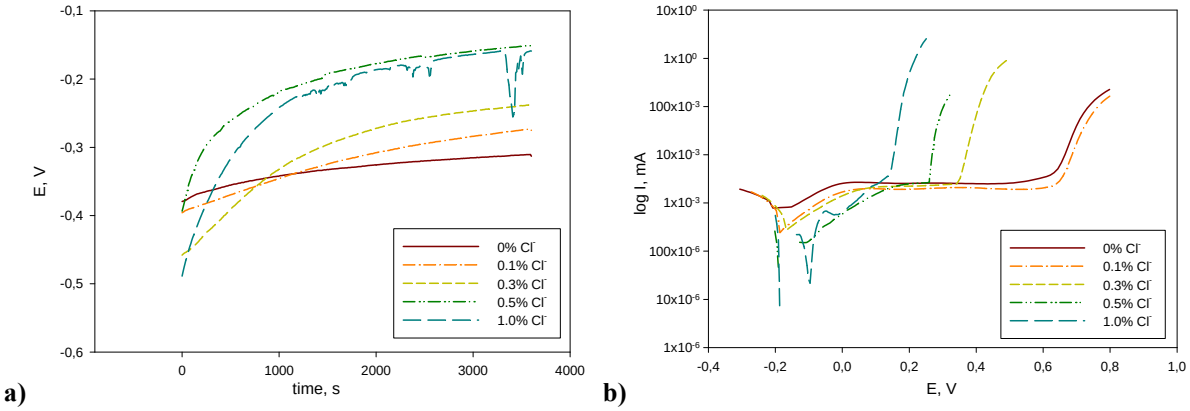
4 RESULTS

Till now corrosion testing of three types of steel (TOP12, stainless steel grades 1.4301 (AISI 304) and black steel) have been performed. Testing have been performed on steel electrodes (Figure 1 a) in pore solution with pH 12,4 and with the following chloride concentration: 0%, 0.1%, 0.3%, 0.5% and 1%. Pore solution was prepared with addition of $Ca(OH)_2$ and KOH to distilled water. The change of corrosion potential in time and relation potential versus current of black steel, TOP12 and AISI 304 are given in Figures 5, 6 and 7 respectively.



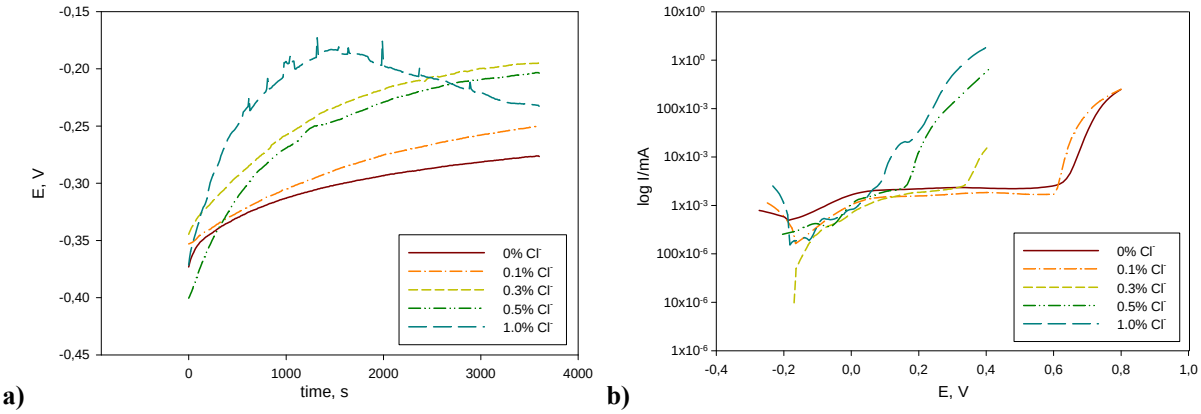
a) **b)**

Figure 5. Black steel: a) corrosion potential vs. time; b) potentiodynamic anodic polarization.



a) **b)**

Figure 6. TOP12: a) corrosion potential vs. time; b) potentiodynamic anodic polarization.



a) **b)**

Figure 7. AISI 304: a) corrosion potential vs. time; b) potentiodynamic anodic polarization.

From the results shown in Figure 5 a) it can be seen that even a small concentration of chloride ions (0.1%) causes a decrease of corrosion potential in time which is an indication that passive layer of black steel that is formed in alkaline media is not stable. This conclusion is confirmed during polarization, because even a concentration of 0.1% of Cl^- caused immediate increase of current and formation of corrosion pit on surface of black steel specimen. On the other side, only chloride concentration of 1.0% managed to unstable the corrosion potential of steels TOP12 (Figure 6 a) and AISI 304 (Figure 7 a). From the results shown in Figure 6 b and Figure 7 b it can be seen that steel TOP12 and AISI 304 have the same behaviour after addition of 0.1%, 0.3% and 0.5% of Cl^-. Only after addition of 1.0% of Cl^- their behaviour changes; pitting potential of steel TOP12 is -120 mV, while pitting corrosion occurs almost immediately after polarization on steel type AISI 304.

5 CONCLUSION

In this paper detailed experimental program that will be used to evaluate corrosion behaviour of different types of alloy steels in concrete is presented. The idea of the research is to evaluate corrosion behaviour of different steels in chemically simplified systems (pore solution) to more complex systems (concrete). Since this research has just begun, till now testing of three types of steel has been performed in pore solution with pH 12,4 and with different concentrations of Cl^-, from 0.1% to 1.0%. From the results of performed testing, which are presented in this paper, it can be concluded that steel TOP12 has satisfying corrosion behaviour when used in high alkaline media such as new concrete. While comparing corrosion behaviour of steel TOP12 to corrosion behaviour of black steel and AISI 304, TOP12 showed longer passivity range in non carbonated pore solution with high concentration of Cl^-.

In order to fully research behaviour of steel TOP12 and other chosen steel types further research will be carried out during the project.

ABSTRACT

Today engineers have to consider durability of structures in the design process which is realized through the choice of materials and material's performance. Chloride diffusion coefficient is main parameter of durability properties of concrete, like compressive strength is of mechanical properties. In this paper chloride diffusion coefficient was determined for the structure of Krk bridge, which is located in aggressive marine environment, exposed to direct influence of chlorides for the period of more than 25 years. Chloride diffusion coefficient was calculated from chloride profiles measured on specimens taken from different testing places on bridge within inspection and maintenance works on the bridge. In this research results from 1989, 1994, 2000 and 2003 are taken into account and analysed. In order to evaluate change of chloride diffusion in time, results of on site testing were compared with chloride penetration testing in laboratory. Specimens for these testing were prepared from the same concrete mixture that was used during construction of this bridge. All results obtained during the research were compared with calculated chloride coefficient from existing durability models (*DuraCrete, Life-365* and *Chlodif*) for given mixture and exposure time.

1 INTRODUCTION

For years, reinforcement corrosion has been recognised as the major problem with respect to the durability of reinforced concrete structures. For structures in marine environment chlorides are the most critical environmental load, which are causing serious corrosion damages. Reliable prediction of chloride ingress in concrete is, therefore, one of the key elements for determining the service life of the structure; which can be theoretically determined by mathematical modelling of a chloride transport mechanism. Existing service life models are mainly based on chloride diffusion process in the concrete, described by Fick's 2nd law, resulting in a prediction model based on an error function complement solution.

In this paper chloride diffusion coefficient was measured on Krk bridge located in aggressive marine environment, exposed to direct influence of chlorides for the period of more than 25 years. Chloride diffusion coefficient was calculated from chloride profiles measured on specimens taken from different testing places on bridge. In order to evaluate change of chloride diffusion in time, results of on site testing were compared with chloride penetration testing in laboratory. Specimens for these testing were prepared from the same concrete mixture that was used during construction of the Krk bridge. All results obtained during the research were compared with calculated chloride coefficient from existing durability models (*DuraCrete, Life-365* and *Chlodif*) for given mixture and exposure time.

2 CHLORIDE PENETRATION TESTING

2.1 Description of the Structure and Location

Chloride analyses were performed on structural elements of Krk bridge, situated at very aggressive marine environment at the Adriatic coast. Krk bridge is a 1430 m long reinforced concrete arch bridge connecting the Croatian island of Krk to the mainland and carrying over a million vehicles per year. It consists of two arch bridges, one with a span of 244 m (the small arch), and the second, between the islet St. Marko and the mainland, with a span of 390 m (the big arch), which is the second longest concrete arch in the world. The bridge was built from 1976 and completed in 1980 [Sram 1981].
Main winds in this area are gale and sirocco, which are producing high waves (few meters) and swirls in the sea, which disperses the sea drops very high, up to 60 meters. The gale wind (from north) as a storm wind is occurring more often in this area, then the wind from south. The average salinity of the sea-water in Adriatic sea is relatively high, around 3.8 %, and by the coast due to the spring of sweet water is decreased to 3.5 %.

2.2 General on the Concrete Quality

For concrete production during the construction of Krk bridge following concrete mix design and materials were used:

- ca 450 kg of Portland Cement class 45 with 20% slag per m^3 of built-in concrete,
- alluvial mined carbonate gravel, with the maximum grain size of 16 mm, divided in fractions 0-4, 4-8 and 8-16 mm,
- 0.15% of air entrainer and 0.2% superplastizicer
- w/c ratio 0.37 by D_{max} = 16 mm.

The same materials and concrete mix design was used in the laboratory chloride penetration testing during 2007. Average compressive strengths of control samples were between 48.8 N/mm^2 and 55.6 N/mm^2. All together 4400 control samples were tested, with the standard deviation from 3.9 to 5.4 N/mm^2. Laboratory testing of capillary suction gave the result of 0.65%, bending tensile strength 9.3 N/mm^2 and static modulus of elasticity 41 300 N/mm^2.

Design values of concrete cover for structural elements of the Krk bridge were 25 and 30 mm, which is one of the main reason why the structure is today locally damaged by sever corrosion [Sram 1981, Beslac 2003].

2.3 Chloride Testing

Chloride profiles had been determined on different parts of bridge several times during its service, performed within the inspection and maintenance works. In this paper results from 1989, 1994, 1997, 2000 and 2003 are taken into account and analysed [Beslac 1997, 2003, IGH 1994, 2003, Durekovic & Calogovic 1991]. From chloride profiles apparent chloride diffusion coefficients were calculated with the application of Fick's 2nd law. In order to evaluate change of chloride diffusion coefficient in time, results of on site testing were compared with chloride penetration testing in laboratory, which simulated concrete diffusion properties at the beginning of structural service life. Specimens for these laboratory testing were prepared from the same concrete mixture (with the same type of cement – CEM II/A-S 42,5), aggregate and same admixtures) that was used during construction of this bridge and tested according NT BUILD 492 in order to get non-steady state migration coefficient [Nordtest, 1999]. It was not possible to compare systematically the change of chloride concentrations in time on the same structural elements and at the same micro environment conditions, since there was no systematic approach in the execution of chloride testing during the service and maintenance of Krk bridge. Typical chloride profiles have been chosen for the analysis, on which basis the calculation procedure for the determination of chloride diffusion coefficient was performed. In Figure 1 is shown longitudinal view of the Krk bridge with marked places of chloride testing during inspections in the period from 1989 to 2003.

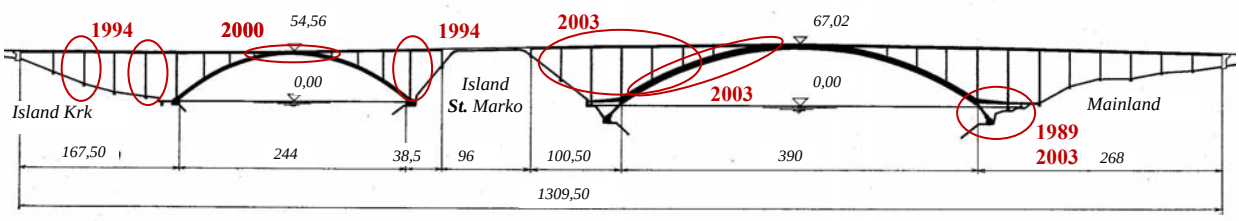

Figure 1. Scheme of Krk bridge with marked places of chloride testing

In Figures 2, 3 and 4 chloride profiles are presented for arch foundation (1989), main beams (2000), arch and columns (2003), depending on the position of testing and height above or under the sea level.

In the *Mathematica* program, the diffusion coefficient for the representative chloride profiles was calculated by curve fitting along with the defined solution of Fick's second law by means of inverse error function. Results of D_{Cl} calculation are presented in Table 1, as well as chloride migration coefficient calculated from NT BUILD 492 measurements.

Results of calculated apparent diffusion coefficients are within the limits from 0.24 to 0.84× 10^{-12} m^2/s for the age of structure from 13 to 23 years, which is in a very good correlation with the values from the literature [Bentz et al. 1996, DuraCrete 1999].

3 APPLICATION OF MATHEMATICAL MODELS

In this research three mathematical service life models were used for the comparison with experimental results, and those are *Life-365*, *CHLODIF* and *DuraCrete*. [Stipanovic 2005]All three models are based on the assumption that the diffusion is the predominant process of chlorides penetrating into the concrete, which can be described mathematically by Fick's second law of diffusion. The time to initiation of corrosion (t_i) may be calculated as the time necessary for the concentration of chloride ions to reach the critical value C_{cr} at the level of reinforcement, which is a

function of the transport properties of concrete (usually the apparent diffusion coefficient), the surface chloride concentration defined by the environment, the thickness of the concrete cover and the chloride threshold value. Within the models *Life-365* and *CHLODIF* deterministic approach is used for the calculation of initiation period t_i and chloride profiles after certain time of exposure, while *DuraCrete* model calculates the probability of corrosion initiation in relation to the time of exposure. By defining the acceptance criteria it is possible to predict structural performance for a pre-determined design service life with a selected level of reliability [Krstic 1994, Bjegovic *et al.* 1995, Bentz, Thomas 2001, DuraCrete 1999]. Each model has different definitions of time-dependency of the chloride diffusion coefficient, which are described in following paragraphs.

27	2003	natural diffusion, non-steady state, non-saturated concrete	foundation arch support (above sea level)	2	0,46	-

3.1 Service Life Model *Life-365*

Life-365 is based on a 1-D and 2-D finite difference implementation of Fick's Second Law, the general advection-dispersion equation [Bentz, Thomas 2001]. The theoretical value of the apparent chloride diffusion coefficient at 28 days maturity, D_{28}, can be calculated by the model with the following relationship:

$$D_{28} = 1 \times 10^{(-12.06 + 2.40\ w/c)}\ \text{m}^2/\text{s} \qquad (1)$$

where; *w/c* is water-cementitious material ratio of the concrete.

The chloride diffusion coefficient is furthermore a function of time and temperature:

$$D(t,T) = D_{ref} \cdot \left(\frac{t_{ref}}{t}\right)^m \cdot \exp\left[\frac{U}{R} \cdot \left(\frac{1}{T_{ref}} - \frac{1}{T}\right)\right] \qquad (2)$$

where: $D(t,T)$ = diffusion coefficient at time t and temperature T

D_{ref} = diffusion coefficient at some reference time t_{ref} (= 28 days in *Life-365*)
m = constant (depending on mix proportions)
m = 0.2 + 0.4 (*%FA*/50 + *%GGBS*/70) ,
FA = Fly ash; *GGBS* = ground granulated blast furnace slag
U = activation energy of the diffusion process (35000 J/mol)
R = gas constant
T = absolute temperature

In this study only time-dependency of chloride diffusion coefficient is analysed. Concrete mixture used in Krk bridge was produced with *w/c* ratio 0,37 and with 20% of slag in the cement, which gives the *m* value of 0.31, and $D_{ref} = 6.73\times10^{-12}$ m^2/s at 28 days and $D_{t1} = 3.04\times10^{-12}$ m^2/s after 1 year. Time dependency of chloride diffusion coefficient calculated by *Life-365* is shown in Figure 5.

3.2 Service life model *Chlodif*

Numerical model *Chlodif* was developed at the University of Zagreb, Faculty of Civil Engineering in the early nineties. The process of a continuous diffusion process of chloride ions into a reinforced concrete structure is also based on a time-varying diffusion coefficient and varying chloride surface concentration [Krstić 1994,Takewaka & Matsumoto 1988]. The empirical formula for the chloride diffusion coefficient depending on *w/c* ratio, based on the conducted research work in Japan [Takewaka & Matsumoto 1988], was accepted in *Chlodif*:

$$log_{10} D_{w/c} = -6.274 - 0.076 \times w/c + 0.00113 (w/c)^2 \quad (3)$$

where: $D_{w/c}$ = "basic" diffusion coefficient (cm^2/s),
w/c = water-cement ratio (%).

The research work was performed on concrete specimens with the age between 1 and 20 years, which were exposed to different marine environment (tidal, splashing, submerged and atmospheric zone). The conclusion of these testing was that diffusion coefficient is not depending on the environment conditions, but it is strongly depending on type of cement and especially on the age of concrete: the older concrete, the lower diffusion coefficient. Accordingly the following relationship was suggested for describing the change of diffusion coefficient with the age of concrete [Takewaka & Matsumoto 1988]:

$$D_{Cl^-} = D_{w/c} \times D_0 \times t^{-0.1} \quad (4)$$

where: D_0 = coefficient which takes into account type of cement,
t =the age of structure (years).

For the cement with the slag addition D_0 is 0.30, which gives the theoretical value of chloride diffusion coefficient for this case study $D_{w/c} = 5.68\times10^{-11}$ m^2/s and $D_{Cl^-} = 4.68\times10^{-12}$ m^2/s after 1 year. Time dependency of chloride diffusion coefficient calculated by *Chlodif* is shown in Figure 5.

3.3 Service Life Model *DuraCrete*

In *DuraCrete* model corrosion initiation is defined as serviceability limit state (SLS) which gives the design service life. The design equation for this SLS is described over Fick's 2nd law of diffusion, where each variable is defined over its design and characteristic value. The design value of the time dependent concrete resistance is derived from:

$$R_{cl}^{d}(t) = \frac{R_{cl,0}^{c}}{k_{e,cl}^{c} \cdot k_{c,cl}^{c} \cdot \left(\frac{t_0}{t}\right)^{n_{Cl}^{c}} \cdot \gamma_{R_{cl}}} \quad (5)$$

where $R_{cl,0} = \left(\frac{1}{D_{\mathrm{RCM},0}} \right)$

where $D_{RCM,0}$:is chloride migration coefficient in [m^2/s] , measured according to NT BUILD 492 test,

$k_{c,cl}$ = curing factor,
$k_{e,cl}$ = environment factor,
t_0 = the age of the concrete when the compliance test is performed,
n_{cl} = age factor,
γ_{Rcl} = partial factor for the resistance with respect to chloride ingress (1.50; 2.35; 3.25 depending on the risk relative to the cost of repair)

For the concrete which was 28 days cured $k_{c,cl}$ is 0.79, while environment and age factors are given in Table 2 [DuraCrete 1999]. For this case study $D_{RCM,0}$ was 6.05×10^{-12} m^2/s after 28 days, which gives $R_{cl,0}$ 1.65×10^{11} s/m^2. Time dependency of chloride diffusion coefficient calculated by *DuraCrete* is shown in Figure 5.

Table 2. Characteristic values of the environment and age factor for GGBS concrete.

Variable	GGBS, Submerged	GGBS, Tidal Zone	GGBS, Splash zone	GGBS, Atmospheric
$k_{e,cl}$	3.88	2.70	0.78	1.98
n_{cl}	0.71	0.60	0.60	0.85

4 ANALYSIS OF RESULTS AND CONCLUSION

In these three chloride ingress models the diffusion coefficient is treated as time-dependent, based on the power law, as given in eq. (2), with some specifics in each of them as previously described. Time dependencies of chloride diffusion coefficient calculated by *DuraCrete*, *Life-365* and *Chlodif* are shown in Figure 5, for this specific type of concrete and exposure conditions, and compared with the experimental results for the Krk bridge.

A number of researches have shown that a chloride diffusion coefficient decreases with time, due to the continuous hydration and binder reactions which densify the concrete with time. The time-dependency is varying very much for different types of concrete, especially for different binders. [Stipanovic et al. 2007].

In this study a comparison of results of initial chloride ingress testing on new concrete and condition survey testing performed in 1989, 1994, 2000 and 2003 showed that chloride diffusion coefficient significantly decreased, about one order of the magnitude. For the age of structure from 13 to 23 years results of calculated apparent diffusion coefficients are within the limits from 0.24 to 0.84×10^{-12} m^2/s. Measurements of chloride migration coefficient D_{Cl} (according NT BUILD 492) at the age of 28 days performed on the copy of concrete mixture built into the Krk bridge, gave the average result of 6,05 $\times$ 10^{-12} m^2/s. Based on these experimental results regression analysis concerning the time dependent decrease of D_{Cl} were performed. Curve fitting of the power law relationship to the experimental results gave the m value 0.47 for this type of concrete (w/c = 0.37, 20 % slag). These results are in a very good correlation with the values from the literature and with the prediction of D_{Cl} decrease in mathematical model *Life-365* and partially with *DuraCrete* model [Bentz et al. 1996, Thomas & Bentz 2001, DuraCrete 1999, Tang & Gulikers 2007].

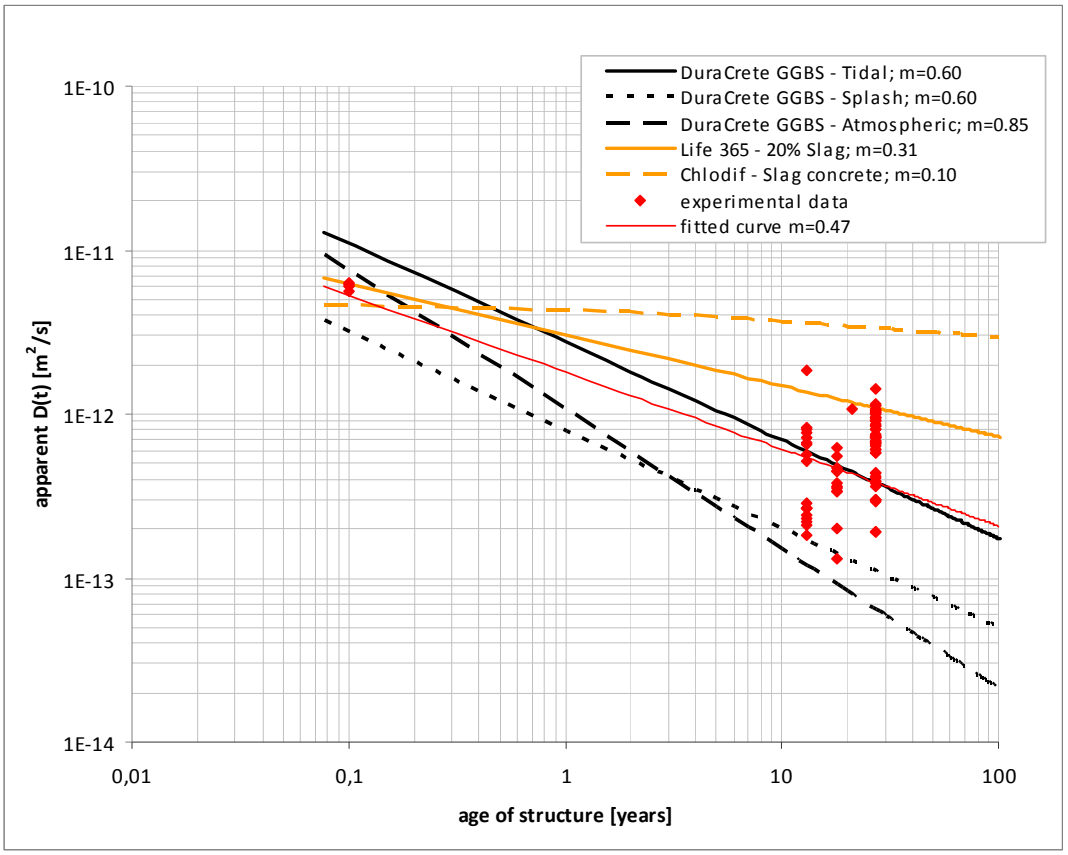

Figure 5. Time-dependency of chloride diffusion coefficient described by 3 mathematical models, depending on binder and environment conditions.

ABSTRACT

The Virtual Cement and Concrete Testing Laboratory (VCCTL) project was initiated at the National Institute of Standards and Technology (NIST) in 2001. The VCCTL is being developed by NIST and a consortium consisting of universities, materials manufacturers and trade associations.

VCCTL has the goal of modeling the materials used in concrete during mixing, and curing so that both fresh and hardened concrete properties can be predicted. Its impact on modeling concrete mixtures could potentially be similar to the effect finite element modeling of structures has had on structural analysis and design. It will permit optimum designs of concrete mixtures to be determined, eliminating a large amount of laboratory mixing and testing now required, and resulting in time and monetary savings. Rheology, curing time, strength, and durability are now or are planned to be within the scope of its predictions.

The elastic properties of concrete, the quintessential building material, have an important effect on the strength and durability of structures. An overview of the capabilities of VCCTL v5.0 is given with emphasis on mechanical property prediction. VCCTL models are able to accurately predict the results of some standard laboratory tests such as ASTM C109 and ASTM C215, when given well-characterized mixture material data as input.

1 INTRODUCTION

The design of concrete mixtures and the evaluation of the properties of fresh and hardened concrete have been done mostly empirically until the present day. Conventional laboratory testing methods are costly and time-consuming, requiring the purchase and disposal of materials, allocation of human resources and money, and sometimes long wait periods before obtaining results.

The Building and Fire Research, and Information Technology Laboratories within the National Institute of Standards and Technology (NIST) formed, in 2001, a NIST/industry consortium to develop a Virtual Cement and Concrete Testing Laboratory (VCCTL) with the goal of developing a world wide web-based virtual laboratory for evaluating and optimizing cement-based materials. Virtual, computer testing of cement and concrete properties permits substantial savings in time, materials, human resources, and money by reducing the number of physical concrete tests performed by private industry [Web reference 1]. Table 1 summarizes the need for the development of a virtual testing laboratory by comparing current (physical) testing with virtual testing.

Table 1. Comparison of current testing methods and virtual testing.

Current Testing	**Virtual Testing**
physical based	computer based
manpower intensive	computationally intensive
materials intensive	small material needs
weeks/months	hours/days
high disposal costs	low disposal costs

A computer model for the hydration and development of cement-based materials, based on over 10 years of research at NIST, is at the core of the VCCTL. Details of this research are available in [Web reference 1]. Other models, including those that predict rheological, mechanical, and transport properties and simulate degradation mechanisms, will eventually allow for durability modeling and service life prediction. In addition to the models, databases of fully characterized cements and aggregates exist which can be used as sources of input data for the models. Figure 1 shows the input needed for the microstructure-based models of VCCTL and the kinds of problems VCCTL can address.

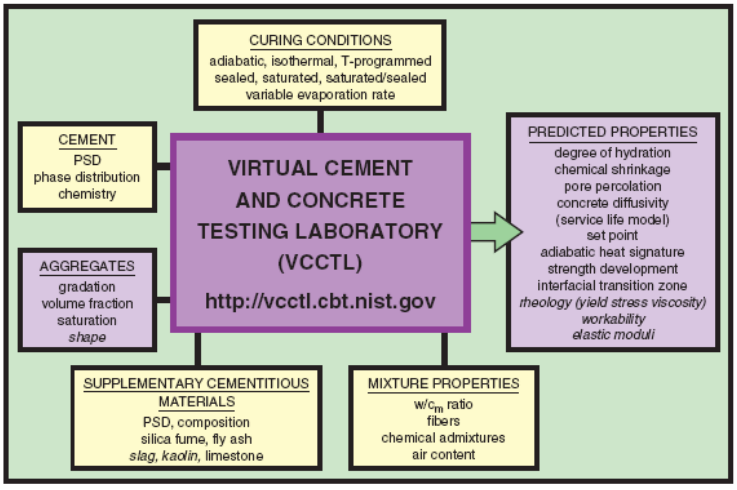

Figure 1. The input required for and the properties predicted by VCCTL [Bullard *et al.* 2005].

Enhancements and additions to the base models and web interface, based on the specific interests of the consortium members, are performed continuously and a new version of the software is made

available to the members annually. An educational version of VCCTL, with limited capabilities compared to the full consortium version, is scheduled to be released in 2008 and will be available at [Web reference 1].

The elastic properties of concrete greatly influence the strength and durability of structures and are particularly important for tall structures. VCCTL can perform standard tests 'virtually' by simulating hydration reactions for well-characterized mixture material data and performing calculations on the hydrated microstructure. Some standard laboratory tests performed regularly in many countries, such as ASTM C109, Standard Test Method for Compressive Strength of Hydraulic Cement Mortars (commonly referred to as the mortar cube strength test) and ASTM C215, Standard Test Method for Fundamental Transverse, Longitudinal, and Torsional Frequencies of Concrete Specimens, can currently be performed virtually, with appreciable accuracy.

2 WHAT VCCTL CAN OR WILL BE ABLE TO DO

As it is, the hydration model satisfactorily predicts the influences of particle size distribution, volume and surface area fractions of cement phases on hydration, and several phenomena involved with the addition of pozzolans. The rheology model uses a multi-phase approach to predict concrete plastic viscosity using a combination of simulation and measurements. In this approach, the paste viscosity can be measured using a paste rheometer and the effect of aggregate size, shape and grading can be added through computer simulations to obtain a concrete viscosity prediction. Work is being done on the interaction between particles in the model to account for the influence of chemical admixtures on the flow of cement paste. The flow of concrete in various geometries is also being investigated.

In the future, VCCTL software will allow users to generate and test virtual concrete mixtures, by selecting cements and fine and coarse aggregates from a database. The user will be able to choose from the fully characterized input materials in the database materials which are similar to the material actually being used or input new values obtained from the users laboratory characterization of the actual materials. The end-product will be a powerful tool for: predicting important values such as degree of consumption of starting ordinary portland cement (OPC) compounds, capillary porosity, non-evaporable water, hydroxyl ion concentration in the pore solution etc.; for conducting virtual rheology tests to check for flow properties thus minimizing the number of physical trial mixtures needed for selecting a mixture with desired properties; and for conducting virtual cylinder or cube tests for strength determination, reducing the number of physical validation tests drastically. The accurate predictions of the hydration model will make it possible to predict durability problems before they occur, potentially preventing great financial losses.

The mechanical properties model can, for a wide-range of water-to-cement ratio (W/C) values and curing ages, predict elastic moduli of cement paste, mortar and concrete accurately. The model can also make compressive strength predictions based on elastic moduli. Future research will investigate the accuracy of elastic modulus predictions of blended cement pastes and concretes. Viscoelastic properties, to be able to make accurate predictions of mechanical properties at early ages, and the effect of aggregate shape on strength are also being investigated. The virtual determination of the compressive strengths of mortars is explained in the following section and the results compared with physical tests on the mortars made using well-characterized cements and prepared under carefully controlled mixing and curing conditions.

3 PREDICTION OF MECHANICAL PROPERTIES OF MORTARS USING VCCTL

Three cements with contrasting chemical composition were selected to evaluate the accuracy of VCCTL predictions: Cement A, an ASTM Type I cement; Cement B, an ASTM Type V cement; and Cement C, an ASTM Type I white cement. Since virtual tests to determine mortar strength require

cement characteristics, and mixing and curing conditions to be input, polished specimens containing cements dispersed in epoxy were analyzed using a combination of scanning electron microscopy/back scattered electron images and x-ray images. This allowed the identification of different phases within cement grains in two-dimensions, and this area fraction was used to calculate the volume fraction of each phase in three-dimensions. This process has been described in detail in [Bentz and Stutzman 1994, Bentz *et al.* 1999, Bentz *et al.* 2003]. The particle size distributions for the cements were measured using wet (with isopropanol used to disperse the cements) low-angle light spectroscopy (laser diffraction - LD). Table 2 gives some characteristics of the three cements used.

Table 2. Chemical (based on SEM/EDS images) and physical characteristics of the cements. The fineness values are based on wet laser diffraction measurements. All units are volume fractions.

	Cement A	**Cement B**	**Cement C**
C_3S (%)	58.85	65.02	65.39
C_2S (%)	17.64	16.43	24.92
C_3A (%)	4.42	3.14	7.13
C_4AF (%)	11.68	8.35	0
Gypsum (%)	5.55	5.58	2.37
K_2SO_4 (%)	0.44	0.44	0.11
Mg/Ca (%)	0.13	1.04	0.08
Free lime (%)	0.67	0	0
Silica (%)	0.36	0	0
Kaolin (%)	0.16	0	0
Slag (%)	0.1	0	0
Fineness (m^2/kg)	483	545	614

The cement composition and some mixture properties were input into the hydration model to create a starting microstructure in 3-D, in which cement particles were randomly placed in a 3-D system of chosen dimensions so that the particle size distribution (PSD) matched experiment. By choosing a system, it is meant that a collection of voxels (3-D pixels), each containing a single starting phase such as C3S, C4AF, or water, is simulated. A water to cement mass ratio (W/C) of 0.485 was chosen for each simulation in accordance with ASTM C109. The system sizes were chosen to be (90 x 200 x 200) µm for cements A and C and (88 x 200 x 200) µm for cement B. Each system had a 10 µm thick aggregate slab dividing the shortest dimension in half to allow the simulation of an interfacial transition zone (ITZ) (see Fig. 2).

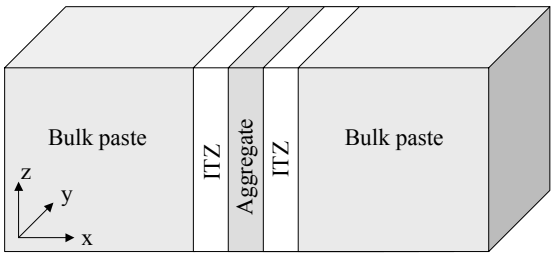

Figure 2. Shape and construction of the system chosen to simulate geometry and elastic properties of ITZ and bulk cement paste.

The system sizes were calculated [Sun *et al* . 2007] to attain the chosen W/C in the bulk of the starting microstructure, outside of the ITZ. The thickness of the ITZ was assumed to be equal to the median of the cement PSD [Bentz *et al.* 1993], and the required system size was determined considering the knowledge of the amount and physically measured PSD of Ottawa sand used in ASTM C109 (and assuming spherical sand particles), and calculating the total amount of paste in the system and the ratio

of the volume of the paste in the ITZ to the bulk paste (outside of the ITZ). Thus, the size of the system in the direction perpendicular to the aggregate surface was restricted so as to maintain the ITZ-to-bulk paste volume ratio. So, for example, the different sections/phases along the shortest dimension (88 μm) of the system for Cement B (for which ITZ thickness was 15 μm) were: bulk paste-24 μm; ITZ paste-15 μm; aggregate slab-10 μm; ITZ paste-15 μm; bulk paste-24 μm. The ITZ was taken as 15 μm for cements A and B, and 12 μm for the finer cement C. The size of the system in the directions parallel to the aggregate surface was made large enough in order to fit in the largest cement grains allowed by the cement PSD used.

Mixing and curing information such as aggregate fraction (to be used in tracking paste temperature), curing temperature and saturation conditions were input, as well as some other hydration parameters like a time conversion factor used to relate simulation time to actual time. The aggregate fraction was 0.53 to 0.54 for the three cements, varying because of their different measured densities). The starting microstructure was then hydrated virtually to age 28 d (6 h to 7 hours in actual computer time) and the resulting paste microstructure with a distribution of various hydration products was obtained. The elastic/mechanical property predictions were based on this hydrated microstructure in each of the three mortar cases. Predictions for different ages were made using the hydrated microstructures after the corresponding amount of time in the simulations, with the degree of hydration increasing with increasing computer time.

The time conversion factor used to relate simulation time to actual time was determined by matching the predicted degree of hydration (doh) to the experimental doh, measured at various ages (more frequently at early ages), using loss of bound water mass on ignition [Bentz, 1997]. The elastic moduli for the hydrated paste was determined using the elastic moduli of individual hydrated phases (from literature, available in Haecker *et al.* [2005]) and a program which, assuming cement paste is linearly elastic, treats each cubic voxel (containing only one hydrated phase) as a tri-linear finite element upon which the elastic equations are discretized and solved using a relaxation algorithm. The average stress for a given strain is used to determine the composite moduli, which are averaged over direction to minimize the effects of having a small, periodic model of a large microstructure. Details of this program and the assumptions involved are available in [Garboczi 1998, Garboczi and Day 1995]. The elastic moduli for the ITZ paste was calculated separately from the bulk paste by averaging the elastic properties of the voxels near the aggregate slab surface at a distance less than the assumed ITZ thickness, which is important because elastic moduli of the ITZ paste are lower than those of the bulk paste, due to its lower density. At the W/C used, this ratio was observed to be about 0.83 to 0.87, at an age of 28 d, for the cement pastes simulated with the ratio increasing with increasing age for a given cement paste. The elastic moduli for the mortars were predicted using the calculated/predicted cement paste moduli, the measured Ottawa sand PSD, elastic moduli for the sand determined averaging published elastic constants for alpha quartz, and a model air content, which was based on physical measurements. The air content for the mortars A, B, and C were determined to be 6.1 %, 5.3 % and 4.8 % by volume, respectively. The calculated mortar moduli were compared with resonant frequency experimental measurements (ASTM C215), on 51 mm x 51 mm x 203 mm (2 in x 2 in x 8 in) mortar prisms that were cured indentically to the ASTM C109 mortar cubes.

Compressive strength predictions were made semi-empirically, using equations relating measured dynamic Young's modulus, E_d, to measured static Young's modulus, E_c [Lydon and Balendran 1986], and relating measured static Young's modulus to measured compressive strength, fc [ACI 318]:

$$E_c = 0.83E_d \quad (1)$$

$$E_c = 4.73\sqrt{f_c} \quad (2)$$

The predicted dynamic Young's modulus was related to compressive strength by combining Eqns 1 and 2:

$$f_c = (E_d / 5.7)^2 \quad (3)$$

The compressive strength predicted for the three mortars and measured (using 2 in cubes as per ASTM C109) for different testing ages are given in Table 3. One standard deviation is reported for the C109 and C215 strength results. The uncertainty for VCCTL predicted strength is uncalculable because the error in Eqns 1 and 2 are meaningful only for the cements used in their development. This research serves in a way to estimate the uncertainty of predicted strength. The only uncertainty involved in the prediction of dynamic Young's modulus comes from the randomization of the placement of cement particles in the microstructure and is negligible. For each age in Table 3, the VCCTL predicted result and the ASTM C215 result are both based on using the dynamic Young's modulus, predicted or measured, in Eqn. 3 to give the predicted compressive strength.

Table 3. Comparison of predicted and measured (using 2 in cubes for ASTM C109 and 2 in x 2 in x 8 in prisms for ASTM C215) strength values for the three mortars. The VCCTL predicted and ASTM C215 based strength values were calculated by using Eqn. 3. All values are in MPa.

Age	Method	Cement A	Cement B	Cement C
3-day	VCCTL predicted	29.24	31.65	37.80
	ASTM C215 based	25.35 ± 0.17	26.00 ± 0.14	36.92 ± 0.23
	ASTM C109	26.58 ± 1.13	29.63 ± 0.31	41.07 ± 1.91
7-day	VCCTL predicted	32.55	34.86	40.79
	ASTM C215 based	30.41 ± 0.16	31.85 ± 0.16	41.15 ± 0.25
	ASTM C109	31.40 ± 0.99	32.59 ± 0.85	49.01 ± 0.95
28-day	VCCTL predicted	36.03	38.19	43.97
	ASTM C215 based	35.58 ± 0.16	39.23 ± 0.16	44.37 ± 0.26
	ASTM C109	38.21 ± 1.47	41.51 ± 1.30	54.39 ± 2.47

4 ANALYSIS OF THE RESULTS AND OBSERVATIONS

Since the VCCTL predicts the dynamic Young's modulus (E_d) for mortars and then uses Eqn. 3 to relate E_d to the compressive strength, f_c, comparison of VCCTL predicted f_c results with f_c results based on the ASTM C215 resonant frequency test, which are also calculated using Eqn. 3, actually gives an indication of how accurately VCCTL predicts E_d. The VCCTL predicted and the C215 predicted compressive strength values are within 18 % at 3 d, within 9 % at 7 d, and within 3 % of each other at 28 d. The percent difference between the predicted and measured E_d values is approximately doubled by using Eqn.3 to predict strength, so that the predictions of VCCTL for E_d are within 9 % of the C215 measurements at 3 d, 5 % at 7 d, and within about 1 % at 28 d. The accuracy of the predictions increases with increasing mortar age because, as mentioned, the VCCTL models assume linear elastic behavior and the effect of viscoelasticity is greater at early ages than at later ages.

It is also useful to compare VCCTL predictions with a direct measurement of strength, the ASTM C109 mortar cube uniaxial compression test, frequently performed to compare the strength of mortars made using different cements. It is seen in Table 3 that VCCTL predicted strengths were consistently lower than the C109 measured strengths, at 28 days. The difference at 28 days was within 8 % for cements A and B, but nearly 20 % for cement C. While this difference is obviously quite large, the C109 28 d strength result is also nearly 20 % higher than the C215 based result for cement C. This suggests that what is predicted by VCCTL, namely $E_{dynamic}$, may be quite accurate, but the equations used to relate $E_{dynamic}$ to f_c do not apply to cement C. This is supported by the observation that the difference between VCCTL predicted and C215 strength results are close for all three cements used. In

fact, the VCCTL and C215 strengths are within 2.5 %, whereas the C109 strength is more than 8 % greater than the VCCTL predictions for cement C at all three ages. Equations 1 and 2 were developed empirically, using a limited data set containing mostly common cement types, therefore it should not be surprising that they work well for some cements and less well for others. In addition, these relations were developed using results for concrete specimens at 28 days. Examining the composition of cement C in Table 2, it is seen that it is very finely ground and contains greater then 25 % of C_2S, notably higher than in typical cements, which may help explain the low accuracy of the strength predictions for the mortars made with this cement, using Eqn. 3.

A reported ASTM C109 strength is the average of three test results and the maximum difference between any result and the average must be less than 8 %. This shows that there is a certain amount of uncertainty in these results and that a compressive strength prediction within 5 % to 10 % of measured values is reasonably accurate. Some other factors that affect strength predicted in this way are air content, sand PSD and Young's modulus, state of saturation, and ITZ thickness. Air content is particularly influential on predicted strength and it was determined that a one percent change in air content used resulted in a ≈ 4 % change in strength. It was observed that the use of two different PSD results on Ottawa sand from the same container at two different times resulted in a ≈3 % change in the strength results. This is probably due to the assumption of a uniform ITZ thickness. It is assumed that the aggregate size is significantly larger than the cement particles and so the aggregate surface can locally be taken as a flat surface. Then, the ITZ thickness can be assumed to be due to the packing of cement particles on the surface. It was observed that varying the ITZ by 3 μm from the median cement size resulted in a 5 % to 6 % change in predicted strength. Considering all these factors, which are difficult to accurately control or determine, it can be said that VCCTL can predict the strength of mortars made using cements A and B quite well, and less accurately for cement C.

5 CONCLUSIONS

VCCTL is a powerful tool which allows the simulation of hydration reactions for cements and to a certain extent, supplementary cementitious materials. This enables or simplifies the prediction of many properties of cement pastes, mortars, and concrete which relate to durability and can eventually significantly reduce the amount of physical testing required for projects. It is well known that the mechanical properties of cementititous materials, such as strength, are closely tied to their performance in different environmental conditions. It was shown that VCCTL can, for well characterized starting materials, accurately predict the Young's modulus of cement mortars, which can then be related to strength. The accuracy of the strength prediction is limited only by the correctness of the equations relating Young's modulus and strength, for the cement used. Development of a better relation will increase the effectiveness of VCCTL as a tool to evaluate the durability of mortars and concrete.

Chloride Ion Measurement for Cement-Based Materials

Ceki Halmen [1]
David Trejo [2]

T 11

ABSTRACT

Measurement of the chloride concentration of cement-based materials is an important issue because chloride ions are known to cause corrosion of metals embedded in cement-based materials. ASTM C 1152 is the widely used standard to determine the chloride concentration of cement-based materials. The method uses potentiometric titration to determine the chloride ion concentration of cement-based materials. A faster and less expensive method to determine the chloride ion concentration of cement-based materials was developed under the Strategic Highway Research Program (SHRP). Samples of grout, flowable low-strength concrete, and normal-strength concrete with different amounts of chloride ions added during mixing were tested using the ASTM C1152 method and the rapid SHRP method. The rapid method was used with 1.5 and 3.0 gram samples. Results indicate that for grout and normal-strength concrete samples both methods are very well correlated for both 1.5 and 3.0 g samples. The slope values of calculated linear regression models were close to unity. Results also indicate that for mixtures that contain unconventional aggregates and supplementary cementitious materials such as the flowable low-strength concrete samples the slope value of the linear regression model is significantly different from unity. Samples of high volume fly ash containing mortar with different amounts of chloride ions added during mixing were tested using the ASTM C1152 and the rapid SHRP method using an internal calibration procedure. Results indicate that the use of internal calibration procedure did not improve the correlation of results of the two methods for mixtures containing high volumes of supplementary cementitious materials, however changed the slope of the linear regression model to unity. These results will allow for the use of the faster testing procedure that can save significant time and money.

1 INTRODUCTION

One of the most important deterioration mechanisms for reinforced concrete structures is the corrosion of metallic reinforcement embedded in concrete. Aggressive ions such as chlorides can diffuse through concrete to the steel interface. They can initiate corrosion by attacking the passive layer of the steel when they reach a threshold concentration level. Therefore accurate determination of chloride concentration in concrete and other cement-based materials is very important to evaluate the current conditions of reinforced concrete structures and to estimate their remaining service lives. To be statistically valid these chloride concentration measurements should be done with a large number of samples collected from different parts of the structures.

The most commonly used method to determine the chloride concentration of cement-based materials is potentiometric titration following the ASTM C 1152. Ground concrete powder is digested in nitric acid, heated, and filtered. The chloride concentration of the filtrate is determined through potentiometric titration using an ion specific electrode and a standard silver nitrate solution. This is a time consuming, labor intense, and costly procedure.

A rapid method to determine the chloride concentration of cement-based materials was developed under the Strategic Highway Research Program (SHRP) [Herald et al. 1993]]. This method requires ground concrete powder to be digested in a mixture of acetic acid and isopropyl alcohol. After the addition of a dilute sodium chloride solution, potential readings are collected from the solution using a chloride specific electrode and a high resistance voltmeter. Potential readings are then converted to chloride concentrations using a linear calibration curve. To obtain the linear calibration curve, potentials of a series of calibration solutions with known chloride concentrations are measured and logarithms of known chloride concentrations are plotted against their corresponding potential readings.

In a separate study related to this rapid method Clemeña and Apusen [2002] stated that using the described calibration procedure may lead to erroneous results due to unaccounted effects of ions in solution coming from different sources. To solve this problem they suggested an internal calibration procedure. In this procedure, small volumes of a solution with known chloride concentration are added to the digested sample solution and successive potential readings are recorded. Then the initial chloride concentration of the digested sample solution is calculated using the change in potential readings for each successive addition. The changes in the volume of the digested sample solution due to the additions are neglected.

If the results of the rapid method are well correlated with the potentiometric titration method results of the ASTM C 1152 standard, it can allow for more frequent and statistically accurate examination of reinforced concrete structures for chloride concentrations. This would lead to substantial cost and time savings

2 EXPERIMENTAL PROGRAM

The study presented in this paper compares the chloride concentrations of cement-based materials measured using the rapid method and the potentiometric titration method following the ASTM C 1152, and evaluates their correlation. The rapid method was used with 1.5 and 3.0 g samples and also an internal calibration method was evaluated. Four different cement-based materials were used in the study; normal strength concrete, low strength flowable concrete (LSFC), grout, and mortar mixtures containing fly ash (fly ash up to 60% by weight of cement replacement).

Grout mixtures were prepared using a proprietary repair grout for post-tensioned bridges that compensates for shrinkage in plastic and hardened states and that contains no chlorides or fine-aggregates. Two grout mixtures with 3 and 6 percent sodium chloride by weight of total mixture were prepared. Both mixtures had a water cement ratio (w/c) of 0.24. They were prepared by mixing 11.34

kg of grout with 2.72 kg of laboratory tap water that had 0.42 and 0.84 kg dissolved sodium chloride for 3 and 6 percent sodium chloride mixtures, respectively. A total of 12 cylindrical samples, 75x150 mm in size, were prepared for each mixture to use in chloride concentration determination.

Four different normal strength concrete mixtures with two different w/c's (0.4 and 0.6) and two different chloride concentrations (3 and 6 percent by weight of total mixture) were prepared. The normal strength concrete mixture with a w/c of 0.4 consisted of 872 kg/m^3 cement, 349 kg/m^3 water, 1359 kg/m^3 crushed limestone, and 1390 kg/m^3 sand. Sodium chloride in the amount of 119 and 238 kg/m^3 was added to obtain 3 and 6 percent sodium chloride by total mixture weight. The normal strength concrete mixture with a w/c of 0.6 consisted of 582 kg/m^3 cement, 349 kg/m^3 water, 1359 kg/m^3 crushed limestone, and 1621 kg/m^3 sand. Sodium chloride in the amount of 117 and 235 kg/m^3 was added to obtain 3 and 6 percent sodium chloride by total mixture weight. A total of 6 cylindrical samples, 100x200 mm in size, were prepared for each w/c and percent chloride combination.

Mortar mixtures had a water cementitious material ratio (w/cm) of 0.33. Mortar mixtures were prepared at four different fly ash contents by replacing 0, 35, 50, and 60 percent by weight of cement with fly ash. Class F fly ash was used. For each fly ash content three mixtures with 0, 1, and 3 percent chloride by weight of total cementitious material (cement and fly ash) were prepared. Table 1 shows the mixture designs of mortars with different fly ash and chloride contents. For each fly ash and chloride content combination 3 mortar cubes, 50 mm in size, were prepared.

Table 1. Mixture designs for mortars with different fly ash and chloride contents.

Fly ash [%][1]	NaCl [%][2]	Cement [kg/m^3]	Fly Ash [kg/m^3]	Water [kg/m^3]	Sand [kg/m^3]	NaCl [kg/m^3]

[1]percent by weight of cement
[2]percent by weight of total cementitious material (cement and fly ash)

Unlike normal strength concrete, grout, and mortar samples, 15 LSFC cylinders, 75x150 mm in size, were prepared without adding any chlorides into the batch water. These 15 cylinders were selected randomly from a large number of samples that were exposed to a 3 percent sodium chloride solution for 26 months. Compressive strength of LSFC cylinders varied from a minimum of 0.12 MPa to a maximum of 1.09 MPa. Table 2 shows the mixture designs of randomly selected samples and the numbers of samples from each mixture.

All cement based materials contained ASTM C 150 type I cement. Normal strength concrete, grout, and mortar samples were cured for 28 days following ASTM C192/C 192M-02, before they were ground using a profile grinder. All ground samples were passed through a No. 20 sieve and tested for chloride content following the ASTM C 1152 and the rapid method. Because LSFC samples were too weak for grinding, they were cut and a sample collected from their center was ground using a ceramic

mortar and pestle. Rapid method was performed using 1.5 and 3.0 g powder samples of normal strength concrete and grout. For mortar and LSFC the rapid method was performed using only 3 g powder samples. Potentiometric titration was performed using 10 g powder samples as required by the ASTM C 1152 standard. A chloride ion specific electrode and a high resistance multi-meter combination with accuracy of 0.001 mV was used to perform the rapid method.

Table 2. Low strength flowable concrete mixtures and the number of samples tested.

3 STATISTICAL ANALYSIS AND RESULTS

Two multiple linear regression analyses were performed with the chloride concentrations measured using the titration method as the response variable. Chloride concentrations were measured from 1.5 and 3.0 g normal strength concrete and grout samples. Chloride concentrations measured using the rapid method and mixture type were used as explanatory variables. Mixture type was a classification variable with three values; grout, normal strength concrete with w/c of 0.4, and normal strength concrete with w/c of 0.6. Both models were significant with an R^2 of 0.98. However, analysis of variance indicated that the mixture type was not a statistically significant variable. Therefore two simple linear regression analyses were performed for 1.5 and 3.0 g samples using the chloride concentrations measured using the titration method as the response variable and the chloride concentrations measured using the rapid method as the explanatory variable. Both models were again statistically significant with an R^2 of 0.98. However, analysis of residuals indicated that the spread of residuals was increasing with increasing chloride concentration for both models. This indicates that the assumption of constant variance of residuals for regression analysis was not satisfied.
If the spread of residuals is dependent on the value of measured chloride concentration then using the model shown in equation 1 to define the relationship between the measured chloride concentrations would be more appropriate.

$$\frac{\left[Cl^-\right]_{ASTM\,C1152}}{\left[Cl^-\right]_{rapid}} = c + k\frac{1}{\left[Cl^-\right]_{rapid}} \qquad (1)$$

Where
$\left[Cl^-\right]_{ASTM\,C1152}$ is the chloride concentration measured using the titration method

$\left[Cl^-\right]_{rapid}$ is the chloride concentration measured using the rapid method

If the assumption of dependence is correct then the simple linear regression model between the chloride concentrations measured using the titration and the rapid method can be obtained by switching the coefficients of equation 1 as shown in equation 2. This model should satisfy the regression assumption of constant spread of residuals.

$$\left[Cl^-\right]_{ASTM\,C1152} = c\left[Cl^-\right]_{rapid} + k \qquad (2)$$

Simple linear regression analysis was performed for the chloride concentration values measured from 1.5 and 3.0 g samples using the form shown in equation 1. Analysis of residuals indicated that all assumptions of linear regression were satisfied. Later the coefficients were switched to get the simple linear regression models in the form shown in equation 2. Figures 1 and 2 show simple linear regression models and their 95% confidence intervals about the mean and their 95% confidence interval for prediction for 1.5 and 3.0 g samples, respectively.

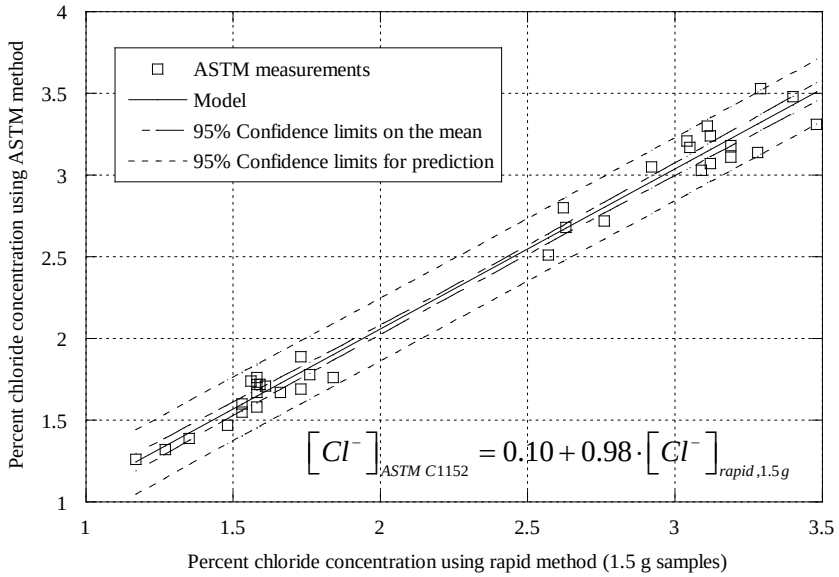

Figure 1. Chloride concentration measured using rapid vs. titration method for 1.5 g samples.

The 95% confidence interval about the mean defines the range of values where the mean of predicted chloride concentration values using the titration method will be with 95% probability. The prediction interval defines the range of values where each individual measured chloride concentration will be with a 95% probability. Since the spread of the means of predicted values is expected to be lower than the individual predicted values the confidence interval about the mean is narrower than the confidence interval for prediction.

Analysis shows that the slope values for both models are statistically significant and they are very close to unity, i.e. a change in the value of chloride concentration measured using the titration method corresponds to an equal change in the value of chloride concentration measured using the rapid method. For the 3.0 g samples the intercept is not statistically significantly different from zero and for the 1.5 g samples there is significant intercept value of 0.1. Both models have an R^2 of 0.98. This means that 98% of variability of the chloride concentration data measured using the titration method could be explained by the model.

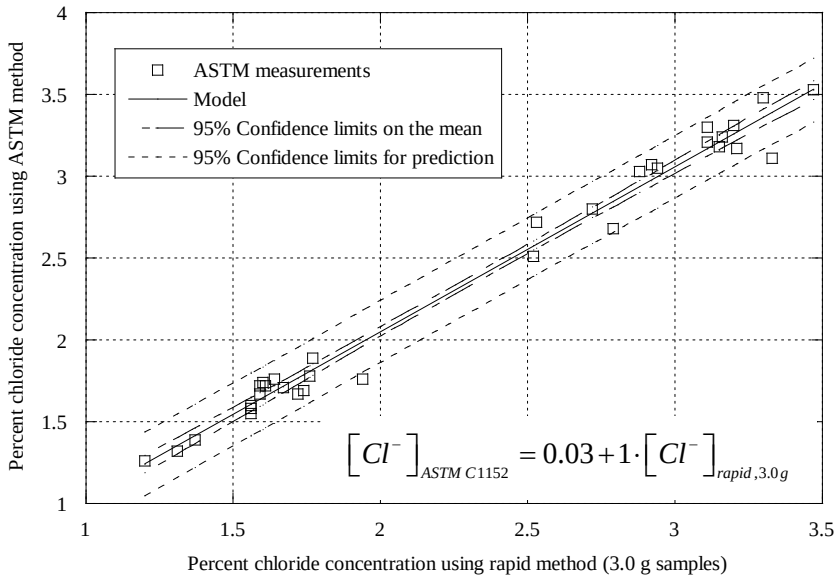

Figure 2. Chloride concentration measured using rapid vs. titration method for 3.0 g samples.

A simple linear regression analysis was also performed between the chloride concentration values measured using the titration method and the rapid method for the LSFC samples. Analysis indicated that using a model in the form shown in equation 1 was not necessary. It should be pointed out that because chlorides were not mixed into these samples, the measured chloride concentrations were much lower compared to the normal strength and grout samples. Figure 3 shows the regression model and its 95% confidence intervals about the mean and for prediction.

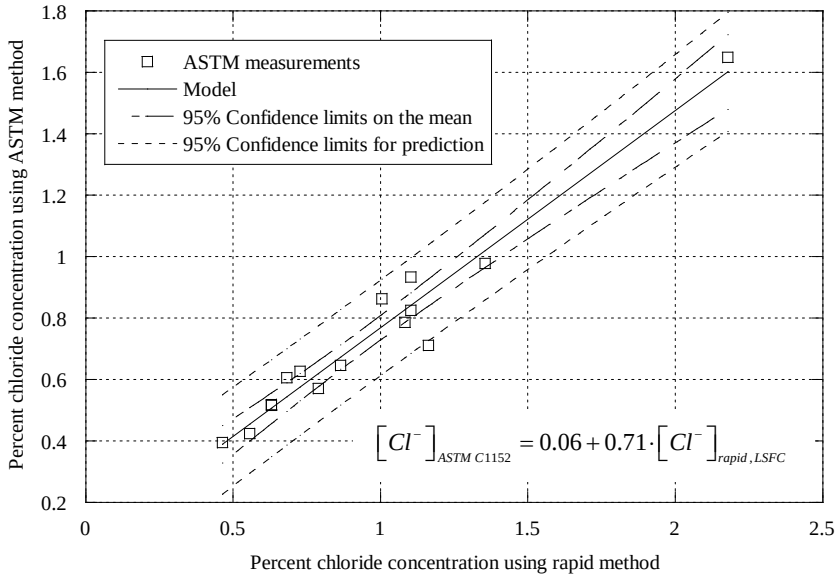

Figure 3. Chloride concentration measured using rapid vs. titration method for LSFC samples.

Analysis indicates that the intersection value was not statistically significantly different from zero similar to the results obtained from 3.0 g normal strength concrete and grout samples. The slope was statistically significant and less than unity (0.71). The model had an R^2 value of 0.95. The LSFC samples are inherently different from normal strength concrete and grout samples due to their low cement content, high w/c ratio, and high amounts of supplementary cementitious materials.
To examine if the difference in results obtained from the LSFC samples and the normal strength concrete and grout samples were due to the calibration procedure used for the rapid method as suggested by Clemeña and Apusen [2002] mortar mixtures containing fly ash were tested. Mortar

mixtures containing fly ash up to 60% by weight of cement were prepared and evaluated using the titration method and the rapid method. The potential readings obtained from the rapid method were converted to chloride concentration values using the internal calibration method described by Clemeña and Apusen [2002].

Analysis indicated that performing simple linear regression using the form of model shown in equation 1 was necessary. Figure 4 shows the regression model and its 95% confidence intervals about the mean and for prediction. The chloride concentration values shown on the x-axis were measured using the rapid method with the internal calibration procedure.

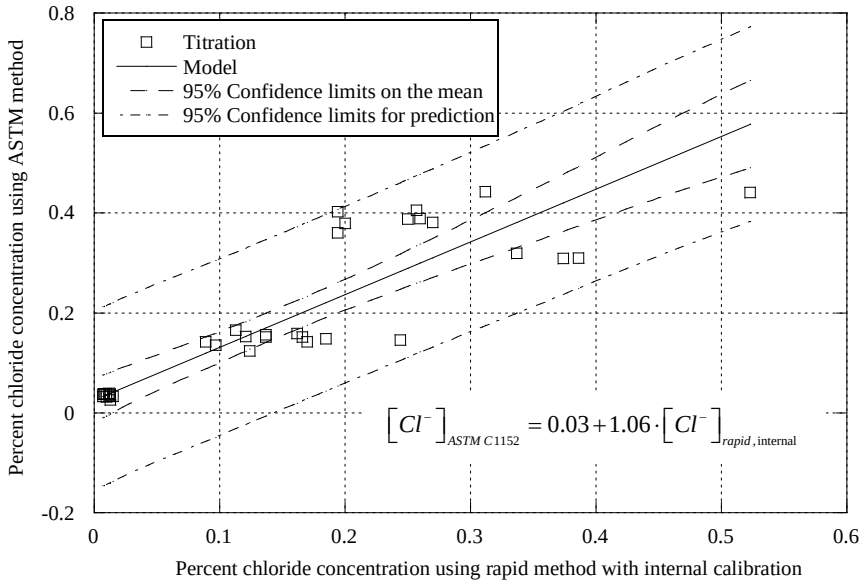

Figure 4. Chloride concentration using rapid method with internal calibration vs. ASTM method.

Analysis indicated that the slope of the simple regression model was statistically significant and close to unity similar to the normal strength concrete and grout samples. However, the R^2 value of the model was 0.89. This indicates that although the slope value was similar to normal strength concrete and grout samples, a smaller portion of the chloride concentration variation measured by the titration method could be explained by the developed model, i.e. predictions made using this model will be less accurate compared to the models developed for normal strength concrete and grout samples. This is also indicated by the wide 95% confidence interval for prediction shown in Fig. 4.

4 SUMMARY AND CONCLUSIONS

The rapid chloride concentration measurement method developed under the SHRP was compared to the commonly used potentiometric titration method for determining chloride concentration of cement-based materials. Normal strength concrete, low strength flowable concrete, grout, and mortar mixtures were used. In general, analysis indicates that the results of both methods are well correlated for a wide variety of cement-based materials.

For normal strength concrete samples and grout samples used in this study, testing performed with 3.0 g samples indicated a very well correlation between the results (R^2 of 0.98). A statistically not significant intercept value and a significant slope value close to unity showed that the results obtained from both methods were almost the same. Neither the type of mixture, concrete or grout, nor the w/c of the mixtures did have an effect on the relation of the results. For 1.5 g samples addition of a constant to the results obtained from the rapid method was necessary to convert them to the results measured using the titration method. The slope was close to unity and the R^2 was 0.98.

For LSFC samples the results of both methods were again very well correlated but the slope and intercept of the model were statistically significant and they were different from zero and unity, respectively. This indicated that chloride results obtained from both methods were not similar for these samples and the simple linear regression model was necessary to convert the results. However, the R^2 of the model was 0.95 showing that a high amount of variation could be explained by the model.

To check the hypothesis that the chloride concentrations measured using the rapid method with the internal calibration will be more accurate for cement-based materials containing supplementary cementitious materials, mortar mixtures containing fly ash were tested. Analysis indicated that the results were highly correlated and the slope of the model was close to unity. However, the R^2 of the model was 0.89 which indicated that a lower amount of variation of the results could be explained by this model. Based on these results authors recommend to test a group of samples with both methods (titration method and the rapid method) to establish a conversion model when the rapid method is going to be used to measure the chloride concentrations of mixtures with supplementary cementitious materials.

ABSTRACT

This study describes a preliminary assessment of non-asbestos fiber cement samples exposed to the elements for forty months in a tropical climate. Fungal colonization was determined by culture, optical and scanning electron microscopy. Preliminary assessment of its correlation with quantitative colour change was carried out. A positive Pearson's coefficient (r = 0.9) was observed only between total fungal structures and color change on the reverse surface, but not on the surface exposed to the north**;** on the latter particulate material from the burning of fossil fuels contributed to the dark colour. *Cladosporium*, *Pestalotia/Pestalopsis* and *Trichoderma* were three main fungal genera detected on fiber cement exposed for 40 months in the tropical climate of São Paulo. Mycelia sterilia also had high frequency.

1 INTRODUCTION

Fiber cement is a composite building material that can be used in a wide range of applications. Since asbestos is considered carcinogenic [Chiappino, 2006] there is a tendency to increase the use of asbestos free fiber cement composed of natural and synthetic fibers. These fibers increase strength and toughness of the composite hence they are extremely important to the mechanical performance of fiber cement products [Dias, 2005].

Cellulose fiber deterioration in the alkaline cement matrix has been considered the main problem of durability of fiber cements [Gram 1983, Sarja 1988, Bentur & Akers 1989]. Synthetic fibers like poly (vinyl (alcohol)) (PVA), on the other hand, have been considered durable in the cement matrix [Kalbskopf et al. 2002]. The main effects of fibers deterioration are embrittlement and decrease of mechanical strength.

Biodeterioration is not a frequent worry in fiber cement technology. Some researchers declare that the alkalinity of the matrix inhibits the deterioration of fiber cement products by this mechanism. De Souza et al. [1997] have studied composites of cement-bonded wood particleboard, which presents a high organic/inorganic ratio compared with conventional fiber cement formulations. These authors concluded that fungi and termites did not cause significant deterioration (weight loss) even after accelerated carbonation of composite. In this research the fungi studied were basidiomycetes (Phylum Basidiomycota).

In the current work the term fungi is designated to moulds (Fungi Imperfecti, also sometimes known as Deuteromycota); they are composed of filamentous structures called hyphae, which can differentiate and produce rounded forms called spores or conidia.

Fungi can grow on the surface of materials and cause dark discoloration. On roofs this can compromise the thermal comfort inside the buildings. However colour changes roof surfaces affect the thermal performance of the entire building, users comfort or energy consumptions, they also can affect urban microclimate due to spectral reflectance and infrared emmitance [Synnefa et al, 2006].

Cellulose is easily transformed by cellulolytic microorganisms including bacteria and fungi. Due to high alkalinity of fresh cement materials usually microorganism can not grow before carbonation occurs. There have been some patents registered for the incorporation of biocides into cellulose to prevent microbial attack on fiber cement. Nevertheless there is little literature describing the colonization of fiber cement in natural weathering conditions and which microorganisms are more frequent.

This study describes mould colonization of non-asbestos fiber cement composed of PVA and cellulose fibers exposed to the elements for forty months in a tropical climate, in São Paulo, Brazil.

2 MATERIAL AND METHODS

2.1 Materials

Table 1 presents the materials and the formulation (labeled PVA 14) that were used for the preparation of specimens. Six-millimeter length poly (vinyl (alcohol) (PVA) fibers, unbleached long cellulose fibers and newspaper waste were employed as reinforcement. Densified silica fume, ordinary Portland cement and limestone filler from the Brazilian market were also employed.

2.2 Natural Aging

Fiber cement specimens were exposed in São Paulo, a large industrial metropolis with a mean annual temperature of 19.5 °C, an annual rainfall of ~1500 mm, a mean relative humidity of 78% and

presence of urban and industrial pollution. These specimens were exposed in metallic racks facing to the true north with a slope of approximately 45° (Fig. 1). After 40 months of exposure they were submitted to fungal analysis.

Table l. Materials and fiber cement formulations [Dias 2005].

Materials	**Dry weight fraction (%)**
Portland cement	75.20
Limestone filler	12.72
Silica fume	6.68
PVA fibers	1.40
Unbleached cellulose fibers	1.20
Newspaper waste	2.80
	Volume fraction (%)
PVA fibers	3.00
Cellulose fibers	8.60

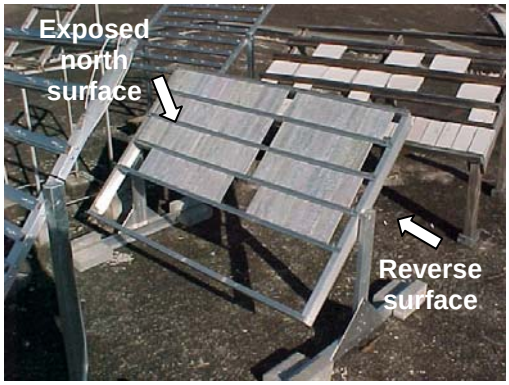

Figure 1. Rack with fiber cement specimens.

2.3 Fungal Sampling Method

Brush sampling was carried out by mean of a toothbrush previously packaged in aluminuim foil and sterilized for 15 minutes at 120° C at 1 atmosphere of pressure and dried for 2 days at 80° C. The toothbrush was moistened in saline sterile solution and brush sampling was performed five times in a clockwise direction. Afterwards toothbrushes were kept in closed tubes containing 10 mL of sterile saline solution (0.85%). Fungi were recovered from the brush in an ultra-sonic bath Thornton C/7, T7 for 10 minutes and diluted 1:10 in sterile saline solution. This suspension was used to evaluate culture and total fungal structures.

2.4 Quantitative Culture

Culture was carried out with 100 µL of the fungal suspension as described in 2.3 and inoculated by spread plate method in two Petri dishes containing Sabouraud Dextrose Agar. The plates were incubated at 25° C for 48-72 hours and colony forming units (CFU) were recorded.

2.5 Quantification of Total Fungal Structures by Neubauer Chamber[1]

Fungal suspensions as produced in Section 2.3 were analyzed in Neubauer chamber[1] in optical microscope in order to quantify total fungal structures (hyphae and spores).

[1] Chamber used in to count biologic structures

2.6 Color Analysis by Spectrophotometry

BYK Gardner Color-Guide 45/ 0.6805 equipment was used. According to CIE Lab, L* : Luminosity (black L*=0 to white L*=100); a*: red to green (positive and negative values respectively) and b*: yellow to blue (positive and negative values respectively) were analysed.

The total difference of colour was defined as $\Delta E = \sqrt{(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2}$, in this case the average values of L*, a* and b* of unexposed samples were used as initial reference color.

2.7 Scanning Electron Microscopy

The samples were submitted to SEM. A LEO Leika S440 microscope with an acceleration voltage of 20 kV and current of 150 mA was used to examine the fractured section and the surface of specimens. All samples received carbon coating in a Spputering Baltec SCD 050 equipment before SEM examination.

2.8 Statistical Analysis

Statistical analysis of fungal quantification was carried out according to the non parametric Mann-Whitney test (α=0.05%). Pearson's correlation was used to analyze differences between colour and fungal quantification. BioEstat program was used for both analyses.

3 RESULTS

Results of fungal growth measurements are presented in Table 2 for both viable fungi and total fungal structures. According Mann-Whitney test viable fungi is significantly lower than total fungal structures in both exposed and reverse surfaces of fiber cement.

Viable fungal colonization assessment by culture method, according Mann-Whitney test, was higher in reverse surface than exposed surface. However, for total fungal structures evaluation there is no significant difference between exposed and reverse surface.

Table 3 presents L*, a* and b* of unexposed samples which average is used as initial reference. Besides of this L*, a* and b* of exposed to north and reverse ones. This Table also presents total difference of colour (ΔE**)** between each measure and the average of unexposed samples as describes in 2.6.

Fungal relative frequency is presented in Table 4. *M. sterilia*, a group of fungi that does not produce spores, was found in high frequency (54% and 67% on exposed and reverse surfaces, respectively).

Table 2. Fiber cement quantification per 5.4 cm^2 of sampled area of viable fungi in CFU and total fungal structures.

Viable fungi CFU		*Total fungal structures*

Curvularia.	8	0
Fonsecaea	0	7

Scanning electron microscopy images obtained after 40 months aging are presented in Figures 3 and 4. Figure 3 (a) shows a fractured region of fiber cement**;** cellulose fibers are bigger and more irregular than PVA fibers. Figure 3 (b) shows fungal hyphae growing on cellulose fiber.

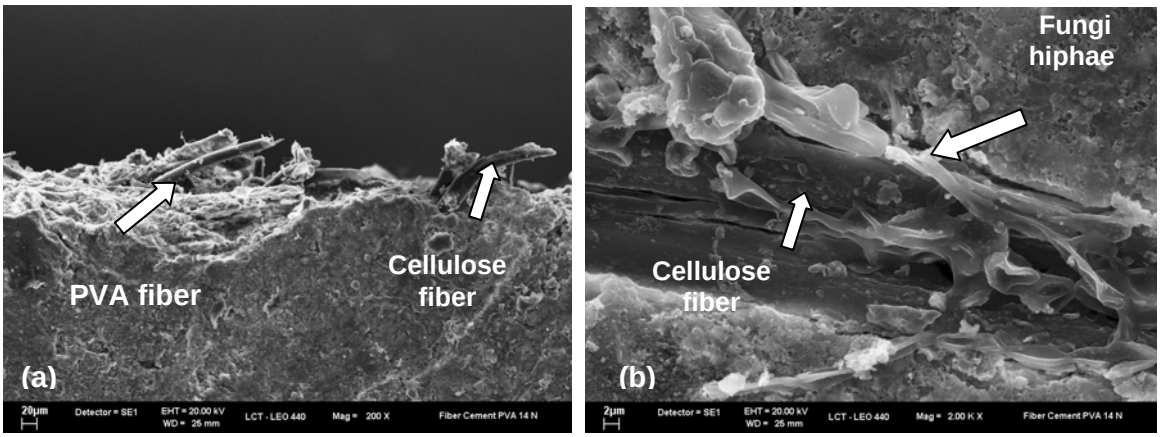

Figure 3. (a) Fractured sample after 40 months exposure, (b) Fungi colonization on cellulose fiber.

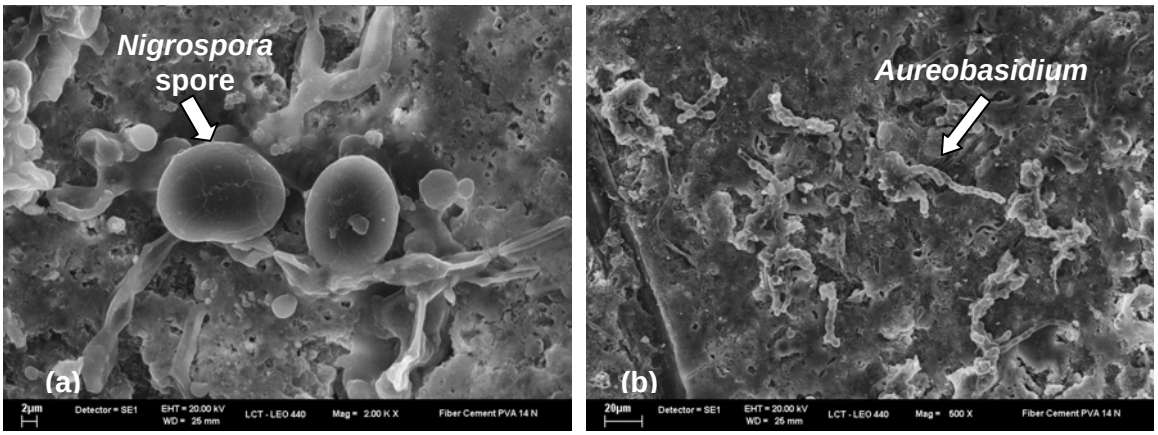

Figure 4. Fungal colonization on fiber cement matrix after 40 months exposure. Round structure is similar to *Nigrospora* spore (a). Structures are similar to *Aureobasidium* genus (b).

4 DISCUSSION

There is no correlation between total fungal structures quantified by Neubauer chamber in the optical microscope and viable fungi quantified by culture. Some portions of these fungal structures could be non viable and hence resistant to culture in the media due to environmental conditions like UV irradiation, temperature and desiccation**.** Another reason could be that the media used were not suitable for xerophilic fungal growth. In addition, some fungal structures detected by Neubauer chamber can be already dead.

As shown by scanning electron microscopy, in this preliminary assesment PVA fibers did not present fungal colonization. The cellulose fibers were colonized by fungi as well as the cement matrix.

In the surface exposed to the north irregular particles about 20% larger than fungal structures were found more often than on the reverse surface. The presence of particulate material from burning of fossil fuels is to be expected, since the natural aging station is located in São Paulo, the biggest city of Brasil with high pollution records.

Regarding L* (black L*=0 to white L*=100) measurement both north-exposed and reverse samples showed significant lower values in relation to unexposed reference ones, confirming the darker surface in relation to unexposed samples after aging.

Fungi can contribute to the darkening of fiber cement as well as particulate material from the burning of fossil fuels. Some species of *Trichoderma* are quoted in the literature as cellulolytic fungi [Persson, 1991] and they are found in a relative frequency of about 30%. Others relevant fungal genera detected in this work, such as *Cladosporium* and *Pestalotia/Pestalopsis*, are also being isolated in different building materials in Brazil. *Cladosporium* has also been described as a cellulolytic fungus [Abrha, 1992]. *Mycelia sterilia*, a non sporulating group, was found in high frequency.

As described above the focus of this study was not to investigate the degradation of fiber cement by fungi, but the influence of fungal colonization on the surface darkening of this material. Future studies will focus on cellulose colonization inside the specimens submitted to natural aging.

5 CONCLUSION

Fungi detected in the current work contribute to darkening of fiber cement since most of them are usually melanin producing and their structures like hiphae or spores are brown to black. Particulate materials from burning of fossil fuels, typical from urban areas, contribute to dark discoloration, mainly on the specimens' surface exposed to the north.

Durability of the HPC Cured in Sulphate Environment

ABSTRACT

The use of integral high performance concrete of the cementitious additions as the fly ash, the silica fume or the cementitious hydraulic slag increased considerably during two last decades. The works in HPC last longer and involve maintenance costs less low than those out of ordinary concrete. Moreover, the HPC uses less cement, which decreases the CO_2 emissions. A vaster use of the integral high performance concrete of the cementitious additions could thus involve benefit as well environmental as financial and build more durable works.

In the current state, research on the concretes with high performances in Algeria is especially centered on their formulations in order to produce concretes of better resistances and durable.

However, an optimal composition depends on several parameters, in particular on the choice of the ingredients. The effect of the cementitious additions and their smoothness remains little undertaken. This is why we propose in this work, to formulate of high performances concretes with and without cementitious addition. And, to treat the influence of the slag of the iron and steel plant of El-hadjar (Algeria), finely crushed and substituted for part of cement, on the physicomechanical characteristics of the elaborate concretes. The mode of conservation is the gypsum water (corrosive condition).

1 INTRODUCTION

The concrete of high resistances to fact the object of many research, since strong a long time, from the very start of the century, the concretes of resistance higher than 50 MPa were obtained on building site, result very meritorious if one compares the quality of materials available at the time to that of cements and aggregates of today. However, for a few years, a renewed interest has appeared, in the whole world, for the concrete with high performances, obtained thanks to the use of thinners and silica smoke. The reason of this new reversal must be sought, makes some not only in the possibility of reducing the structures by an increase in the pressures in services, but rather in the improvement of the durability of material in service in chemically aggressive mediums [Mekki 2002].

The action of sulphated underground water offers the simplest case of an aggression giving rise to expansive new compounds starting from the components of cement. The calcium sulphatic combines with aluminates of cement to form a salt (the ettringite) or salt of Candlot $C_3A.3CaSO_4.32H_2O$, whose crystallization accompanied by expansion causes the cracking of the concrete. It facilitates the penetration of the aggressive agents to the reinforcements which are, in their turn attacked.

It is possible to modify the microstructure of the concrete by incorporating mineral products. These cementitious additions modify the microstructure of the concrete in term of physical and chemical characteristics. The pozzolanic mechanism of reaction of the cementitious additions can be briefly described like the reaction of silica with the lime released by the hydration of cement, in the presence of water. It results from it from the C-S-H with poor Ca/Si report/ratio. Although this reaction is prompt and early, it is limited by the quantity of water in the HPC.

The slag of blast furnace is a by-product of the manufacture of the cast iron in blast furnaces starting from flux and coke, iron ore (the oxides FeO, Fe_2O_3, Fe_3O_4 in variable proportions) possibly. One collects it liquid towards 1550°C above the cast iron. The vitrified slag, granulated is a product hydraulic, i.e. likely to give by basic activation, of the stable products of hydration. It is obtained by brutal cooling by water under pressure; it is a sand of granulometry 0/5 mm.

In the slag cements, the clinker is the principal activator of the slag; however the first produced hydrates will be those of the clinker; C-S-H and $Ca(OH)_2$ which uniformly cover the grains with the slag and the clinker ; thereafter the lime excess activates the hydration of the slag with a texture C-S-H similar to that of cements; it then results from it from calcium silicate hydrates and hydrated aluminates tetracalcic [Baron and Olivier [1997]; Jiang and Grandet [1989]].

What allows the solubilization of a new quantity of products until a concentration involving a new precipitation of hydrated compounds. It is this repetition of the cycle dissolution - concentration - precipitation (several years), which constitutes the catch and the hardening of the slag vitrified [Alexandre and Sebileau [1988].

Resulting precipitations are normally intended to seal the large pores; however, precipitations of the slag cements are fixed and impermeable whereas those of Portland cements are not it. Consequently the ordinary concrete is more porous than the concrete with the slag [ACI [1974]; Venuat [1971]].

[Sarkar *et al.* 1970] had shown that with a ground slag with a smoothness of 800 m^2/kg, one obtains a significant reduction of the heat of hydration of cement, a high-strength concrete and with more compact structure. [Péra *et al.*1988] showed that more the granulometry of the slag is high, better are its performances.

2 EXPERIMENTAL

2.1 Materials

2.1.1 The Cement

The *Portland cement* used is a CPA CEM I 52,5 of the factory Saint Pierre Lacour, whose chemical composition is deferred on table 1.

Table 1. Chemical composition of cement CEM I 52,5

Elements	*CaO*	*SiO_2*	*Al_2O_3*	*Fe_2O_3*	*MgO*	*SO_3*	*K_2O*	*Na_2O*	*IR*	*PF*	*CaO_l*
%	64,50	21,01	4,90	2,80	0,90	3,00	0,90	0,20	0,20	1,10	0,45

The mineralogical composition of this cement calculated by Bogue's method is as follows :
- C_3S ..... 65,94 %
- C_2S ..... 10,47 %
- C_3A ..... 8,24 %
- C_4AF ..... 8,52 %

2.1.2 The Slag

The slag used is a by-product of the manufacture of the cast iron, factory of El-hadjar ' Annaba'. It is a sand of granulometry 0/3 mm, granulated slag cooled with the jet of water, vitrified i.e. amorphous. Table 2 gives its chemical composition. It is tiny room powders some until obtaining a large surface specific compared to cement.

The slag of El-hadjar has the advantage of being rather acid (the CaO/SiO_2 report/ratio varies within the limits of 0,95 - 1,04); it is relatively stable. The result of the micro-analysis (figure 1) comes to confirm this assumption.

Table 2. Chemical composition of slag.

Elements	*CaO*	*SiO_2*	*Al_2O_3*	*Fe_2O_3*	*MgO*	*SO_3*	*K_2O*	*Na_2O*	*IR*	*PF*
%	39,77	41,69	7,05	1,41	5,49	0,15	0,44	0,10	0,12	0,11

Other physical properties: Specific surface = 8 500 cm^2/g.

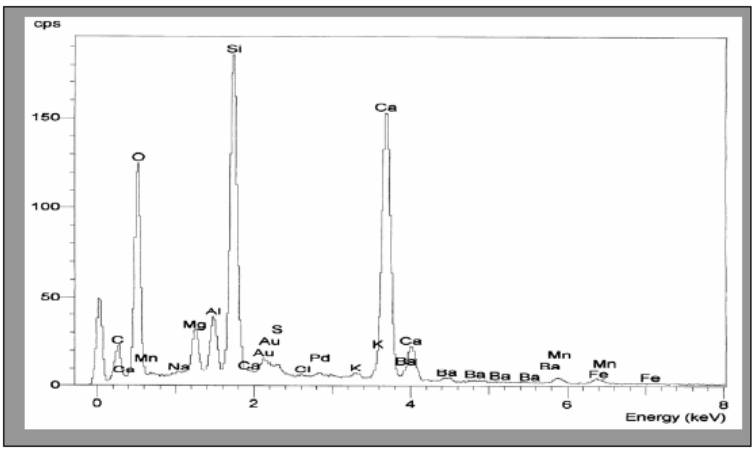

Figure 1. Micro-analysis (x2000) of slag.

In addition to its pozzolanic capacity, the slag with such a granularity (specific surface doubles cement), will ensure the thickening of the matrix : these particles can fit between the cement grains [Behim *et al.* 2002].

2.1.3 Aggregates

Obtaining the characteristics necessary for the concrete passes imperatively by the settling of optimal compositions of the various aggregates.

These aggregates for a great part are rolled: quaternary deposit of Unpleasant (Ille and Vilaine, France), primarily siliceous in the form of quartz and, for a weak part, crushed : corneal and metaquarzite.

For this work, after preliminary tests relating to as well the rheology of the mixtures of concrete as its crushing as a hardened material, the choice was concerned the aggregates of class 3/8 and 8/15.

As for sand used, it is a coarse river sand, whose fineness modulus is worth 2,47.

2.1.4 The Additive

The additive used is a plasticizing water reducer for concretes with high performances in conformity with standard *NF EN 934-2* provided by company SIKA.

The SIKAMENT FF 86 allows the concrete clothes industry very weak report/ratio W/C having mechanical resistances very high in all term and in particular to the youths.

2.2 Formulation

The final composition of High Performances Concrete (HPC) without addition and that of High Performances Concrete with addition of slag (HPCS), after optimization [Chaïd *et al.* 2004] are reported on table 3.

Table 3. Compositions of concretes with and without slag.

Components	*Cement*	*Sand*	*Gravel 3/8*	*Gravel 8/15*	*Water*	*Additive*	*Slag*
(HPC)	500 kg/m^3	573 kg/m^3	130 kg/m^3	915 kg/m^3	150 l/m^3	8 l/m^3	-
(HPCS)	425 kg/m^3	573 kg/m^3	130 kg/m^3	915 kg/m^3	150 l/m^3	8 l/m^3	75 kg/m^3

The procedure of malaxation to make the concrete specimens is the following :

1 - The aggregates and the binder (cement + slag) are mixed dry during for one minute.

2 - The mixing water is added with a third of the volume of superplastifiant and malaxation continues for 2,5 mn.

3 - The remaining superplastifiant is added with a final malaxation of one minute.

The concrete specimens are preserved in their mould in wet place (20°C, 95% HR) during 24 hours. They then undergo immersed in gypsum water at 20° C until the fixed terms.

The physical, mechanical and microstructural characteristics of the concretes with and without addition of slag are compared.

3 FINDINGS AND ANALYSIS

3.1 Densities and mechanical resistance

Figure 2 shows the evolution of the density of the various concretes preserved in gypsum water. One note a thickening of the concrete with slag addition. Indeed, the high grinding of the slag, combined with its interaction with Portlandite to form no soluble calcium hydrosilicates, favors the increase of the compactness of the hardened concrete. This explains the increase of its density compared to the control concrete.

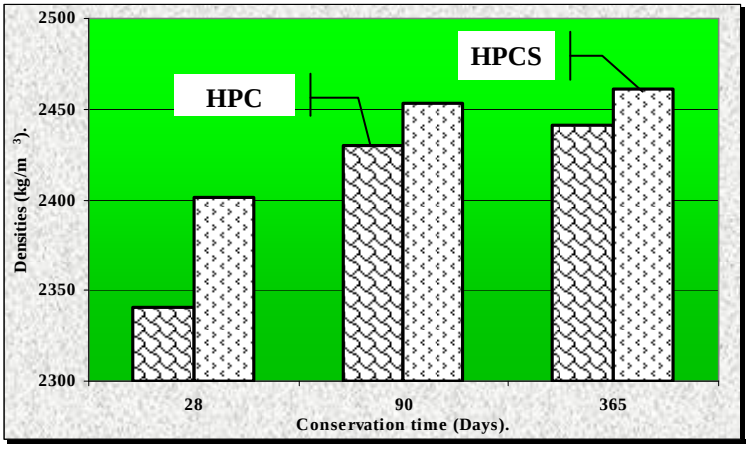

Figure 2. Evolution of the densities of the concretes according to the cured time.

Figure 3 shows the increase in resistance, with respect to the period of conservation in gypsum water. It is definitely higher for the concrete with the addition of slag (HPCS). After 365 days of conservation, the constraint reached is about 100 MPa, whereas for the concrete without addition (HPC) it is only 69 MPa.

The thorough grinding of the slag supported the increase in the compactness of the HPCS, which explains the increase in its density compared to the HPC. On the physicomechanical level, the slag reacts by its fineness and its pozzolanic activity, thus generating a more coherent skeleton and consequently a more resistant and more durable concrete in gypsum water.

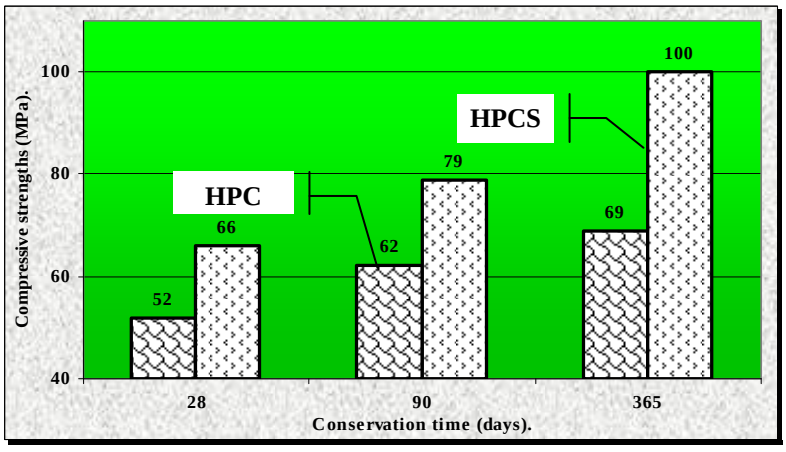

Figure 3. Evolution of the compressive strengths according to the cured time.

3.2 Internal Structure

The reactions known as pozzolanic are faster because of the very low dimension of the reactive particles. On the one hand the newly formed products are more easily dispersed or better set out in materials; on the other hand their composition is more favorable to the incorporation of alkaline in their crystalline structure.

The reactions known as pozzolanic are faster because of the very low dimension of the reactive particles. On the one hand the newly formed products are more easily dispersed or better set out in materials; on the other hand their composition is more favorable to the incorporation of alkaline in their crystalline structure.

The microstructure of cement with addition of slag is characterized by a dense matrix with a growth of the C-H-S on the surface of the particles of the slag. Compared with cement, products of hydrations of the cement mixture - slag also have a weak Ca/Si ratio but rich in magnesia and alumina [Sarkar and XU [1996].

The observation under the scanning electron microscope (Figure 4) enabled us to examine the microstructure of the hydrates formed within the concretes after 365 days of hardening. A microstructure relatively improved in the concretes with addition of slag was noticed with interfaces relatively more densified and rich in C-S-H, characteristic of the high quality concretes.

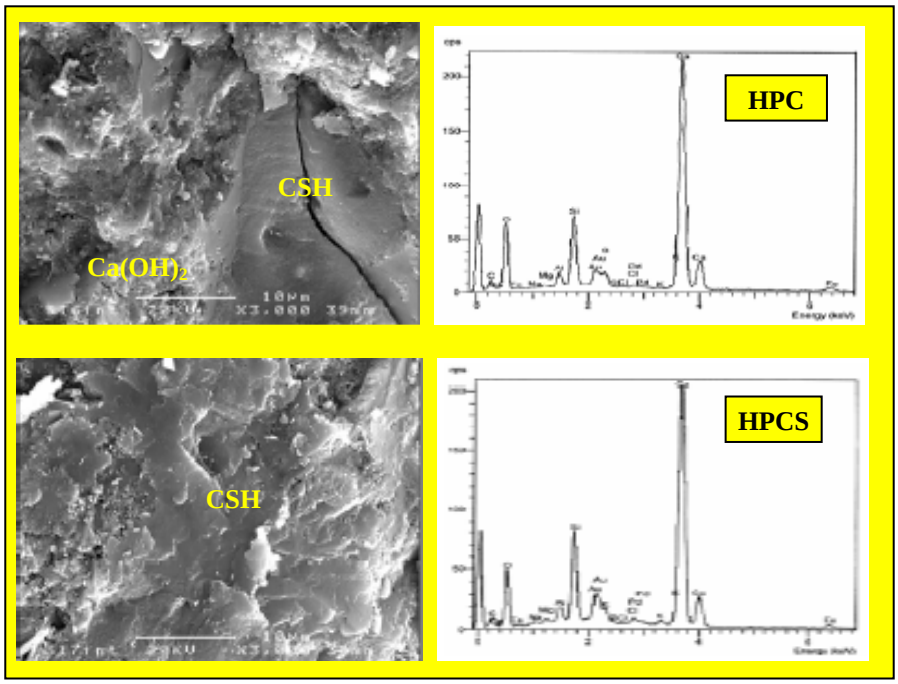

Figure 4. SEM Observation of the internal structural of concrete specimens after 365 days of curing.

However, one can notice some plates of the lime and the presence of needles of ettringite in the cavities of the HPC. For the HPCS, the matrix having become very dense, it does not support the blooming of certain products, which thus find a free field only in the bubbles of air and the interfaces stamps aggregates.

The analysis by x-ray diffraction (Figure 5) illustrates the various crystalline phases. Which are identical for the concretes with and without slag. However, the hydration of the anhydrous compounds of the slag concrete is considerably slowed down, contrary to that of the concrete without addition.
This is the consequence of the thickening of the matrix. By supporting the formation of a more compact skeleton (structure) and consequently of much higher chemical resistances.

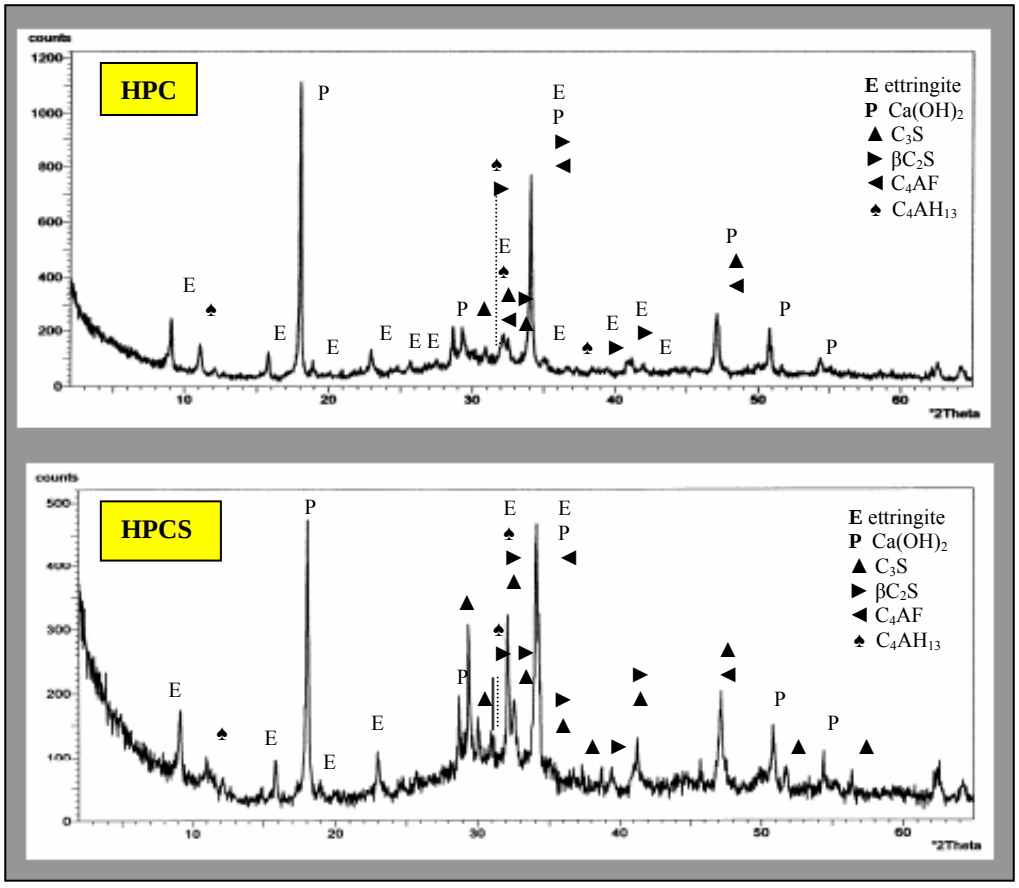

Figure 5. Radiogram of different concretes cured in gypsum water.

In addition, the incorporation of the finely crushed slag also generates a granular effect related to the induced modifications on compactness of the granular skeleton. This effect acts during the hardening of the concretes and influences the extent of the modifications made on the porosity of the cementitious matrix. This explains the high propagation velocities of wave measured on the slag concrete specimens compared to the concrete without addition (Figure 6), on various terms with an increasing rise and this in spite of the character prejudicial of the medium of conservation (gypsum water).

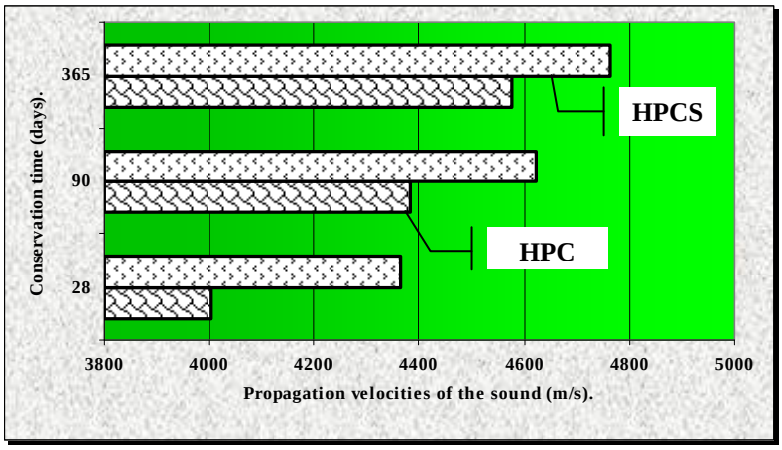

Figure 6. Evolution of propagation of sound velocities through the concretes according to the cured time.

3.3 Concrete Skin

On the surface of the specimens preserved in gypsum water one observe an important deposit of gypsum needles (Figure 7), covering almost all the surface of the concrete of control unlike that of the slag concrete where the presence of the calcite crystals on the surface of the concrete is relatively more noticed compared to the concrete of control.

In addition, one note that the slag which presents the strongest contribution to the mechanical resistance also contributes in reducing the degradation of the external surface of the concrete specimens preserved in gypsum water and consecutively contributes to increase their chemical resistance.

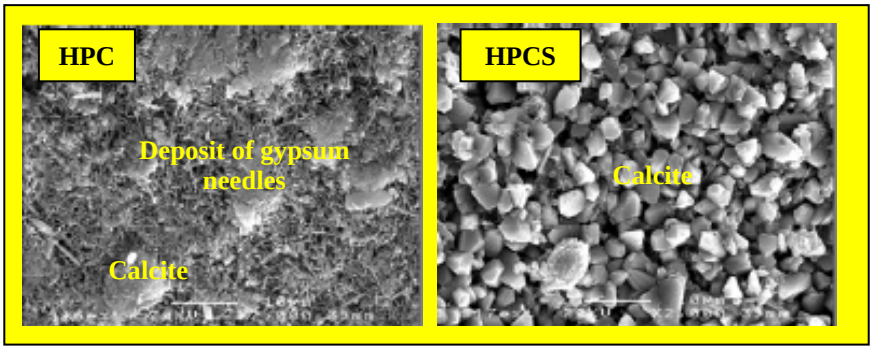

Figure 7. SEM observation of the surface of concrete specimens cured in gypsum water.

In other words, the addition of slag contributes to the reinforcement of the connections in the cementitious matrix and also contributes to its chemical resistance by the formation of an impermeable layer made up of calcite crystallites.

A considerable deposit of the gypsum needles observed on figure 7 for the concrete of control puts in danger the permeability of the skin of concrete without addition of slag, this yield weaker chemical resistance.

CONCLUSION

The study undertaken in this communication deals with the study of degradation of the concretes with and without addition of slag by the sulphates ions.

The thorough grinding of the slag has favoured the increase in the compactness of the concretes. This explains the increase in their resistance compared to the resistance of the concrete without addition.

The observation by the scanning electron microscope enabled us to examine the microstructure of the hydrates formed within the concretes after of 365 days of hardening. A microstructure relatively improved in the concretes with addition of slag has been noticed with interfaces relatively more densified and rich in C-S-H.

The incorporation of the finely crushed slag also generates a granular effect related to the modifications induced on compactness of the granular skeleton. On the physicochemical aspect, the slag entails the formation of a concrete skin relatively more impermeable and, consequently a more durable concrete.

In conclusion, it is important to emphasis on the fact that the influence of the fineness of the slag becomes more and more significant, when one seeks to manufacture more powerful concretes.

Effects of Ternary Blended Binders on Chloride Diffusivity of Concrete

Özkan Şengül [1]
Mehmet Ali Tasdemir [2]

T 11

ABSTRACT

There are several studies on the microstructure, production, durability and mechanical properties of high strength concrete using superplasticizers and mineral particles such as fly ash, ground granulated blast-furnace slag and silica fume. In recent years, for ultrafine particles it was shown that the filler effect is more important than its pozzolanic effect. Thus, the fineness of the pozzolan is very important for the modification of aggregate-cement interface zone in high strength concretes. The main objective of this study is to investigate the combined effects of finely ground blast furnace slag and fly ash on the resistance of concrete against chloride penetration. In the experimental study 16 concrete mixtures were prepared in which ordinary portland cement was replaced by the ground fly ash and ground slag up to 60 % with the increments of 10%. The average particle size of both the fly ash and slag used were relatively low with Blaine fineness of 600m^2/kg. Water/binder ratio was kept constant in all concrete mixtures. Chloride diffusivity of the concretes were obtained using a non-steady state migration testing. Electrical resistivities of the concretes were also recorded. The results indicate that concretes containing the pozzolanic materials show a significantly better resistance against chloride penetration compared to that of the pure portland cement concrete. Electrical resistivities obtained with the two electrode method were significantly higher for the pozzolan blended binders.

1 INTRODUCTION

Poor durability; and as a result uncontrolled and short service life, is a major concern for structures and can lead to great economical losses. One of the effective ways of minimizing the chloride diffusivity of concrete is to substitute a part of Portland cement by pozzolanic materials which are fine particles and can react with calcium hydroxide at ordinary temperatures to form calcium silicate hydrates. The most widely used pozzolanic materials are fly ash and granulated blast furnace slag which are industrial by-products.

Fly ash is a by-product of the combustion of coal in thermal power plants for electricity production. It is also known as pulverized fuel ash. It is removed by the dust collection system as a fine particulate residue from the combustion gases before discharging into atmosphere. Fly ash is the most common artificial pozzolan worldwide. It is estimated that about 450 million tons of fly ash is produced worldwide annually, but only about 6 percent of the total available fly ash is used as a pozzolan in blended cements or in concrete mixtures [Mehta, 2000]. There are twelve active coal-burning power plants in Turkey [Bayat, 1998] and the annual fly ash production capacity in the country is about 15 million tons [Tokyay, 1998]. Fly ash includes meta-stable alumino-silicates that react with calcium ions, in the presence of moisture and lime to form silicate hydrates. The reaction of fly ash depends on the breakdown and dissolution of the glass phase which occurs when the pH value of pore solution is higher than 13 [Fraay, 1989]. The increase in the alkalinity of the pore water is because of the hydration of portland cement. The amount of CH formed during the first days is not enough for the dissolution of the glass phase of fly ash and because of this, the fly ash is usually considered inert during the early days of hydration. Fly ash can be utilized as a blending component in blended cement or can be added separately during the concrete production.

Ground granulated blast-furnace slag is a by-product of iron production. During the iron production process about 300 kg of slag is obtained for each ton of pig iron [Neville, 2004]. In production plants with older technology, however, the amount of slag obtained is usually higher. About 100 million tons of slag is produced annually worldwide but only a very small fraction is utilized. Today slag is widely used in Europe as a component in blended cements but the degree of usage varies significantly between different countries. Netherlands, for example, utilizes about 90 % of its slag production [Regourd, 2004] and slag cement has a market share of about 60 % in the country [Bijen, 1996]. The pozzolanic reaction of the blast furnace slag is more rapid when compared to that of the fly ash [Bijen, 1996]. For the dissolution of the glass phase of blast furnace slag, pore water pH of about 12 is enough and this alkalinity level occurs in a short period after mixing the slag – portland cement blend with water. This more rapid reaction is one of the factors causing a higher early strength of slag concretes.

By using pozzolans in concrete with higher amounts, it is possible to obtain better properties than normal concrete. Replacing high amounts of portland cement by pozzolans, however, may have some drawbacks such as low early strength or high early permeability. In order to overcome the disadvantages of using pozzolans in high amounts, pozzolanic reactions can be increased using very fine paricles and different pozzolans in combination.

The main objective of this study was to investigate the combined effects of finely ground blast furnace slag and fly ash on the resistance of concrete against chloride penetration. In the experimental study, 16 concrete mixtures were prepared in which ordinary portland cement (OPC) was replaced by the ground fly ash and ground slag up to 60 % with the steps of 10%.

2 EXPERIMENTAL

2.1 Materials

The same ordinary Portland cement (PC 42.5), finely ground fly ash and finely ground blast furnace slag were used in the concretes. The 7- and 28-day compressive strengths of the standard RILEM-Cembureau cement mortars were 45.8 MPa and 57.3 MPa, respectively. The fly ash used in this study was brought from Catalagzi power plant, which is located in the northwest coast region of Black Sea in Turkey. The Blast furnace slag was obtained from Karabük iron production plant. The fly ash and blast furnace slag were ground in a laboratory ball mill. The original Blaine fineness of the fly ash was 222 m^2/kg and was increased to 604 m^2/kg by grinding. The ground blast furnace slag used in this study also had a Blaine fineness of 600 m^2/kg.

2.2 Mixture Proportioning

In the study, 16 concrete mixtures were prepared in which ordinary portland cement was partially replaced by the ground fly ash and slag up to 60 % with the steps of 10%. Water/binder ratio was 0.35 and kept constant in all the mixtures. In all concretes, partial replacement of cement by fly ash and slag was made on one to one weight basis. Portland cement concrete without any pozzolan was also produced for comparison. Basalt type coarse aggregate was used in all concretes in order to obtain better concrete strengths [Sengul et al. 2002]. The aggregates were washed and used in saturated air-dry state. The grading curve of concrete aggregate was chosen between ISO A32-B32 and closer to B32. The aggregate grading, water-binder ratio, and the maximum particle size were kept constant in all concrete mixtures. A superplasticizer was used to maintain approximately the same slump. The mixture proportions are shown in Table 1.

Concretes were coded as follows; PC shows the concrete with ordinary portland cement, xySwzF defines the concretes with pozzolan replacements where; S shows slag and F: the fly ash. xy and wz represent the replacement amounts for slag and fly ash, respectively. For example 40S20F represents the concrete with 40% slag and 20% fly ash. All mixtures were prepared in a laboratory mixer with vertical rotation axis by forced mixing. All the specimens were demolded after 24 hours, stored in a water tank saturated with lime at 20°C until the testing day.

2.3 Testing Procedures

Chloride diffusivity of the concretes were measured according to NT 492 which is a non-steady state migration testing. Concrete disc specimens of 100 mm in diameter and 50 mm thickness were used for the test. Electrical resistivity of the concretes were also recorded. Some mechanical properties of the specimens were also obtained. Mechanical properties of the concretes were obtained at the ages of 7, 28 and 180 days. Due to limited amount of specimens, chloride diffusivity and electrical resistivity tests were carried out on only one year old specimens. Pozzolanic reaction continues for a long period and diffusivity testing carried out at later ages indicates the potential diffusivity that can be achieved. For the same materials and similar mixture proportions, resistance to chloride ion penetration at 28 and 90 days were given in another study [Şengül et al., 2003].

3 RESULTS AND DISCUSSION

3.1 Chloride Diffusivity

Chloride diffusivity of the concretes produced with ternary blend of ordinary portland cement, ground fly ash and slag are given in Figures 1 and 2. For a clearer and easier evaluation of the chloride diffusivity of the concretes, the results obtained for different replacement ratios are presented together with that of the portland cement concrete without pozzolan.

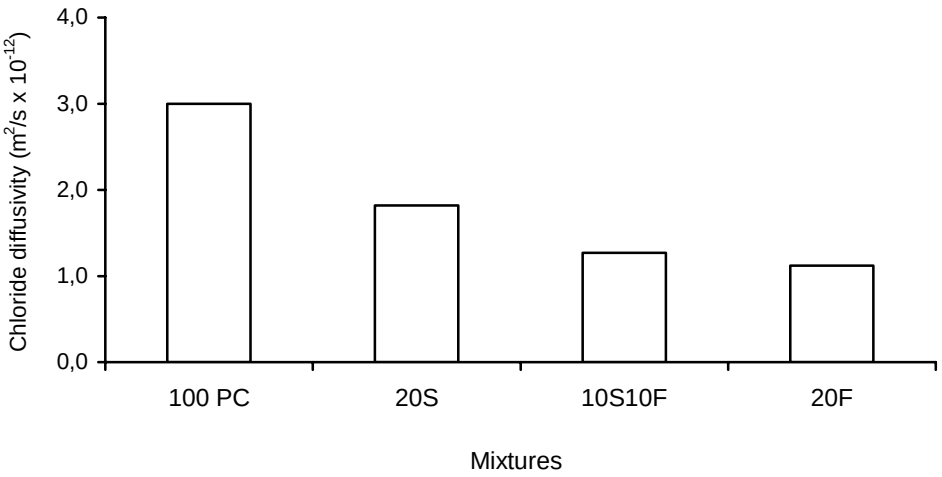

Figure 1. Chloride diffusivity of the mixtures containing 20% pozzolans.

As seen in the figures, partially replacemenet of portland cement by fly ash or blast furnace slag improves the chloride diffusivity of the concrete substantially. The chloride diffusivity of the portland cement concrete is $3.0x10^{-12}$ m^2/s, but it drops to $1.8\ x10^{-12}$ m^2/s for the concrete produced with 20% slag (20S) and $1.1x10^{-12}$ m^2/s for the mixture with 20% fly ash (20F) replacement, respectively. As the replacement amount increases lower diffusivity values are obtained. For example, the diffusivities of the mixtures containing 40% and 60% slag (40S and 60S) are $1.4x10^{-12}$ m^2/s and $1.1x10^{-12}$ m^2/s, respectively.

The test results indicate that, for a given replacement ratio, the fly ash used in the study is more effective than the slag in reducing the diffusivity and this reduction is more significant for the replacement ratio of 20%. For each replacement ratio, the mixtures containing the highest amount of the fly ash have the lowest chloride diffusivity. Although the concretes containing less amounts of fly ash have slightly higher diffusivities, the values for the various mixtures were close to each other. As seen in the Figures 1 and 2, mixtures containing ternary blends of cement, slag and fly ash performed similar to the binary blended mixtures.The chloride diffusivity test was carried out on one year old

specimens which were cured in water and extensive pozzolanic reaction took place during this period which reduced the diffusivity further. As a result of the long pozzolanic reaction, the difference in the diffusivity of the fly ash and slag concretes become smaller.

The lower chloride permeability of the concretes with high volume pozzolans is a result of a denser microstructure. The pozzolanic reaction may cause lower amount of capillary pores and clogging of the pores, which reduce the chloride ion transport in concrete [Li and Roy 1986]. Improvement of the aggregate – cement paste interface by the pozzolanic reaction may also play a role in decreasing the chloride ion permeability. Better chloride ion resistance of high volume fly ash concretes was also shown in other studies [Sengul et al. 2005; Zhang et al. 1999]. The ground fly ash and slag used in this study has a high fineness which may have contributed to obtaining lower chloride ion permeability [Dhir and Jones 1999].

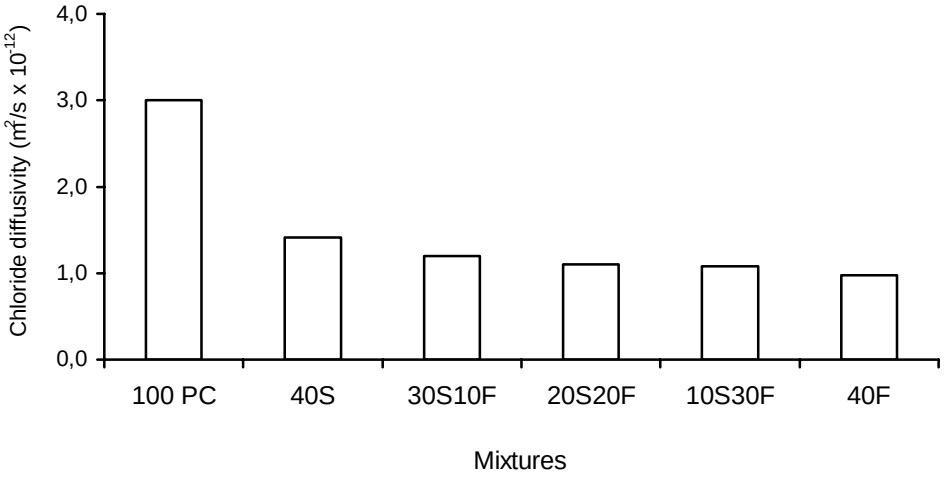

Figure 2. Chloride diffusivity of the mixtures containing 40% pozzolans.

3.2 Electrical Resistivity

Electrical resistivity of the concretes obtained by the two-electrode method are presented in Figures 3 and 4. As expected, the resistivity of the concretes containing slag or fly ash are substantially higher compared to that of the pure Portland cement concrete. For example, the increases in resistivity are about 65% and 250% for the mixtures containing 20% slag (20S) and 20% fly ash (20F), respectively (Figure 3). With the increase in the replacement ratio, higher electrical resistivities were obtained. For example, the electrical resitivity of the mixture containing 20%, 40% and 60% slag are 65%, 140% and 270% higher than that of the control mixture. Most significant increase in the resistivity was obtained for the mixture containing 60% fly ash which is about 8 times higher than that of the portland cement concrete (Figure 4). Test results indicate that for a given replacement ratio, fly ash is more effective in obtaining higher resistivity. As illustated in the figures, for the ternary blended mixtures resistivity increased slightly with the fly ash amount.

Electrical resistivity is a material property and can be defined as the resistance of concrete to an electrical current. Electrical current is carried by the dissolved ions in the pore solution and the factors affecting the pore structure of concrete also affect the resistivity of the concrete. As illustrated in the Figures 1 to 4, there is a good aggrement between the diffusivity and resistivity values obtained. For example, the portland cement concrete which has the highest chloride diffusivity but the lowest electrical resistivity. However, the mixtures containing pozzolans have lower diffusivity but higher resistivity. Based on these test results, it may be concluded that electrical resistivity can be used as an indication of the diffusivity of concrete.

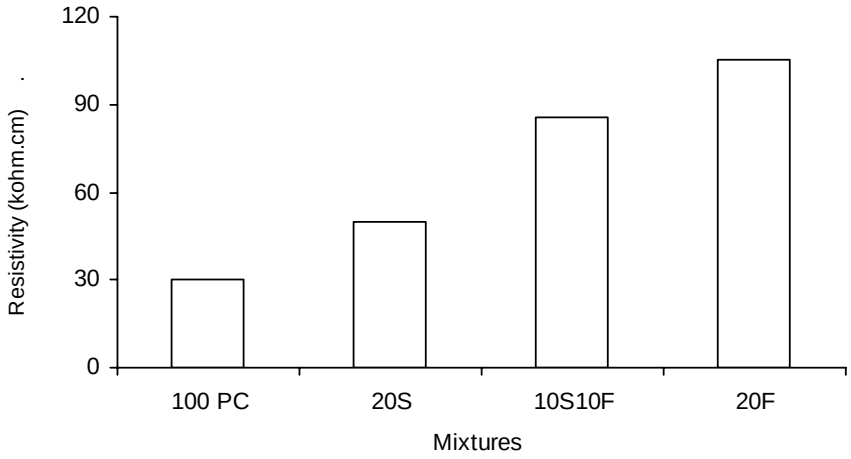

Figure 3. Electrical resistivity of the mixtures containing 20% pozzolans.

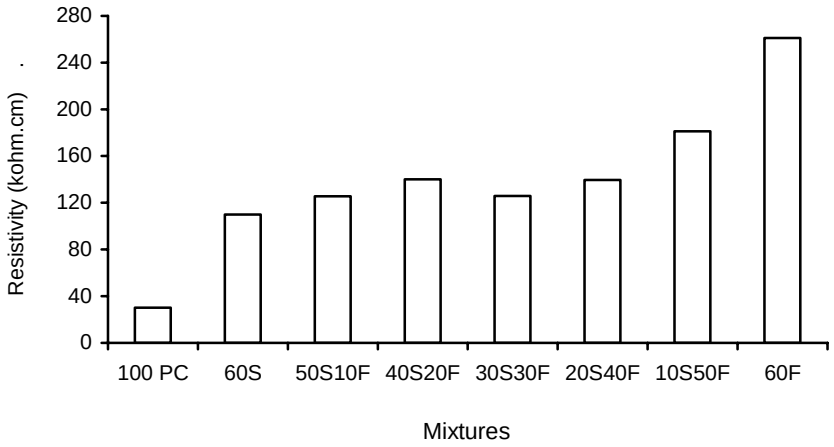

Figure 4. Electrical resistivity of the mixtures containing 60% pozzolans.

3.3 Mechanical Properties

Mechanical properties of the concretes are shown in Table 2. Compressive strength tests were carried out on the specimens at the ages of 7, 28 and 180 days. At the 20% replacement level and age of 7 and 28 days, there are slight decreases in the strengths of the concretes containing slag or fly ash. At the age of 180 days, however, the concretes produced with 20% pozzolans perform better. Similar results were also recorded for the mixtures containing 40% pozzolans. For the concretes containing 60% pozzolanic materials, at the age of 7 days, concrete strength decreased with the increase in fly ash content. Compared to portland cement concrete, concrete cast with 60% fly ash have about 55% lower strength at the age of 7 days. Although this strength reduction is substantial, the strength is 29.4 MPa. Strength decreases with the increase in fly ash content was observed also for the 28 and 180 days. The test results obtained indicate that for obtaining higher compressive strength, the slag used in this study is more effective than the fly ash used.

Modulus of elasticity and brittleness index of the specimens were obtained at the age of 28 days. Test results indicate that modulus of elasticity of the concrete is not affected significantly at the 20% and 40% replacement levels. For the 60% replacement level, however, the modulus elasticity decreased slightly with increasing fly ash content. The lowest value was obtained for the 60% fly ash concrete which is about 16% lower than that of the portland cement concrete. Test results indicate that the brittleness index increases with compressive strength. Brittleness index is an indication of the strength of aggregate – cement interface and a higher brittleness index value represents a stronger interface.

This result may be attributed to the modified interface in these concretes. As the inteface becomes more dense and homogeneous, mechanical properties and also permeability of this region is improved. The permeability of concrete depends on the permeability of the cement paste phase and also that of the interface. As the interface becomes less permeable, the permeability of the concrete decreases. Thus, the brittleness index can indirectly indicate the permeability of the concrete. For the concretes containing pozzolans, the brittleness index decreases with the increase in fly ash content. Compared to the slag, the slower pozzolanic reaction of the fly ash can be responsible for the slightly lower brittleness index. For all the replacement levels, however, the brittleness index of the concretes containing slag and fly ash are higher than that of the portland cement concrete.

Table 2. Mechanical properties the concretes.

4 CONCLUSIONS

Following conclusions could be drawn from the results obtained in this study:

1. Chloride diffusivity of the concrete is substantially reduced with the partial replacement of portland cement by the slag or fly ash. The test results indicate that for the reduction of chloride diffusivity, the fly ash used in this study is more effetive than the slag used.

2. Electrical resistivity of the concretes containing slag or fly ash are substantially higher compared to that of the pure portland cement.

3. High compressive strengths were obtained with the use of finely ground fly ash or slag. Compared to the fly ash used, better mechanical properties were obtained using the slag.

Critical Evaluation of the Definition of "Sulfate-Resistance" A Focus on the Flexural Strength Performance of SR Cements

Pınar Akpınar [1]*
Ignasi Casanova [2]

T 11

ABSTRACT

Sulfate attack in concrete has different consequences such as expansion, cracking, reduction in overall strength and cohesion depending on the type of the attack products that may be formed. Secondary ettringite, secondary gypsum and thaumasite, are the attack products that can be formed individually or sometimes even simultaneously, causing severe deteriorations in concrete

Current standards define sulfate-resistant cement by limiting only the amount of aluminates in the clinker phases. Limiting the aluminates is known to be effective in reducing the occurrence of ettringite-related expansions in the concrete. On the other hand, the formation of other attack products like secondary gypsum does not depend on the aluminates in the clinker. Therefore, reduction in the overall strength of concrete can still be possible as the result of a sulfate attack in a concrete made with a "sulfate-resistant" cement.

This study focuses on the strength performance of the "sulfate-resistant" cements. A sulfate resistant (low C_3A content) and a non-sulfate resistant (high C_3A content) cement were used throughout the experiments. The length change behavior and the flexure strength development of these two cements that were exposed to sulfate solutions of different concentrations were observed systematically for more than a year. Results show that even though their expansion behavior can be quite different, the strength performance of these two cements can be very similar.

This paper involves the results obtained from the experiments and the detailed interpretation of these results.

1 INTRODUCTION

Majority of cement standards define "sulfate-resisting" cement by limiting the aluminates in its clinker composition. The limit defined varies from country to country, depending on the exposure conditions and other specific requirements that each geographical zone might have.

Besides these national standards, one of the most world-widely recognized and commonly used standards is for sure the ASTM. ASTM C150, Standard Specification for Portland cement [2000], defines clinker composition of high sulfate resistant cement by limiting C_3A and (C4AF+2(C3A)) to maximum values of 5% and 25%, respectively. These limiting values were estimated according to results of the experimental studies carried out by using another ASTM test method, C452 [1995]. ASTM C452 basically involves the submersion of Portland cement mortars prepared with the addition of gypsum in the mixing stage, into distilled water for 14 days. The expansion recorded in the samples, at the end of the test period is compared by some expansion limits that are previously defined by ASTM, in order to be able to classify the tested cement as severe, moderate or non-sulfate resistant.

However, it is well known that expansion is not the only type of damage that the concretes under sulfate attack may experience. Different sulfate attack products may be formed in the concrete micro structure due to the reactions between the attacking sulfates and the hydration products of cement, leading a variety of durability problems, such as loss of overall strength and cohesiveness, disintegration and spalling, besides the expansion and cracking. Secondary ettringite, result of the reactions between the sulfates and the C_3A or C_3A-based hydration products, is known to be the main responsible of the expansion. On the other hand, secondary gypsum and thaumasite are the sulfate attack products causing strength-related problems. It is generally accepted that thaumasite is a special type of sulfate attack product that forms only under some specific conditions. Secondary ettringite and gypsum are the most commonly seen attack products, causing damage to the concretes exposed to sulfates.

Secondary gypsum is formed from the reactions between the sulfates and CH and/or C-S-H, which are the hydration products of cements that do not depend on the initial C_3A content of the cement's clinker composition. Therefore, the "sulfate-resistant" cements that are defined according to their C_3A contents might not be necessarily providing a better resistance against secondary gypsum-related durability problems. This study investigates the strength resistance of low-C_3A sulfate resistant cements. Cements of high and low C_3A content are exposed to sulfate solutions having both high (commonly used in standard accelerated tests) and moderate (field-like) sulfate concentrations. Besides the length change behavior (usual measurement approach in standard tests), the flexural strength development of the mortar samples was also measured systematically up to an age of maximum 72 weeks. The results obtained, as well as the details about the experimental campaign are discussed in the following sections.

2 MATERIALS AND METHODS

Two commercial Portland cements were used throughout the experimental campaigns. They were chosen on the basis of their relative C_3A contents, and labeled as HA and LA (for high- and low-aluminates contents, respectively), as shown in Table 1. Standard method ASTM C1012 [1995] was used as a reference for the preparation and storage of mortar samples in two different solutions of sodium sulfate (50000 ppm as originally described in the method, and also additionally 6000 ppm).

Six mortar bars were produced from two different batches of each cement to be tested for expansion and stored in the prepared sodium sulfate solutions. Although this standard method suggests just a 6-month testing period, we extended the observations for 88 weeks (1.7 years) in order to have a more complete data set of the long-term behavior. In each test, length changes were recorded twice with two Sylvac S229 digital extensometers that had been independently calibrated to ±3µm before each

measurement. The bars were placed in the extensometer with the same orientation (same face is kept in front with the same edge being kept at the top each time). As a result of this procedure, twelve length changes (6 samples by 2 extensometers) are obtained each time.

Table 1. Oxide and calculated Bogue's compositions of high-aluminate (HA) and low aluminate (LA) cements.

	Cements	
Oxide	**HA**	**LA**
SiO_2	19.86	19.73
Fe_2O_3	3.40	4.24
Al_2O_3	5.61	4.43
CaO	62.38	63.34
MgO	2.14	1.68
K_2O	0.97	0.59
Na_2O	0.15	0.14
SO_3	3.36	3.03
LOI	2.14	2.3
Phase		
C_3S	50.86	63.48
C_2S	18.57	8.68
C_3A	9.13	4.56
C_4AF	10.34	12.89

Twelve additional mortar bars (6 from each batch) of each type of cement were fabricated for tensile strength measurements carried out for a total period of up to 72 weeks, with a Multitester-Normatest type Universal Press. Span length and loading velocity of the equipment are 100 mm and 5.08 mm/min, respectively.

3 RESULTS

3.1. Length-Change Data

I. HA and LA cements are observed to experience similar expansion values for the *initial* ages (i.e. t<24weeks), under both concentrations (please note the y-scale differences in figs 1 & 2).

II. HA cement mortars are observed to experience higher *final* expansions compared to LA samples both at high and moderate sulfate concentrations.

III. Both cements yield in higher expansion values under high concentrations than what they yield in under moderate concentrations.

IV. The rate of the expansion at the later ages is observed to be increased, for both cements under both concentrations. This increase in the expansion rate is observed to be higher for HA cement.

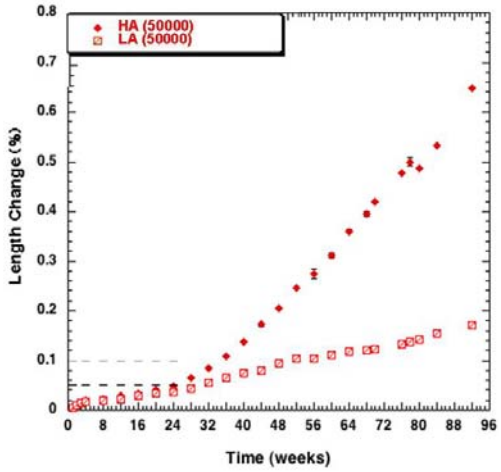

Figure 1: (Left) Expansion behavior of HA and LA cements exposed to a 50000ppm sodium sulfate solution.

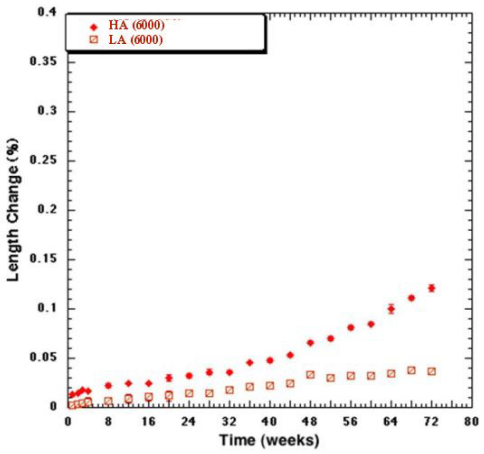

Figure 2: (Right) Expansion behavior of HA and LA cements exposed to a 6000ppm sodium sulfate solution.

3.2. Flexural Strength Data

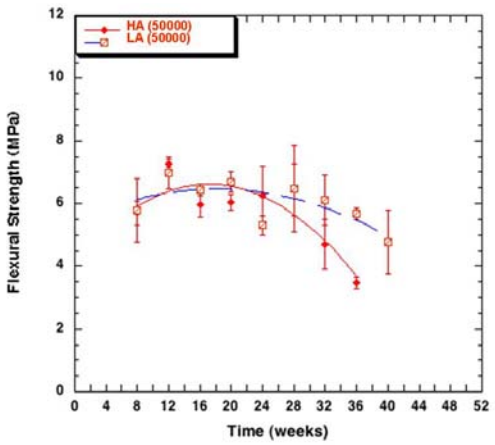

Figure 3: (Left) Flexural strength evolution of HA and LA cements exposed to a 50000ppm sodium sulfate solution.

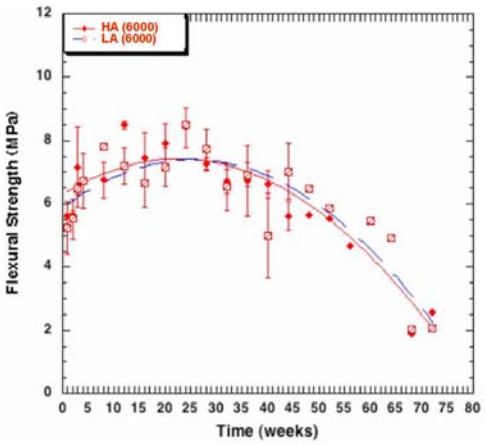

Figure 4: (Right) Flexural strength evolution of HA and LA cements exposed to a 6000ppm sodium sulfate solution.

I. The evolution of flexural strength show an increase during the early ages (first 24-25 weeks), reaching a peak strength and then an evident decrease in a manner that can be fitted with a second degree polynomial, in the cases of both cements under all sulfate concentrations.

II. Before reaching the peak flexural strength at a given concentration, HA and LA perform similarly (i.e. similar strength values). After the time for peak strength, especially at high sulfate concentration, HA looses strength more rapidly; LA has higher strength till the end of testing period. (See Fig. 3).

III. For lower sulfate concentrations, like 6000 ppm, the compositional differences of HA and LA cements do not seem to have a critical effect on the flexural strength behavior of the mortars (seeFig. 4). It seems that at 50000 ppm the difference in the behavior of the two cements can be defined as more notable (Fig. 3).

4 DISCUSSIONS

4.1. Discussions on Length-Change Data

It is observed that at higher concentrations (e.g. 50000ppm) both HA and LA cements experience higher length changes. In their paper dealing with sulfate attack mechanisms, Santhanam et al. [2001] report that Na_2SO_4 yields firstly in secondary gypsum formation when the sulfate concentration is high (e.g. >8000 ppm). Later, it is known that by the consumption of secondary gypsum formed, secondary ettringite is produced [Taylor 1990; Irassar et al. 2000]. In accordance with this suggestions, samples submerged into the 50000ppm solution in this study expand more than the samples in 6000ppm (see figures 1 & 2), since there are more sulfate ions present in the system capable of producing more secondary gypsum, which later is used to produce more secondary ettringite.

More total expansion is also observed in HA cement's samples when compared to LA samples that are stored in the sulfate solutions of same concentrations. This can be considered as a commonly expected result, since LA cement is defined by standards to have less susceptibility sulfates.

The sudden increase in the rate of expansion noted at the last stage is expected to be due to the initiation of micro cracks in the samples under sulfate attack, strongly suggesting that the samples in the 50000 ppm solution get into the micro cracking stage earlier than those in the 6000 ppm solution (see figs 1 & 2). Another coherent observation can be made when the behavior of HA and LA samples compared: HA samples is observed to experience a sudden increase in their lengths with a higher expansion rate; indicating that the expected micro cracking that the HA samples have experienced is much more significant than that of samples made with sulfate-resisting LA cement.

It is observed that the difference in the sulfate reactivity of HA and LA samples cannot be clearly detected before the micro cracking stage (i.e. before the start of the sudden increase in length change) of the samples. The difference in the performance of different cements becomes more evident in later ages, as Cao et al.[1997] had reported as well. Although the HA cement has much more C_3A than the LA cement, the majority of the observed difference in the expansion behavior of these cements could only be recorded after an age of an at least 24 weeks, under the exposure conditions suggested for accelerated tests (see fig 1). Therefore, especially in the case of testing PC blends with previously unknown characteristics, the decision on the level of their sulfate resistance should not be taken by considering their length-change behavior only at initial ages, which does not succeed in reflecting the reality completely.

In any case, although the length change measurements might be carried out for a longer period, authors emphasize the importance of using additional measurement approaches, like flexure strength testing, in order to be able to evaluate the resistance of cements against *all* aspects of sulfate attack. Secondary ettringite is usually accepted to be the cause of the most of expansion recorded [Collepardi 2001]. In our tests, the difference in the etrringite-based expansion behavior of both high- and low-aluminate cements is observed to be well detected by length change measurements, at the end of the whole testing period. However, gypsum is not considered to be expansive, when compared to ettringite [Kurtis et al. 2001; Irassar et al. 2000]; but, it may have a "filling effect" like ettringite as they both may accumulate in the porosity, and may result in an increase of strength of the tested sample. It is presumed that gypsum is not likely to be present in the system in high amounts, since it is continuously used for secondary ettringite formation [Irassar 1990]. Apart from its effects as an attack product, the formation process of gypsum is also very important: CH is consumed during the process and the pH level in the system eventually drops, causing decalcification of C-S-H. As in the case of leaching in which low alkalinity of the system causes dissolution of CH for balancing the pH, leading the decomposition of hydrated silicate and aluminates, gypsum formation also yields severe strength loss and disintegration. [Kurtis et al. 2001] However, these possible influences of secondary gypsum on the overall strength of the samples could not have been observed, if the length change was the only measurement approach used during this study.

4.2. Discussions on Flexure Strength Data

One of the most significant results obtained from the flexural strength testing is the convenience to use a second degree polynomial fit for the observed strength development behavior of the samples. This result is in accordance with the findings of Irassar (1990). Using second degree polynomial curve-fits could be a promising approach to be used in future modeling studies aiming to simulate the mechanical consequences of sulfate attack in concrete. This mathematically definable behavior observed in the samples has the potential to enable us to detect and interpret the different stages of sulfate attack that progresses in the samples.

The initial increase in the flexural strength is expected to be the strength development due to hydration process of cement. In addition to this, Irassar (1990) suggests that the increase in the flexural strength can be also attributed to pores being filled by secondary ettringite and gypsum. Samples in the 50000ppm solution show a faster strength drop, when compared to the samples in 6000ppm solution, after reaching to their peak strengths (figure 3). As discussed before, higher amounts of secondary gypsum is formed during the early ages under such high sulfate concentrations. Accordingly, this higher amount of gypsum formed, later yields in the formation of more secondary ettringite, especially in the high-aluminate cement samples, causing more expansion and consequent crack formation faster than it can be observed in the low-aluminate samples in the same solution, justifying the faster strength loss observed in the HA samples. The effect of CH consumption during the formation of secondary gypsum (more under 50000ppm) should be also taken in to account as an important cause of the detected faster strength loss. However, it should be emphasized that 50000ppm is a value mainly used in laboratory tests to accelerate the reactions. Most of the standards define the sulfate concentration level for severe sulfate attack always around or less than 10000ppm [Neville 2004; and references therein].

The samples stored in 6000ppm solution also experience the second degree polynomial strength evolution that is observed in the samples in 50000ppm solution: After an increase during the first ages, both HA and LA samples reaches to their peak flexural strength and then experience the expected strength loss (fig 4). However, the differences observed in the time to reach to peak strength and the evolution of the flexure strength loss of both cements are in fact too small to be taken into account to classify HA and LA cements to be "non-sulfate-resistant" and "sulfate-resistant" cements, respectively. Both cements experience practically the same strength development; even though their length-change behaviors were significantly different (see figures 2 and 4).

These findings show that low-C_3A cements are only good at minimizing expansion-related problems; in spite of being generally classified as “sulfate-resisting” cements, they do not necessarily provide a better strength, or better resistance against all aspects of sulfate attack. Similar findings were also reported by Mehta [1993]. Therefore, limiting only the C_3A content of the cements as suggested by many standards may help to improve the performance only in some aspects, but seems to fail to be an adequate solution to the entire problem of sulfate attack. Properties like strength performance, which is crucial for civil engineering, should also be covered with a more extended definition of “sulfate resistance”.

These findings also imply the importance of using adequate testing approaches during the evaluation of cements’ sulfate attack performance. Using only one type of measurement approach might not be sufficient to detect all consequences of sulfate attack going on in the samples. On the other hand, using length change and strength development approaches at the same time, like it was done in this study, provides us a more complete overview of the resistance of the tested cements against consequences of all sulfate attack products being formed.

5 CONCLUSIVE REMARKS

This study involves a data-based evaluation of the strength performance of "sulfate-resistant" cements. Meso-scale laboratory experiments focusing on the systematical measurements of the length change and the flexural strength development of two Portland cements, having a high and a low C_3A content, were carried out. A high (accelerated laboratory tests) and moderate (more realistic) sulfate concentrations were used in the exposure solutions, in order to be able to compare the performance results obtained under standard conditions with the ones that may occur in the real cases.

Results show that the cement having high C_3A content, which is defined to be not "sulfate-resistant" by the standards, experiences more expansion, in both sulfate concentrations, when compared to low C_3A content cement. However, when their strength development is compared, both cements show a very similar performance, especially under the more realistic moderate sulfate concentration. This finding implies that the so-called "sulfate-resisting" cements do not always provide a high resistance against all known consequences of sulfate attack, and also that the definition of sulfate resistance should perhaps be extended to include strength-related requirements, as well.

Another remarkable observation is the necessity of using different measurement approaches at the same time, in order to be able to determine the resistance of cements against all aspects of sulfate attack. Using only length change measurement approach, as suggested in many test methods, is observed to be not adequate to detect the influence of the strength reducing attack products, such as secondary gypsum.

ACKNOWLEDGEMENTS

This work was partially supported by grants MAT2002-00077 and BIA2006-12717 from the Spanish Ministry of Education and Science, through the National Plans of Materials and Construction, respectively. Financial support to P.A. from the International Graduate School of Catalonia is also gratefully acknowledged. We also wish to thank Paulo J.M. Monteiro (UC Berkeley) and Silvia Vieira (Holcim) for insightful comments, Eufronio Beyret (Laboratory of Construction Materials, UPC) for technical assistance, and Joan Puig (Ciments Molins) for providing the cement and continuous encouragement and support to this study.

ABSTRACT

Fiber reinforced cement composites are often employed in severe conditions. These might be exposed for instance to high temperatures and/or high mechanical loads. However, their durability and mechanical properties are mostly measured in laboratory conditions only, so that designers cannot take into account changes in their material parameters after loading. In this paper, basic durability and mechanical properties of hybrid (glass and polypropylene) fiber reinforced cement composite material are determined as functions of thermal load, the loading temperatures being 600 °C, 800 °C and 1000 °C. Water vapor diffusion coefficient, water absorption coefficient, moisture diffusivity, adsorption isotherms, thermal conductivity, specific heat capacity, tensile strength and bending strength are the investigated parameters. The experimental results show that the decomposition of calcium hydroxide is the principal factor affecting the behavior of thermally loaded specimens. The most important changes in moisture diffusivity, water vapor diffusion resistance factor, adsorption isotherm and thermal conductivity occur between the unloaded state and the loading temperature of 600 °C which is safely above the calcium hydroxide decomposition temperature.

1 INTRODUCTION

Cement-based materials are characterized by very good properties in compression but their brittle manner of failure under tensile or impact load was a limiting factor for their applicability range from the very beginnings. Fiber reinforcement is a traditional and effective method how to improve the toughness and durability of cement-based products. The steel rod reinforcement became very popular during the whole last century and remains the most frequently used type of concrete reinforcement until now. However, in the second half of the 20th century, an application of uniformly dispersed short fibers strengthening the brittle cementitious matrices appeared with an increasing frequency. In the current practice, steel, glass, carbon and various polymeric fibers such as polyethylene, polypropylene, nylon, polyester, polyurethane, cellulose, etc., are commonly used in cement-based materials.

Glass-fiber reinforced cement composites (GFC) are produced by incorporating a small amount of alkali-resistant glass fiber in cement mortar to overcome the traditional weakness of inorganic cements, namely poor tensile strength and brittleness [Majumdar 1991], [Young 1978], [True 1986]. The length and content of the glass fiber reinforcement can be chosen to meet the strength and toughness requirements of the product. Also, the type of aggregates can be varied in order to control thermal properties. GFC are often employed in severe conditions. These might be exposed for instance to high temperatures and/or high mechanical loads.

The properties of glass fiber reinforced cement composites were studied in an insufficient way until now. However, the most frequently analyzed were the mechanical properties. The durability properties such as hygric and thermal properties were measured only rarely. In addition, the specimens were tested mostly in the reference state, i.e., in room temperature conditions. The properties of this type of materials in high-temperature conditions or after high-temperature loading were studied only exceptionally.

A basic survey of mechanical properties of various Portland cement GFC, namely bending, tensile and impact strength and Young's modulus can be found in Majumdar [1991] where the work until 1990 is compiled. Basic values of thermal and hygric properties, such as thermal conductivity, thermal expansion coefficients, air and water vapor permeability are also included. Within the last ten years, the number of references describing measurements of GFC properties decreased significantly compared to 1970s and 1980s, and the few remaining were concentrated on mechanical properties. For instance, Zhang et al. [1997] measured flexural strength of GFC with high content of fly ash, Huang et al. [1997] analyzed the interfacial mechanical properties of carbon-coated GFC, Marikunte et al. [1997] determined the flexural and tensile strength of GFC after hot-water durability tests, Park et al. [1999] measured compressive strength, compressive modulus of elasticity, tensile strength, flexural strength of low-density/low cost GFC, Mu et al. [2000] determined tensile strength and impact resistance of short fiber GFC with high slag content, Mu et al. [2002] analyzed the possibilities of improving the interface bond between fiber mesh and cementitious matrix of GFC and used fracture toughness to evaluate the flexural behavior of GFC.

It seems to be quite logical that mechanical properties of GFC under common environmental conditions are in the center of interest of most researchers working on those materials, particularly taking into account why GFC were developed, i.e., to improve the tensile and flexural strength of cement based composites. However, there are numerous applications where determination of mechanical properties is not sufficient. There are also situations when testing in normal conditions does not provide enough information on the behavior of GFC in a structure. For instance, lightweight GFC can be used as thermal insulation materials. Here certainly thermal properties are very important. GFC can also be used as fire protection materials. In this case, it is useful to know not only the properties in usual conditions but also the material's response to high temperatures. For GFC used in any wall systems hygrothermal performance should be assessed so that both hygric and thermal properties are to be known.

In this paper, basic mechanical, thermal and hygric properties of hybrid glass and polypropylene fibers reinforced cement composite were measured in reference state and after heating up to 1000 °C.

2 MATERIAL AND SAMPLES

The measurements were done on glass and polypropylene fibers reinforced cement composite produced in the laboratories of VUSTAH Brno. The composition of the material is shown in Table 1. Water in the amount corresponding to the w/c ratio of 0.33 was added to the mixture. The samples were produced by vacuum technology using the OMNI MIXER 10 EV mixing device.

Table 1. The mixture composition.

Composition [% of dry substances]	
Cement CEM I 52.5 Mokrá	54
Quartz sand aggregates 0-1 mm Bzenec	40
Microsilica	3
Glass fibers - 12 mm length	2.7
Polypropylene fibers	0.3

In the experimental measurements the following specimens were tested:

- reference specimens not exposed to any load (denoted as SC in what follows)
- specimens exposed to a gradual temperature increase up to 600, 800 and 1000 °C during two hours, then left for another 2 hours at the final temperature and slowly cooled (denoted as SC-600, SC-800 and SC-1000 according to the loading temperature).

3 EXPERIMENTAL METHODS

3.1 Basic Physical Properties

As fundamental physical material characteristics, bulk density ρ [kgm^{-3}], vacuum saturation moisture content w_{sat} [kgm^{-3}], porosity Ψ_0 [Vol.-%] and matrix density ρ_m [kg m^{-3}] were determined. They were obtained using the vacuum saturation method [Roels et al. 2004].

3.2 Mechanical Properties

The measurement of tensile strength was done using the electromechanical testing device MTS Alliance RT 30 with the maximum tension force of 30 kN. The rate of loading was 0.025 mm/min. The bending strength was measured in the same device provided with the three-point bending track 642.01A which allows the maximum load of 27.80 kN. The rate of loading was 0.04 mm/min. The values of tensile strength and bending strength were calculated from the measured force values using the common formulas.

3.3 Water Vapor Transport Properties

The wet- and dry cup methods were employed in the measurements of water vapor transport parameters [Roels et al. 2004]. The water vapor diffusion coefficient D [m^{2}s^{-1}] and water vapor diffusion resistance factor μ [-] were determined.

3.4 Adsorption Isotherms

In the measurements of adsorption isotherms the samples were placed into the desiccators with different solutions to simulate different values of relative humidity [Roels et al. 2004]. The initial state for all the measurements was dry material. The experiment was performed parallel in all desiccators in

a common way. The mass of samples was measured in specified periods of time until steady state value of mass was achieved. Then, the moisture content by mass was calculated.

3.5 Water Vapor Transport Properties

The water sorptivity A [kg m^{-2} s $^{-1/2}$] and apparent moisture diffusivity κ [m^2 s^{-1}] were measured using a water suction experiment [Černý et al. 2002].

3.6 Thermal Properties

Thermal conductivity λ [W m^{-1} K^{-1}] and specific heat capacity c [J kg^{-1} K^{-1}] were measured using the commercial device ISOMET 2104 (Applied Precision, Ltd.). ISOMET 2104 is a multifunctional instrument. The measurement is based on analysis of the temperature response of the analyzed material to heat flow impulses. The heat flow is induced by electrical heating using a resistor heater having a direct thermal contact with the surface of the sample.

4 EXPERIMENTAL RESULTS AND DISCUSSION

4.1 Basic Physical Properties

Table 2 shows basic parameters of the studied material depending on the loading temperature. The most important change in porosity occurred between the unloaded state and the loading temperature of 600 °C where the increase of porosity was as high as 35 %. Later porosity changes were lower than 10 %. This is in accordance with the behavior of most Portland cement based composite materials where the most important chemical reaction in the high temperature range is decomposition of calcium hydroxide at about 460-480 °C [Černý and Rovnaníková 2002].

Table 2. Basic physical properties.

Material	Ψ_0 [%]	ρ [kg m^{-3}]	ρ_m [kg m^{-3}]
SC	24	2021	2660
SC-600	32	1947	2899
SC-800	35	1909	2954
SC-1000	33	1871	2799

4.2 Mechanical Properties

Tables 3 and 4 show deformation, tensile strength and bending strength. The most important changes in tensile strength were observed between the loading temperatures of 600 °C and 800 °C. After heating to 800 °C the tensile strength decreased to about 9 % of its reference value. The most remarkable changes of bending strength were observed between the reference state and the specimens heated to 600 °C, where the bending strength decreased to about one fifth of its original value. The results are in a reasonable qualitative agreement with the basic parameters in Section 4.1.

Table 3. Deformation and tensile strength

Material	*Deformation* [mm]	*Tensile strength* [MPa]
SC	0.51	4.18
SC-600	0.49	3.73
SC-800	0.30	0.32

SC-1000	0.16	0.14

Table 4. Deformation and bending strength

Material	*Deformation* [mm]	*Bending strength* [MPa]
SC	0.32	15.08
SC-600	0.17	3.78
SC-800	0.17	2.43
SC-1000	0.16	1.93

4.3 Water Vapor Transport Properties

Table 5 shows water vapor transport properties of the studied SC material. We can see that the values of water vapor diffusion resistance factor decreased very rapidly with the increasing load temperature for both configurations of the cup experiment. The most important was the change between the unloaded state and the loading temperature of 600 °C. This is in basic agreement with both the porosity and mechanical parameters data. The water vapor diffusion resistance factor for wet-cup arrangement was significantly lower than in dry-cup measurement. This concurs with the measurements obtained for many other building materials and reflects the partial inclusion of liquid water transport into the water vapor transport coefficient in the wet-cup experiment [Černý and Rovnaníková 2002].

Table 5. Water vapor transport properties

Material	*Dry cup*		*Wet cup*	
	D [m^2s^{-1}]	μ [-]	D [m^2s^{-1}]	μ [-]
SC	2.9E-07	77	6.0E-07	38
SC-600	9.6E-07	24	1.5E-06	15
SC-800	1.2E-06	19	2.7E-06	8.4
SC-1000	1.2E-06	19	5.1E-06	4.5

4.4 Adsorption Isotherms

Figure 1 shows that water vapor adsorption capacity of the studied material increased with increasing loading temperature. This behavior can be explained by the changes of the porous structure after high temperature exposure. The observed increase in porosity (see Table 2) due to the thermal decomposition reactions was apparently caused by the increase of the amount of larger pores but the amount of smaller pores probably did not decrease on that account in a significant way as it is usual in similar cases. This seems to be a positive effect of polypropylene fibres which decomposed at lower temperatures. In this way, they could provide channels for vapor escape and thus help to reduce the further thermal damage in some extent.

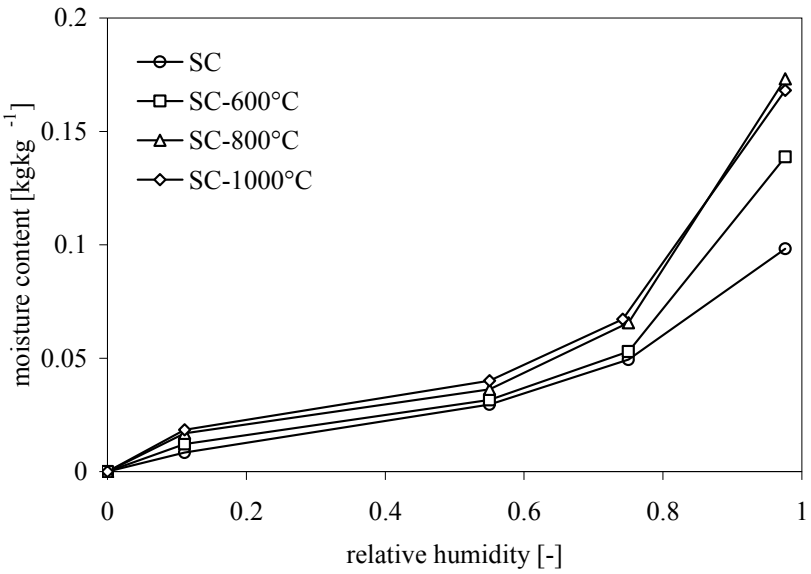

Figure 1. Adsorption isotherms.

4.5 Water Transport Properties

Table 6 presents liquid water transport properties. Once again, the thermal decomposition processes at high temperatures were the dominant factor for the differences in water transport parameters measured for thermally loaded samples. The increase of both water absorption coefficient and moisture diffusivity of thermally loaded specimens was in a comparison with reference specimens very high, up to two orders of magnitude, which indicated very remarkable damage of the structure of the analyzed material. The most important increase in water transport parameters was observed between the reference state and the samples exposed to 600 °C, similarly as for all other studied parameters in this paper.

Table 6. Water transport properties.

Material	*A* [$kgm^{-2}s^{-1/2}$]	κ [m^2s^{-1}]
SC	0.0096	1.65E-09
SC-600	0.0465	2.13E-08
SC-800	0.0718	4.20E-08
SC-1000	0.275	6.91E-07

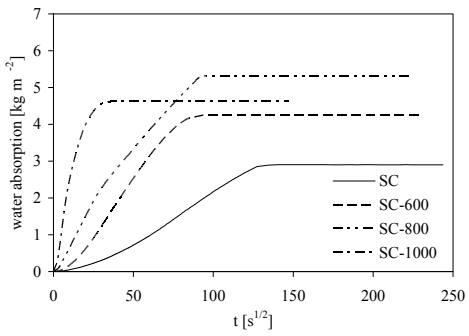

Figure 2. Water absorption.

4.5 Thermal Properties

The results of measurements of thermal parameters in Table 7 showed that thermal conductivity in dry state significantly decreased after high temperature loading. This is in qualitative agreement with the increase of porosity due to decomposition reactions in high temperature range leading to an increase of significance of the low thermal conductivity of air in the cement matrix-air system. The principal loading temperature was again 600 °C where the thermal conductivity decreased by about 10 % compared to unloaded specimens. The specific heat capacity was affected in a similar qualitative way. The changes were only up to 5 % in this case, which may reflect the mass loss due to the thermal decomposition reactions. The thermal diffusivity basically followed the changes of thermal conductivity which were more remarkable than changes of specific heat capacity.

Table 7. Thermal properties in dry state.

Material	λ [$Wm^{-1}K^{-1}$]	c [$Jkg^{-1}K^{-1}$]	a [$10^{-6}\,m^2s^{-1}$]
SC	1.02	810	0.65
SC-600	0.90	790	0.54
SC-800	0.84	780	0.55
SC-1000	0.63	760	0.44

5 CONCLUSIONS

The cement-based composite material with hybrid glass-polypropylene fiber reinforcement studied in this paper was found to resist to high temperatures only slightly better than similar composites with common fiber reinforcement. The decomposition of calcium hydroxide at about 460-480 °C remained clearly the most important factor for the damage of the porous matrix after high-temperature exposure. The use of polypropylene fibers in addition to glass fibers led to certain improvement of water vapor adsorption capacity but the majority of other mechanical and durability properties was not affected in a very significant way.

ABSTRACT

When concrete is reinforced with technical textiles, a cheap load bearing concrete composite can be produced. Since – in contrast to classical reinforced concrete – no concrete cover is necessary, very thin plates and shells of any desired shape can be produced without necessarely increasing the need for skilled labourers and consequently increasing the cost price. When glass fibres are used to form technical textiles, a relatively high strength and stiffness can be combined with the formation of a finer crack pattern and relatively low cost price.

One of the main reasons why glass fibre reinforced concrete (grc) has seldomly been used as structural reinforcement in concrete structures is the durability. Common glass fibres are attacked by the alkalinity of the concrete matrix and rapidly lose strength. In the past a proper lifetime of a grc structure could not be guaranteed, but recent developments led to more durable material combinations.

In this paper the potential of TRC with glass fibres is illustrated by means of a dimensioning example. A roof structure, made of a shell with a hypar surface shape will be dimensioned and the effect of durability will be evaluated. The minimal thickness to provide a certain lifetime will be calculated for several material combinations with different ageing behaviour.

1 INTRODUCTION

Textile reinforced concrete (TRC), which is the material that will be discussed in this paper, is a special type of fibre reinforced concrete (FRC). Classical fibre reinforced concrete can be used to enhance the thoughness and to obtain a better crack control of cementitious mixtures, but seldomly leads to an enhanced load-bearing capacity. The production techniques (mixing and casting/pressure forming or use as shotcrete) allows the implementation of a limited amount of fibres (approximately 1-2 vol%). Moreover, the spatial homogenity and orientation of the fibres are not easily controlled.
When fibres are introduced in the form of textiles, orientation and spatial homogenity carefully controlled. When other production techniques – which are more conforming to composite technology than to concrete technology (hand lay-up, calendering, pulltrusion) – are used, a higher fibre volume fraction (approximately 15%) can also be obtained. As a consequence, textile reinforced concrete can be used as a load bearing material and steel rebars could be ommited. Therefore, no concrete cover is needed and very thin plates (1mm minimal thickness) and thin shells with a high curvature (thanks to the high flexibility of the textile) can be produced. The aim of this paper is therefore to study the potential and the limits of TRC for shells. This evaluation will be limited to structural analyses (design-examples) of shells of different spans and this with several materials combinations. Within the subsequent discussions, only the effects of the possible use of a smaller thickness (material saving effect) will be discussed in detail. Other advantages concerning e.g. the fact that less skilled labourers are needed (for bending and forming of the reinforcement) and the consequent lower cost price are not discussed in detail.

Fig. 1 shows the type of structure that will be analysed for illustrative purposes in this paper. A hypar shell was chosen for several reasons: (1) it is a typical shape which can be produced easily with TRC, but is less obvious with a classical steel reinforced concrete, (2) the use of technical textiles as flexible and reusable moulds for TRC is currently under study. The presented shape can be constructed, using a textile mould under pre-tension (3) due to the curvature, the external load will be transferred partially through 'compression-arc' and 'tensile-chain' paths within the shell, but the shell can also withstand bending. Although relatively complex stress patterns could already occur, interpretation of the global behaviour is still not too awkward.

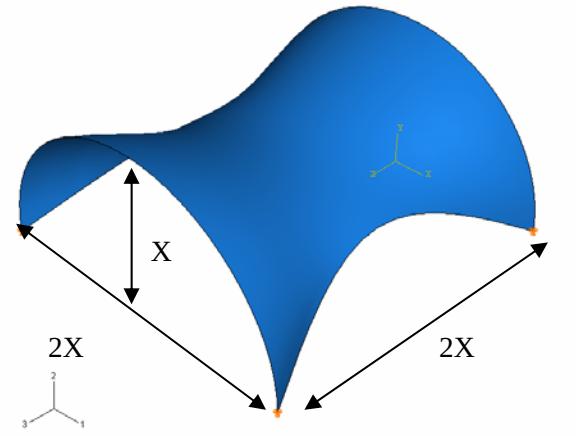

Figure 1. Global shape of the studied hypar surface. X is the maximal height of the surface and is variable. The projection of the hypar surface fits into a plane with dimensions 2X*2X.
(X = 1, 5 or 7.5m)

Three values were chosen for the height in the FEM analyses: 1, 5 and 7.5m. The length of the sides of the horizontal square in which the hypar shell can be projected is twice the height for the three studied cases. This means that the mathematical description (and thus also the curvature) of the three studied surfaces is the same and only the global dimensions are varied.

Since the material behaviour of TRC is rather complex, it will be briefly explained, before it is implemented into the finite element models. Focus is put on the stress-strain behaviour and the durability.

2 MATERIAL BEHAVIOUR

There are two points of attention that should be considered when a structure, comprising TRC, is to be dimensioned. (1) Although the behaviour of TRC is linear elastic in compression up to failure, the stress-strain behaviour in tension is nonlinear – as is shown in figure 2. In serviceability limit state, the variation of the stiffness with increasing load will have its consequences on the total deflection of the structure. (2) Since for some material combinations a considerable loss of strength can be expected within the lifetime of the studied structure, this is also included in the dimensioning examples. Two types of TRC materials (with different fibres and matrix) will be discussed in more detail and will be included into the FEM analyses. The behaviour of these two exemplary TRC materials is discussed in this section. The influence on the dimensioning is discussed in the next section. The first material combination under study in this paper is a mortar matrix with ordinary Portland cement (OPC), reinforced with AR-glass fibres. The second material under study consists of a combination of E-glass fibres with an Inorganic Phospate Cement (IPC). The similarities and differences between these materials will be discussed in more detail in following sections.

2.1 Tensile Loading

The global behaviour of TRC in tension and the underlying mechanisms are briefly explained in this section. Fig. 2 shows the three stages of a typical stress-strain curve. These three stages are globally defined as follows:

1. in the linear elastic stage or pre-cracking stage, the matrix and fibres both carry part of the applied load and generally exhibit the same deformation.
2. within the multiple cracking stage, matrix cracks are formed and stabilised by the fibres, which bridge these cracks. A fine crack pattern is built with increasing stress and existing adhesive bonds between matrix and fibres are releaved in the vicinity of the crack faces and replaced by a purely frictional stress transfer.
3. in the post-cracking stage, no new cracks develop any more in the matrix. Only the fibres contribute to the load bearing capacity with the increasing load and thus define the composite stiffness. The TRC composite fails when the fibres eventually fail or when they are pulled out of the matrix.

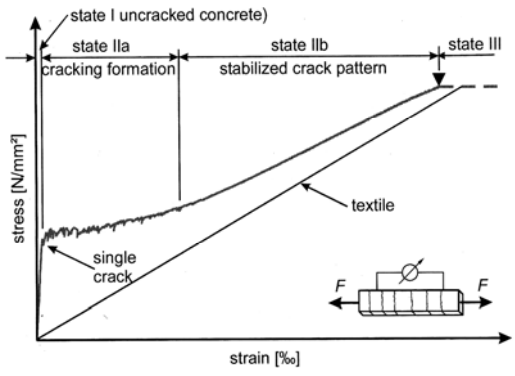

Figure 2. Typical stress-strain behaviour TRC composites

Several models, based on the global description explained above, have been developed, verified and described in detail over the years [e.g. Aveston *et al.*[1971]; Cuypers and Wastiels [2006]]. In the scope of this paper, it is sufficient to know that the stress-strain behaviour is nonlinear. The specific

curves that were implemented into the FEM calculation are shown in Fig. 3. This figure shows that the OPC mixture has a higher stiffness in the pre-cracked state (mainly due to the higher stiffness of the matrix), which can be advantageous in serviceability limit state, but the IPC combination shows higher strength (mainly due to the higher fibre volume fraction).

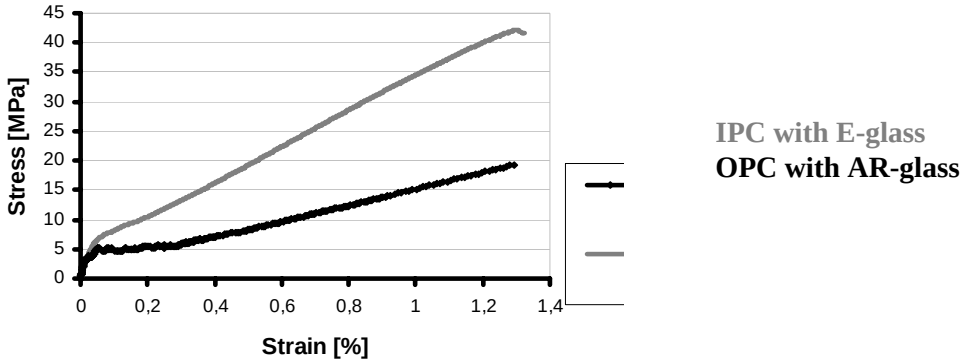

Figure 3. Stress-strain behaviour of the two studied types of TRC composites

2.2 Durability

In the early days of glass fibre reinforced concrete (grc), it was soon recognised that the fibres were aged under chemical attack by the matrix material itself (see e.g. Budd [1961]; Majumdar and Tallentire [1968]). This degradation of glass fibres in a concrete matrix occurs slowly but surely during the service life of the structure. Ageing of materials due to chemical attack under service conditions can globally be determined in two ways: (1) from specimens which were subjected to real environmental conditions and (2) from results obtained on similar specimens stored in a well-controlled environment in the laboratory. Unfortunately, when the studied processes are slow the first method is not a viable option to study "new" material combinations. Basic knowledge of the degradation mechanisms can however be used to study the materials of interest under "accelerated" ageing, meaning that the nature of the attack is not modified and processes are only accelerated within a laboratory environment. For grcs this method is commonly used (e.g. Litherland *et al.*[1981]). Rather than focussing on the description of detailed chemical reactions for several material combinations, this section aims to present a global methodology for the modelling of ageing due to chemical attack from an engineering point of view. Nowadays the majority of the authors agree on some important conclusions that can be used to model the loss of strength of glass fibres due to chemical attack in simulated pore solutions as function of temperature, humidity and time:

1. The remaining strength of the glass (and thus also of glass fibres) is determined by fracture mechanics: the loss of strength of the fibres is thus not due to global loss of fibre diameter, but due to the growth of the flaws (small defects) inherently present in the fibre. The order of magnitude of these flaws is about 10-100nm (e.g. Gao *et al.* [2003]; Orlowsky *et al.* [2005]). The rate of loss of strength is directly linked to the flaw growth rate.
2. The temperature dependency of the rate of chemical attack is expressed according to an Arrhenius relationship (Litherland *et al.* [1981]; Purnell et al. [2001]). Usually it is assumed that only one (e.g. Litherland *et al.* [1981]; Purnell et al. [2001]) or two (according to Orlowsky *et al.* [2005]) mechanisms occur as a function of the studied time-temperature frame. This Arrhenius relationship is thus usually used to express the dependency of maximal two rate constants as function of temperature.

3. The rate of chemical attack of glass is function of the humidity. For example Wiederhorn [1967] and Freiman [1980] noted that the rate of chemical attack of glass increases with increasing partial pressure of water within the surrounding environment. Orlowsky [2005] describes an increasing rate of ageing of full composite TRC specimens with increasing relative humidity.

The OPC material combination discussed in this paper has been tested under several temperatures and relative humidities at several ageing times. Based on these callibration tests, that were conducted in a well-controlled laboratory environment, a theoretical prediction of the loss of strength with time under real outdoor weathering was performed. Details are described by Cuypers and Orlowky [2007] and Fig. 4 shows the theoretically predicted loss of strength within four years of weathering in Aachen together with the experimental values.

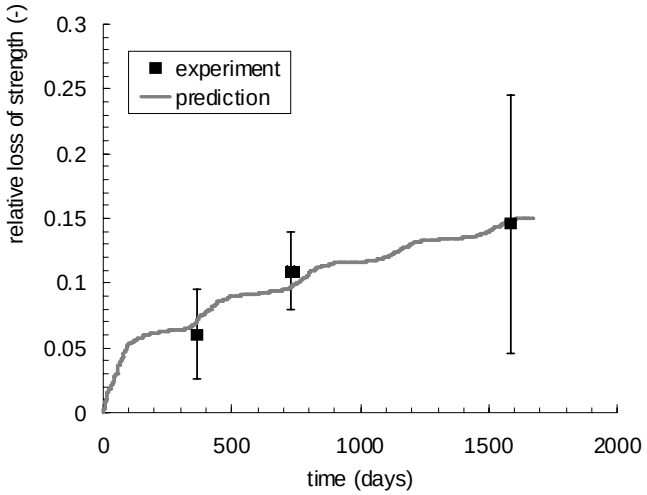

Figure 4. Evolution of the experimental and theoretical loss of strength of the OPC composite under natural ageing in Aachen after 4.5 years

Based on Fig. 4 it is clear that the required lifetime of the structure will have an influence on the necessary thickness: the remaining strength at the end of the lifetime of the structure will be lower when the ageing time increases. With the above mentioned methodology the remaining strength of the studied OPC composite is calculated for a lifetime of 10 years and for a lifetime of 50 years. It was found that for the OPC material combination under study, that the calculated loss of strength was 30% after 10 years of outdoor weathering and 40% after 50 years of outdoor weathering.

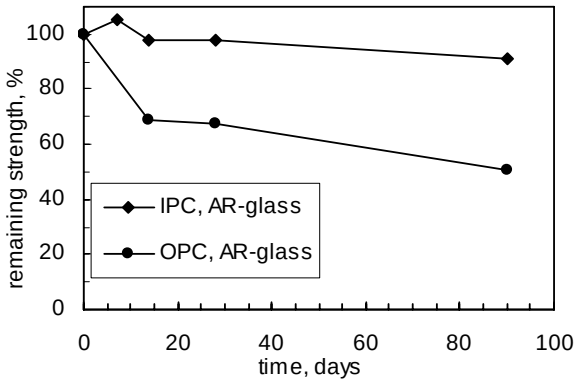

Figure 5. Evolution of the experimental loss of strength of OPC with AR-glass and IPC with E-glass under water at 50°C

Fig. 5 shows the evolution of the loss of strength of the OPC composite, as discussed before, and of the IPC composites within the same environment: after storage under water at at 50°C. This figure clearly shows that, although the OPC composites show distinct loss of strength, this is not the case for the IPC composite. It can therefore reasonably be assumed that the loss of strength of the IPC composites can be neglected.

3 FEM ANALYSIS

3.1 Implementation of Loads and Materials

Dimensioning was done following the Eurocodes as much as possible. This means that in ultimate limit state (ULS) it was checked whether the shells do not fail under all possible load combinations (including snow, wind, own weight) that can be defined under ULS. In serviceability limit state, no load combination that should be considered, is allowed to lead to too large deflections. In this case the maximum deflection was limited to span/250. In serviceability limit state (SLS), the engineering constants of the materials that are used, are average values. The non-linear stress-strain curves, as shown in Fig.1, represent the average behaviour of the two studied TRC materials and can thus be inserted into the FEM model as such. In ULS however, design values should be determined for the strength. The characteristic values of the strength (< 5% probability of failure, assuming a Weibull probability distribution function for the strength) were determined from series of experiments. After a material safety factor was applied to these characteristic values, the dimensioning values - which were then used in the FEM analysis and dimensioning – that were found were approximately 10MPa for the OPC composite and 20MPa for the IPC composite. These values represent the initial strength of the used materials and do not include possible effects of ageing yet.

In order to obtain representative values for the external loads, according to the Eurocodes, it was assumed that the building resides in Belgium on a flat topography terrain in an urban area, in which at least 15% of the surface is covered with buildings and their average height exceeds 15m. The design loads in ULS and SLS are determined according to this assumption.

The shell is pin supported at its four corners; the edges are free. This design leads to stress concentrations in the four corners. Therefore, the contact surface will be enlarged when constructing the doubly-curved shell. The global minimal thickness of the doubly-curved shells will be determined without considering these stress concentrations.

3.2 Overview of results and discussion

The minimal values of the necessary thickness of the hypar shells are listed in Table 1. For all dimensioning examples, the ultimate limit state was the decisive design state. As can be seen from Table 1, the necessary thickness is relatively low for all calculated cases. Since it was assumed, based on experimental results, that the E-glass reinforced IPC does not show considerable loss of strength with time, the calculated necessary thickness was not considered to be a function of time.

The calculation example with AR-glass fibre reinforced OPC shows that the necessary minimum thickness should be increased when the required lifetime of the studied structures is increased. Globally, for the studied type of hypar surface, the combination of IPC with E-glass seems to be the most advantageous from point of view of minimal thickness.

Table 1. Calculated necesarry mimimum thickness of hypar surfaces: influence of span, material combination and lifetime used.

material	*2m span*	*10m span*	*15m span*
IPC + E-glass	0.8	4.0	6.0
OPC + AR-glass, initial	1.1	5.5	8.5
OPC + AR-glass, 10 years	1.3	6.5	9.5
OPC + AR-glass, 50 years	1.4	7.0	10.5

Note: the calculated values for minimal thickness are depicted in cm

4 CONCLUSION

In this paper, the potential of TRC (textile reinforced concrete) in structural applications was studied by means of some illustrative design examples. The type of structure that was chosen here was a doubly-curved shell with varying span. The influence of the material choice was also discussed briefly. Generally, the design examples showed that shells with relatively limited thickness could be theoretically designed with TRC. If a newly developed durable material combination is used, only 6cm thickness should be sufficient to span a doubly curved shell with 15mx15m ground surface. If a less durable (but slightly cheaper) material combination is used, the necessary thickness increases up to about 10cm for a required lifetime of 50 years. The next step that is foreseen in the near future is an experimental verification on the studied shells with 2mx2m ground surface.

Permeability and Porosity as an Essential Factors in the Long-term Durability of Steel Fibres Reinforced Concrete

Beddar Miloud [1]

T11

ABSTRACT

Steel fibres have gained popularity in recent decades for use in concrete at relatively low volume fractions, mainly to ameliorate toughness, strength and shrinkage cracking. However, little information is available about the effects of fibers on the permeability and the porosity, which play an important role in long –term durability of concrete.

This paper presents the results of an experimental study that was carried out to examine the influences of steel fiber addition on the permeability and porosity of a concrete prepared mainly from local materials. The results tests are discussed in this paper and many interpretations of the results are reported as well as many reliable conclusions regarding effects of steel fibers on water and gas permeability of concrete.

KEYWORDS

Porosity, Permeability, Voids, Steel fiber concrete.

1 INTRODUCTION

Permeability of concrete generally refers to the rate at which water or other aggressive substance (sulphates, chlorides ions, etc.) can pass through the concrete. It plays an important role in the long-term durability of concrete material [Jackson, 1978]. Low permeability is an important requirement for hydraulic structures and in some cases water tightness of concrete may be considered to be more significant than strength although, other conditions being equal, concrete of low permeability will also be strong and durable. A concrete, which readily absorbs water, is susceptible to deterioration. This deterioration is determined largely by the ability of the cover zone concrete to resist the ingress of deleterious agents from the environment.

Concrete is inherently a porous material. This arises from the use of water in excess of that required for the purpose of hydration in order to make the mix sufficiently workable and the difficulty of removing all the air from the concrete during compaction. If the voids are interconnected concrete becomes pervious although with normal care concrete is sufficiently impermeable for most purposes.

Steel fibres have gained popularity in recent years and are used in concrete mainly to improve flexural and toughness strength, to reduce shrinkage cracking [Antoine, 1985; ACI Committee, 1984]. The arrest cracks shrinkage in young concrete by fibres could lead to reduce permeability of SFRC when compared with plain concrete [Tsukamoto and Worner, 1991]. But, little information is available about the effect of fibre addition on both porosity and permeability of concrete.

The main aim of this experimental study is to examine the influence of fibre length and fibre content on the porosity and permeability as essential factors in the long-term durability of a concrete prepared mainly from local materials. The work reported herein is based on laboratory experiments and carried out according to the ASTM standards [Astm, 1982] concerning the porosity property while gas and water Permeability were measured using the test rigs illustrated in Figures 1and 2.

2 MATERIALS AND METHODS

2.1 Basic Ingredients. The basic ingredients of steel fibre reinforced concrete were:

2.1.1 Portland cement

Type CPJ45, comes from AIN TOUTA factory and is conform to NF.P. 15.301. Chemical composition and physical properties are given in tables 1 and 2.

Table 1 Physical and mechanical test results

Blaine fineness m^2/ kg	Autoclave expansion, percent	Setting time(Vicat) Initial	Final	Compressive strength, MPa	Shrinkage µm/ml
324	0.01	105	220	45 (28days)	800

Table 2 Chemical composition (%, by weight) of CPJ cement

Constituent, %	SiO_2	Al_2O_3	Fe_2O_3	Ca O	Mg O	Ca O free	SO_3	P.F	Insoluble
CPJ45	19.48	5.06	3.72	61.95	0.85	1.63	1.1	3.44	1.26

2.1.2 Coarse aggregate

this is local aggregate obtained by crushing of the limestone rock from the COSIDER carry. It has two fractions 3/8 and 8/15. Its physical properties are given in tables 3 and 4.

Table 3 Some characteristics of the sand and gravel used in the tests

Materials	Density	Porous/dense	Compactness	Porosity	Sand equivalent
Sand	2.56	1.64/1.83	36.42/70.76	36.58/29.24	75.4/77.2
Gravel 3/8	2.68	1.28	47.46	52.24	……
Gravel 8/15	2.68	1.32	49.25	50.75	……

Table 4 Some physical and mechanical and morphological properties of the gravel used

Gravel Grading	Superficial tidiness (P)	$CaCO_3$ (%)	Flattening Coef	Los Angles (LA) MDE
3/8	1.5	8.5	18	20	16
8/15	1.28	8.3	13	23	17

2.1.3 Dune sand

this is a clean, siliceous and fine sand of fraction 0/5 taken from BOUSAADA region. Its characteristics are regrouped in tables 3 and 5.

Table 5 Chemical composition (%, by weight) of the dune sand used.

Constituent, %	SiO_2	Al_2O_3	Fe_2O_3	Ca O	Mg O	Ca O free	SO_3	P.F	Insoluble
Sand of dune	86.04	1.35	0.86	6.63	0.08	…..	…….	5.00	…….

2.1.4 Steel fibers: all fibers used in this study were steel fibers having 1.2 mm diameter, 10÷30 mm length, the average fiber density was 7.89. The fiber content was varying from 0.5 to 2% by volume. Its characteristics are regrouped in table 6.

Table 6 Some physical and mechanical properties

Density	Tensile strength MPa	Elasticity modulus MPa	Dilatation Coef (µ/m)	Fire resistance °
7.8	1000 to 3000	2×10^5	11	1500

2.2 Mix Proportioning

Concrete mixes were designed to provide a slump of (60±10mm) for ease of handling, placing and finishing. The air content of all mixes is 3 ± 0.5 %. The concrete mix proportion used (class 350 dan/m^3) has been determined by absolute volume method [Komar, 1982] and were follows: Cement 350 kg/m^3, Sand 758 kg/m^3, Gravel 1073 kg/m^3 and total water 215 l/m (This quantity takes into account the degree of aggregates absorption)

3 SPECIMEN PREPARATIONS AND CONDITIONNING

3.1 Mixing, Casting and Curing

A total of nine plains (three for porosity tests, three for gas permeability tests and three for water permeability tests) and forty five fibre reinforced mixes were prepared. Materials were mixed in a linear-cum-flow mixer type 'O' which had a capacity of 0.043 cubic metres and a power driven rotating pan and paddle. This mixer was sturdy enough for fibrous mixes, and a good uniformity of fibre distribution could be achieved. The mixer was first loaded with the coarse aggregate and a portion of the mixing water; after starting the mixer; sand, cement and the rest of water were added and mixed for 5 min. The fibres, in the case of fibrous mixes, were added following the addition of all mix ingredients.

Three 16×32 mm cylinders were cast from each mix. They were cast in cylindrical steel moulds and compacted on a vibrating table. Specimens were placed under plastic sheet membrane for 24 hours in an ambient temperature. Following removal from the moulds, they were individually sealed in plastic bags and stored at room maintained at 24°C and 65% relative humidity until testing at an age of 7, 14 and 28 days for porosity tests and only at age of 28 days for permeability tests. But, before testing, the cylinders were removed from the plastic bags, and cut (in the case of porosity and gas permeability tests) using specimen cutting machine into 50 mm- thick slices having removed a 10mm thick slice from the top and the bottom.

4 POROSITY AND PERMEABILITY TESTS

4. 1 Porosity Test in Hardened Concrete

The porosity of steel fibre reinforced concrete, as well as plain concrete, is an important characteristic, which determines to a large extent their mechanical properties. High porosity is strongly detrimental to the strength and permeability of a concrete, particularly if the pores are of large diameter.
To evaluate the porosity of hardened concrete and following ASTM C642 testing procedures, apparent, bulk saturated surface dry, and bulk dry specific gravities of hardened concrete (in both cases: plain concrete and steel fibre reinforced concrete) were evaluated by using the following formula:

$$T.V = (1 - y_1 / y) \times 100 \ldots\ldots..(1)$$

Where T.V = Volume of permeable pore space in concrete, percent
y_1 = Concrete bulk dry specific gravity
y = Concrete apparent specific gravity

4.2 Water Permeability Test in Hardened Concrete

Water permeability was measured using the apparatus illustrated in Figure 1. It consists of a metal stand with three permeability cells, unit pressure regulator range from 0 to 30 bars, and a graduated gauge glass. Each cell comprises a top and bottom steel plate which bolt together by three steel shafts fixed on the stand (Fig. 2). The base plate is mild steel with a 20mm diameter hole drilled to form the water inlet. The top is also steel but with a circular window, through which the top face of the test specimen can be observed. After putting the test specimen in the cell and making the water pressure on, Flow test is normally measured by observing the rate of flow of water through the calibrated glass

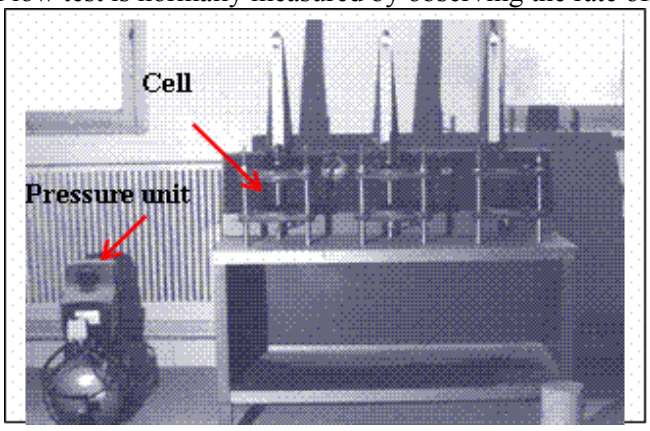

Fig .1 Water Permeability Test Rig

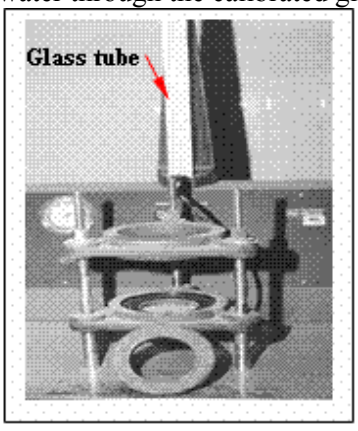

Fig .2 General View of the Cell

Generally, for concrete complete penetration of the specimen may take several days or more. In our case, the specimens are removed from the test after one week, and the permeability coefficient calculated from the depth of water penetration.

4.3 Water Permeability Coefficient

The test, in this case, consists in making an amount of water, under a determined pressure, flows through a cylindrical specimen of concrete and then measure the flow.

♦ To measure the coefficient of water permeability by flow, the DARCY'S Law [Darcy, 1856] can be applied as the flow is continuous:

$$K_{1D} = Q.X \ / A.\ h \qquad (2)$$

Where Q is the volume flow rate given in (m^3/s), A is the cross-sectional area of the test specimen in (m^2), h is the head of water given in (m), X is the specimen thickness in the direction of thickness (m), K is the permeability coefficient.

♦ To measure the water coefficient by penetration, VALENTA'S Law |Valenta,1970] can be applied if the material is less permeable:

$$K_{1V} = \chi^2_{P}.\ V / 2.h.t \qquad (3)$$

Where K_{1V} : Water permeability coefficient (m/s)
χ^2_P : depth of penetration (m) V : Volume of voids filled by water in the penetrated zone.
t : Time to penetrate to depth χ_P (s) , h : Applied press ion (eg: 1 bar = 10m)

The two coefficients calculated from equation 2 and 3 are derived for a specific fluid flowing through a specific porous medium. To compare the permeability of concretes obtained from tests using different liquids it is necessary to define the "intrinsic permeability" K_i, which should depend only on the pore structure of the concrete:

$$K_{1c} = Q\ \chi\ \eta\ /\ A(\ P_1 - P_2) \qquad (4)$$

Where K_{1c} = intrinsic permeability of concrete (m^2) η = viscosity of liquid
P_1 = upstream pressure (N/m^2) P_2 = downstream pressure (N/m^2)
$P_1 - P_2$ = pressure differential = h ρ g, P = density (kg / m^3) and g = 9.81 m/s

Substituting for $P_1 - P_2$ in equation 4.

$$K_{1c} = Q\ \chi\ \eta\ /\ A\ h\ \rho\ g \qquad (5)$$

Then $K_{1c} = K_{1D}\ \eta\ /\ \rho\ g$; for water $\rho = 1000 kg/m^3$, hence $K_{1c} = K_{1D}.\ 10^{-3}/1000.\ 9.61 = 1.02.\ 10^{-7}\ .\ K_{1D}$
For water, therefore, the intrinsic permeability coefficient in units of m^2 is approximately 10^{-7} times the Darcy coefficient in units of m/s.

4.4 Gas Permeability Test

The test rig used to measure gas permeability is illustrated in Figure.3. It is an apparatus with measurement of bubble flow, it is made up mainly:

- A pressure unit automatically-controlled leading to cell entry
- Glass tubes of different volumes (1.5-5-15-150ml)

The test cell is made up of 5 parts: an aluminium receiver, two milled plates being used for recuperating oxygen crossing the concrete disc, a polyurethane membrane surrounding the disc of concrete and a lid (Fig 4).

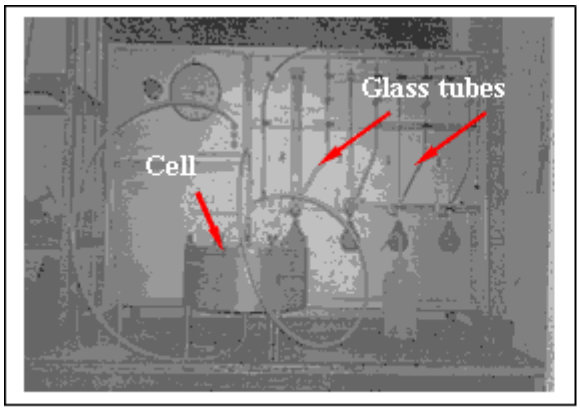

Fig 3. Gas permeability test rig

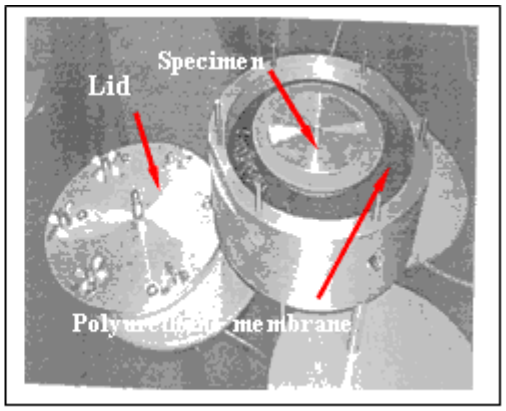

Fig 4. General view of the cell

4.5 Gas Permeability Coefficient

The principle is the same one as for water, a gas overpressure is applied to one of the test disc and a flow is measured at the exit. Thus, The permeability coefficient obtained using a gas normally defined by the Hagen-Poiseuille 's formula:

$$Kg = 2.\ Q.x.P_0.\ \mu.\ /\ A\ (\ P^2 - P_a^{\ 2}\ ) \qquad (5)$$

Where K_g is the intrinsic permeability coefficient of gas in units of m^2,μ is the dynamic viscosity of liquid, P is the downstream pressure , P_0 is the pressure at which the flow is measured (generally =Pa), Pa is upstream pressure , Q , A, x are as defined previously. Here, it very important to mention that the flow rate is measured at downstream face. If the flow rate is measured through the upstream face, then P replaces $P_a$in the numerator.

5 TEST RESULTS

5.1 Porosity Test Results and Discussion

Porosity in hardened concrete (nine unreinforced concrete specimens and twenty seven steel fibres reinforced concrete specimens) was determined according To ASTM C642 standard method. The results given in this paper are the average values obtained from three specimens per mix. A relationship between porosity and curing age, fibre content, fibre length and slice position was established using data calculated by equation 1.
In this investigation, pores distribution throughout the plain and reinforced concrete specimens were evaluated after slicing each cylindrical specimen into six cylindrical slices (from top to the bottom).

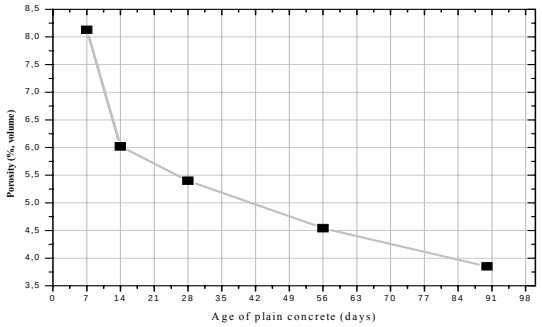

Fig 5. Relationship between pores percent and cure age (Average values of the whole specimen)

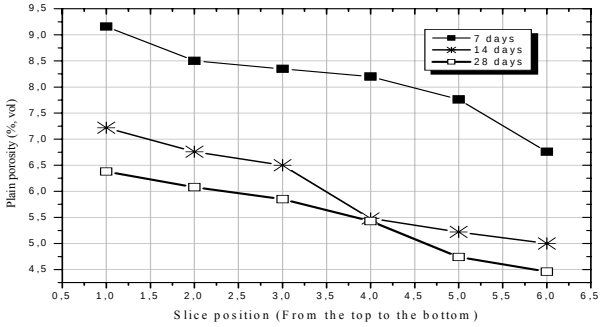

Fig 6 Relationship between pores and cure age at different positions

The porosity percentage decrease from 6.38 % in the top slice to 4.46 % in the bottom slice, which is the most compacted part of the specimen. This indicates that pores content are not uniformly distributed throughout the specimen .The 28 days porosity values for plain concrete specimens cured in the laboratory were shown in figure 5. These values were in the range of 4.46 percent (in the bottom slice) to 6.38 percent (in the top slice). It can be also seem from figure 5 that porosity content decrease with increasing cure age. The 7 days porosity content value was 8.13 percent. But this percent was only on the average of 5.49 at the age of 28 days. This can be explained by the hydration process in which the capillary pores and air voids are partially or completely filled with the hydration products and the possibility of water flow is gradually reduced. This fact is also confirmed by other researchers [Brandt, 1995; Husseyin, 1995] who reported that the duration and quality of cure of the fresh mix determine the process of hydration and the volume of hydration products, which may eventually fill the capillary pores and reduce their permeability.

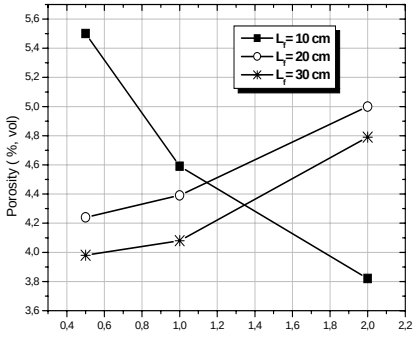

Fig 7 Relationship between porosity and

Generally, it can be seen from figure 6 that the value of porosity is lower after 28 days at ambient temperature, because the pores accrete. On the contrary, concrete with steel fibers exhibits lower porosity values compared with plain concrete at the same slice and in the same direction. With fiber amount varied in the range of 0.5 to 2 % by volume (L_f= 10mm), the porosity varied from 5.5 to 3.82 %, as it can be seen from figure 7, whereas with fiber length of 20mm the porosity increased with increasing fiber content. The addition of fibers, with length of 30mm, did not affected the porosity in the amount values ranged from 0.5 to 1 % but, beyond the 1 % there was a slight increase in the porosity. The slight decrease reported in the porosity of specimens reinforced with steel fibers compared to the plain concrete can be explained by the fact that reinforced concrete specimens needed a long duration of vibration which surely affected the pores rate and their sizes and their distribution. It is important to mention that many studies [Brandt, 1995; Husseyin, 1995; Bencheick &Baali, 2003; Bhattacharjee et al., 2004] have reported that fibers addition did not significantly increase the amount of pores above those calculated for plain concrete.

6.2. Water permeability results and discussion

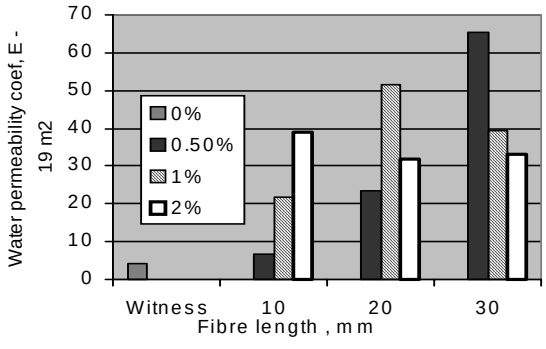

Fig 8. Relationship between Kw and Fibre length

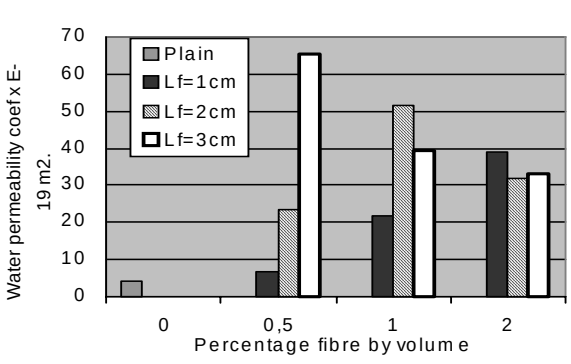

Fig 9. Relationship between Kw and fibre content

Generally in the cases of a concrete as a composite a great porosity does not mean high permeability. Indeed only the interconnected of these pores is significant for permeability. The results given in this paper are average values obtained from three specimens per mix and were derived from penetration measurements using the Valenta equation 3. All results are reported in figure 8 and 9. Steel fibre addition to concrete clearly increases water permeability coefficient whatever fibre amounts or fibre lengths as it can be seen from figure 9 and 10. Water permeability coefficient of a plain concrete was around 4.02×10^{-19} m^2, while it can be said that all the three fibre lengths, with an amount of 0.5% by volume, caused water permeability coefficient to range from 6.71×10^{-19} m^2 for L_f =10 mm to 23.36×10^{-19} m^2 for L_f =20mm and 65.49×10^{-19} m^2 for L_f = 30mm. At 1 % fibre content, water permeability coefficients were 21.87×10^{-19} m^2, 51.39×10^{-19} m^2 and 39.21×10^{-19} m^2 for 10mm, 20mm and 30mm fibres respectively. But, at 2% fibre content this coefficient varied from 38.83×10^{-19} m^2 L_f = 10mm to 33.18×10^{-19} m^2 for L_f = 30mm.

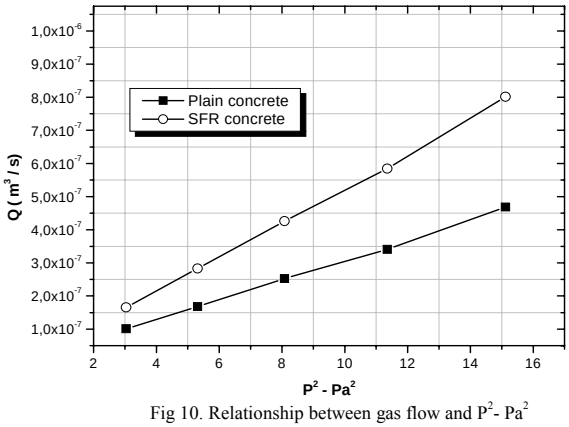

Fig 10. Relationship between gas flow and P^2- Pa^2

Generally water permeability tests are very complicated to be realized and results given in this paper can be explained by the fact that the presence of fibres, whatever their lengths or their contents facilitated the interconnection between pores which were reduced according to the porosity results. The fibre acted as a bridge between pores so that the flow rate had been increased and water permeability coefficient was subsequently increased.

6.3.Gas Permeability Results and Discussion.

The permeability was determined by using equation 3 of Hagen-Poiseuille. Tests were carried out on a ordinary concrete disc with thickness of 65 mm, having undergoes a 28 cure days as mentioned before. A pressure of 5 bars is selected on the pressure gauge of the permeameter and fluid movement is observed in the tubes during 5 minutes. This enables us to check that oxygen does not pass by the disc edges when the tire is inflated. Typical results of a plain concrete specimen as an example are given in table7, while some results, which represent steel fibres reinforced concrete specimens, are given in table 8. The average value of permeability coefficient K_g for plain concrete is 3.6950×10^{-17}, while that of concrete reinforced with 1 % by volume of steel fibres is 4.0916×10^{-17} . This means that steel fibres increased gas permeability coefficient. To explain such increase in the gas permeability coefficient of steel fibre reinforced concrete, it may be assumed that even permeability is determined more by matrix properties [Brandt, 1995; Husseyin, 1995, Bamforth, 1987] than the fibres ones.
Particularly, the matrix-fibre interface has the largest content of pores and micro cracks that effect overall permeability. Also, it is very important to mention here that fibres act as ties between pores so that great interconnections can be created which allow gas flow to penetrate easily inside the concrete structure.
All results were obtained at the time of a rise in pressure followed by a descent. The final result being an average of each pressure of the calculated permeability.In the large majority of the cases, the average value obtained in the downward phase in the pressure is the same as that measuring of the rising phase.

All results of the gas flow (Q_g) can be plotted against pressure variation. Figure 10 is a typical example that can confirm the influence of fibre addition on gas permeability concrete. It can be seen from figure 10 and from all other obtained that all curves are very close to be approximately straight lines which ensure the correct operation of the equipment, of the assembly carried out and the aptitude of oxygen to cross material.

6 SUMMARY AND CONCLUSIONS

At 0.5, 1 and 2 percent volume fraction, effects of steel fibres, with three different lengths, on water and gas permeability of concrete were investigated experimentally. Results of this investigation indicate that high porosity does not mean high permeability. The only factor which governs the permeability process is the pores interconnections. The porosity results presented in the paper indicates that steel fibres can reduce porosity. This reduction may be referred to the vibration duration that was longer with steel fibres reinforced concrete specimens compared to plain concrete specimens. More tests will be required to allow the determination of the exact influence of the fibres in this respect. Steel fibre addition to concrete clearly increases water permeability coefficient whatever fibre amounts or fibre lengths. This increase is also observed with gas permeability coefficients. The fibers acted as bridges between pores so that the flow rate had been increased and both water and gas permeability coefficients were subsequently increased. As a conclusion, it is important to mention that with 1 % fibre content, water permeability coefficient was 21.87×10^{-19} m^2, while the average value of gas permeability coefficient K_g for a concrete reinforced with 1 % by volume of steel fibres was 4.0916×10^{-17}. So, concrete permeability coefficients obtained using water and gas was considerably different, due to the phenomenon of gas slippage.

T 11

ABSTRACT

This study provides data regarding the characteristics of three carbon fiber reinforced polymer (FRP) laminates with three types of resins exposed to accelerated natural weathering conditions according to ASTM G-154-00a for 1000hrs. The FRP laminate consists of three layered CFRP sheets bonded together with an adhesive. Three-point bend testing according to ASTM D790 showed that ultra violet (UV) light exposure decreased the flexural modulus of the three- layered FRP samples by 10%, 36% and 2% for samples A, B and C respectively. While the reduction for the resin samples was 11.8%, 8.3% and 14.3% for samples A, B and C respectively. SEM analysis showed cracking and deterioration in the resin and FRP systems as a result of the exposure to natural weathering.

1 INTRODUCTION

FRP composite materials have been widely used in strengthening concrete structures in the past few decades. One of the most important issues with using FRP materials to strengthen concrete structure is the durability and long term performance, especially in hot and humid environments. FRP composite materials can provide longer lifetimes and lower maintenance than equivalent structures fabricated from conventional materials if it is designed and applied appropriately. The feasibility of strengthening concrete structures through the external bonding of FRP composites has been extensively demonstrated through laboratory tests and field applications [1-11], there are still significant unanswered questions related to durability and extent of service life that can be expected. For any application it is critical that a designer know not just the short-term behavior of the materials under consideration, such as strength and modulus, but also the rates of deterioration of these properties as a function of exposure condition and time. In the case of strengthened structures, the assessment of service life is complicated and difficult to define precisely since it depends on the intrinsic durability of not only the FRP system used to strengthen the structure, but also on the integrity of the adhesive bond between the FRP and the concrete substrate. There are many factors affect the performance of an FRP and adhesive materials. Among these factors is the ultraviolet (UV) exposure [12]. UV exposure is usually confined to the top few microns of the surface [13]. This causes surface degradation which can affect the mechanical properties disproportionately, as flaws that results from degradation can serve as stress concentrators and initiate fracture at stress levels much lower than those for unexposed specimens.

The purpose of this research was to evaluate the three different types of FRP laminates and resins and assess the UV impact on their mechanical behavior. These systems are to be used in stregthening the concrete structure in Abu Dhabi Company for Onshore Oil Operations (ADCO), hence the most durable system was recommended.

2 EXPERIMENTAL PROGRAM

2.1 Materials and Sample Preparations

A group of carbon fiber reinforced polymer sheets and resins were considered for this experimental program. These materials were provided by three different manufacturers and are labled as A, B and C. A total of six samples per group of FRP materials were made by gluing three layers together using the corresponding adhesive. The size of these samples was 25 mm width and 150 mm length. The above mentioned adhesives were applied to the FRP sheets using a brushing process followed by a rolling process to evacuate the entrapped air between the different layers. Similarly six resin samples were made with the same size and a thickness of 4 mm. In the case of the resin samples, the resins were prepared and poured into a mould of the required dimensions.

2.2 Exposure Environment

WETHEROMETER BS3900 UV accelerated testing machine was used to expose a total of 18 samples for a total of 1000h. The exposure cycle consisted of 8 hr UV exposure at 60˚C and 4h condensation at 50˚C.

3 RESULTS AND DISCUSSION

3.1 Mechanical Behavior Testing

The three point bending flexural test provides values for the modulus of elasticity in bending EB, flexural stress σf, flexural strain εf and the flexural stress-strain response of the material. The three-point bending machine, shown in figure 1, was used to evaluate the flexure behavior of controlled and

weatherd samples. The Modulus of elasticity of resin samples are shown in figure 2. All weathered resin samples have experienced reduction in the modulus of elasticity due to the UV exposure. The percentage in modulus of elasticity reduction are 11.8%, 8.3% and 14.3% for A, B and C samples, respectively. It should be noted that the highest modulus of elasticity is for sample C with values of 5.6 GPa and 4.8 GPa for the control and weathered samples respectively.

Figure 3 shows the elastic modulus comparison for the three-layered FRP system. The three-layered FRP samples have shown the same trend, UV exposure has reduced the elastic modulus elasticity by 10%, 36% and 2% A, B and C samples, respectively.

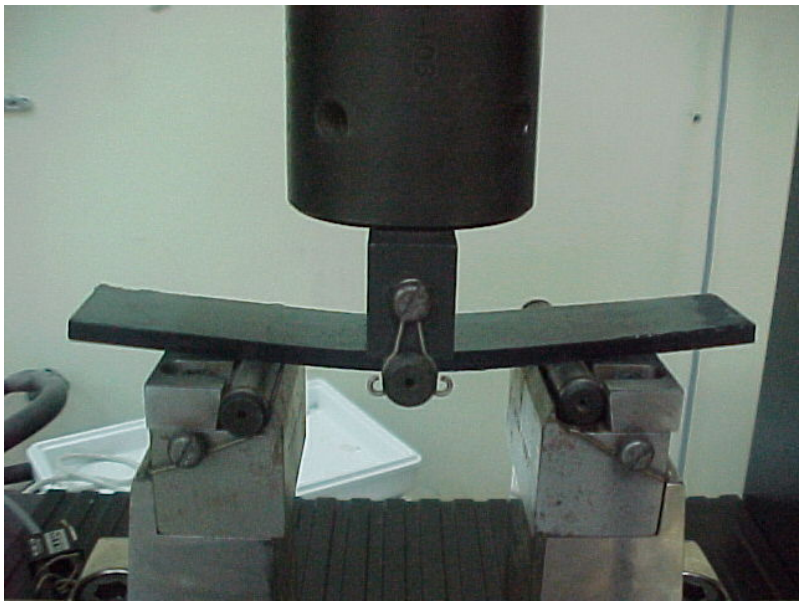

Figure 1. Three-point testing machine.

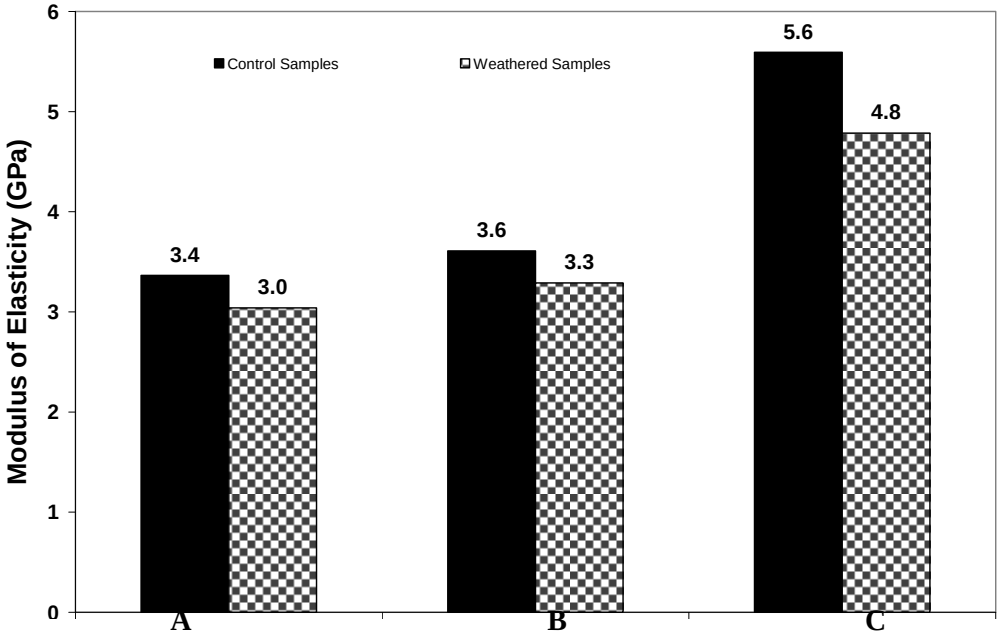

Figure 2. Modulus of elasticity for weathered and control resin samples.

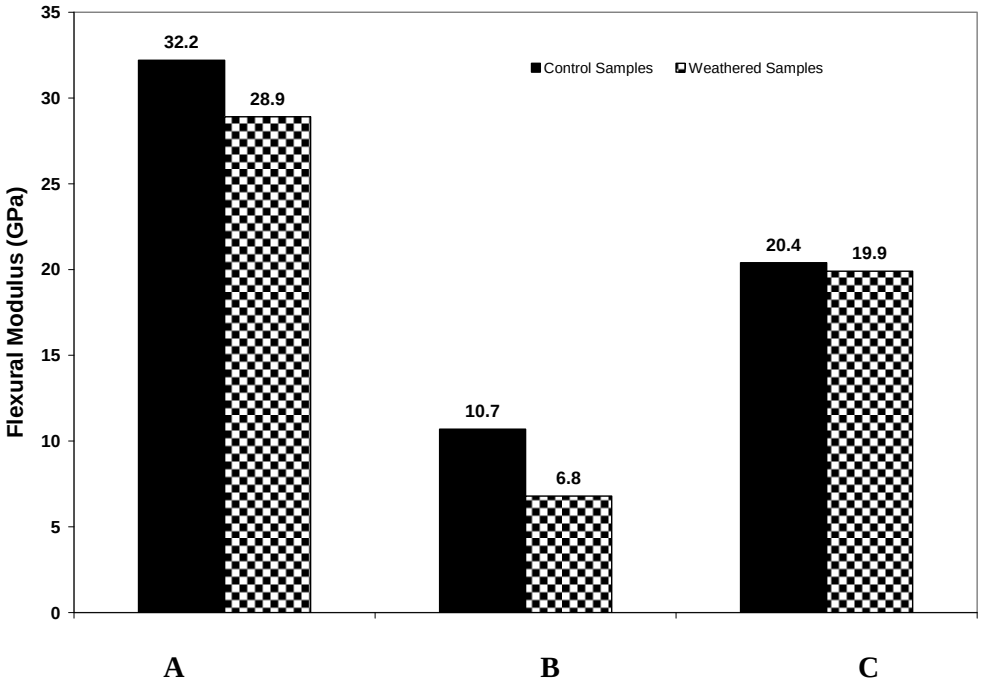

Figure 3. Modulus of elasticity for weathered and control three-layered FRP samples.

3.2 SEM Analysis

Specimens that were subject to accelerated weathering were tested under a three point flexural bending test and the fractured surfaces were analyzed using the scanning electron microscope. Fractured surfaces of virgin samples were also analyzed for benchmarking. For the virgin specimens, failure occurred mostly through matrix delamination as shown in figure 4-6. It can be seen from this figure that fibers and matrix exhibited a strong bond for the control samples. For the specimens subjected to environmental testing, the failure resulted from a matrix cracking and matrix fiber debonding.

Similary it was obvious to see the resin deterioration under the scanning microscope. All resin samples exhibited deterioration with microcracking as a result to the UV exposure. Figures 8-10 show SEM pictures of control and weathered samples.

(a) **(b)**

Figure 6. Enhanced magnification showing fractured **C** samples with (a)good adhesion between the fibers and the matrix for virgin samples, and (b) matrix cracking.

4 CONCLUSIONS

The extended exposure of UV light to the composite materials would decrease the mechanical strength and flexure modulus. Examinations of composite and resin fractured samples under SEM revealed that the failure of the weathered three-layered samples was due to debonding between the matrix and fibers, while for the control samples failure occurred due to delamination. This is attributed to the reactions between the UV ray and the matrix. T

Based on the results of this research it was reccommended to use sample A FRP composites wraps for sregthening ADCO concrete structures due to the fact that the modulus of elasticity value was higher than B and C samples.

Monitoring Moisture Content in Autoclaved Aerated Concrete as a Mean to Achieve Higher Durability

Zbyšek Pavlík [1]
Lukáš Fiala [2]
Zbigniew Suchorab [3]
Robert Černý [4]

T 11

ABSTRACT

Autoclaved aerated concrete (AAC) is a structural material which is commonly used around Europe, particularly as it combines ease of construction with excellent combination of its mechanical and thermal properties. However, the empirical principles employed in construction design until now have led in many countries to a series of failures which are beginning to have serious consequences for the practical applications of the material. High moisture content in AAC blocks in the construction phase belongs to most serious flaws because it can lead to hygric shrinkage related problems in the structure. In this paper, the time domain reflectometry (TDR) method is presented as a universal method for monitoring moisture content in AAC both during the production phase and in situ. TDR can be generally classified as a dielectric method, based on an analysis of the behavior of dielectrics in a time-varying electric field, and consists in the measurement of permittivity of moist porous media. In contrast to most methods used for determination of moisture content, TDR method does not require calibration for every material. Another advantage of the TDR method is that it is well applicable for the materials with higher salinity, where an application of methods such as the resistance method or the capacitance method is impaired by a significant loss of accuracy. TDR also enables continuous long-term non-destructive monitoring of moisture content in constructions.

1 INTRODUCTION

In spite of the autoclaved aerated concrete (AAC) is a structural material commonly used around Europe, high frequency of AAC structures defects has become well known among the potential investors what leads in consequence to the weakening of the position of AAC on the European building materials market which is unfortunate because the material can be considered as environmentally friendly and has considerable potential for future applications. The new precise walling technologies (thin joint systems) lead to much better thermal properties of the envelopes because the thermal bridges characteristic for classical brick-like walling with AAC are practically excluded, and this results in significant savings of both heat energy and the amount of material necessary for construction.

The main problem with the current applications of AAC is that the major European AAC producers (with their whole corporate chain in different European countries including Czech Republic) restrict themselves just to the advertisement of their products and neglect further research work. They often prescribe unrealistic conditions of walling for instance concerning the initial moisture content in AAC blocks. Unsuccessful applications of "user-unfriendly" technologies offered by the AAC producers logically lead to a negative response of both designers and investors, and if the producers would insist on these improper technologies, the development could aim to a dead end.

In the current building practice one can find different walling technologies of AAC structures based on classical walling principles or on precise-walling technology (thin joint system). The differences are as follows. In the classical way of walling the AAC blocks are built using standard mortar joint of 10 mm nominal size. The AAC walls are built on site in standard masonry construction and productivity can often be low. Problems such as the use of overstrong mortar or missing movement joints can lead to cracking of AAC walls. However, problems are generally not found with classical AAC masonry providing that good practice is followed.

Precise walling requires the use of mortar joints that are not greater than 3 mm thick, typically 1 - 2 mm. The blocks are often larger than those used in classical walling. The potential benefits of precise walling are improved productivity and better thermal performance of the completed building. The system can be constructed faster than classical systems and it does not rely so heavily on traditional masonry methods. The precise walling also generates less waste from both blocks and the mortar on site and the amount of mortar used is much less than in classical walling. These precise-walling systems are often referred to as thin joint AAC blockwork.

The precise-walling technologies are being employed over Europe with an increasing frequency but they are still considered as innovative. Compared to the classical walling technologies (large joints), precise walling technologies lead to much better thermal properties of the envelopes because the thermal bridges characteristic for classical brick-like walling with AAC are practically excluded. Therefore, the use of precise-walling technologies should be encouraged and a growth in the use of the technology should be expected. However, good design parameters are required for precise-walling AAC with render systems.

There are clearly benefits to be gained from precise-walling AAC but problems have become evident and this could diminish the growth and use of the technology. When problems do occur they are often due to the differences between AAC and the traditional renders that are used. In particular, the moisture conditions and transfer between the materials often determines the suitability of the AAC system with a particular render finish.

The design of AAC building envelopes has mostly been done by empirical rules for construction until now. As a result, approaches to design have differed case by case and failures have resulted as a result of incorrect specifications and errors in construction. Typical failure examples are cracking of both

external and internal finishes, detachment of renders from the AAC block (sometimes with the AAC itself), cracks around windows and doors, frost failure of external render.

Experience has shown that reasons of defects were due to the use of methods for brick structures being employed by the designers for AAC blockwork. However, the brick-based technologies which were proven by their successful applications over centuries cannot be applied to anything other than brick structures. The properties of AAC differ from those of bricks to such a degree that any analogy between systems based on AAC and on bricks has always to be doubtful.

The current standards cannot help to the designers in preventing failure. Moisture analysis in both Czech and European codes is restricted to water vapor transport in steady-state conditions. This presents a risk for a designer as water suction, water vapor convection, and the cross effects between heat and moisture transport are not considered and this can often lead to the underestimation of the amount of liquid water in the envelope or the condensation zone can appear in another place than predicted by the standard calculation. Hygric and thermal movements are also not considered in standards and the designer is not required to evaluate the thermo- and hygro-mechanical response of the envelope.

On this account, there is very difficult to perform durability and service live assessment of AAC-based envelope systems because complex view on AAC material performance is missing and a precise and serious analysis of hygro-thermo-mechanical performance of the new AAC technologies based on sound scientific knowledge is a very actual problem.

From the above given information results the necessity to determine moisture transport and storage parameters of AAC that will enable to estimate its hygric performance. Since the experimental assessment of hygric material parameters requires measurement of liquid moisture content, the suitable moisture measurement method for application for AAC has to be chosen and calibrated.

Because water possesses many anomalous properties that also affect the properties of materials, various methods of determination of moisture content were devised and various moisture meters constructed which can take advantage of it. Basically, the measuring methods can be divided into two main groups; absolute and relative methods. The absolute methods (or direct methods), which are based on the removal of water from the specimen (by drying, extraction, etc.) are usually used as reference methods for calibration of relative methods. The disadvantage of these methods consists in fact that they are time consuming and they are not applicable for instantaneous determination of moisture profiles. Therefore, relative methods which determine the amount of water in material on the basis of measuring another physical quantity (permittivity, electrical conductivity, absorption of radiation energy etc.) are widely used in technical practice. However, the application of particular methods is limited for prescribed types of materials and specific conditions of measurement. For instance, frequently used resistance moisture meters are practically inapplicable for materials with a higher amount of salts, because the measuring errors rapidly increase with the increasing moisture content. The same problem can be found for capacitance moisture meters working on lower frequencies.

On the basis of the theoretical analysis of the currently used moisture measurement method we have chosen for the moisture measurement in AAC the time domain reflectometry (TDR) method that has proved to be very reliable for various applications and materials. Already in 1930s it became a recognized technique in cable testing. Other applications were focused on investigation of electrical properties of liquids. A fast development of the TDR technology was initiated in 1980s in soil science where the method found an increasing use in soil moisture measurement (see e.g. [Topp *et al.*, 1980], [Dalton & van Genuchten, 1986]). Nowadays is the TDR technique frequently used in many fields for instance for moisture measurement in building materials and structures [Kupfer & Trinks, 2005], [Kupfer *et al.*, 2007], [Aghaei *et al.*, 2005], for monitoring of quality of food products [Schimmer *et al.*, 2007], etc.

Since the possibilities of using TDR method for measurement of moisture content were proven for wide range of materials, in this paper we present the TDR method as a universal method for monitoring moisture content in AAC both during the production phase and in situ.

2 TIME-DOMAIN REFLECTOMETRY METHOD

TDR method can be generally classified as a dielectric method, based on an analysis of the behavior of dielectrics in a time-varying electric field, and consists in the measurement of permittivity of moist porous media. The determination of moisture content using the permittivity measurements is based on the fact that the static relative permittivity of pure water is equal to approximately 80 at 20 °C, while for most dry building materials it ranges from 2 to 6 [Katze, 1989], [Owen *et al.*, 1961].

The permittivity of materials is strongly affected by the orientation of molecules in the electric field. This characteristic is high for water in gaseous and liquid phase, but is significantly lower for water bound to a material by various sorption forces, which makes the orientation of water molecules more difficult. This feature makes it possible to distinguish between the particular types of bond of water to the material using the permittivity but on the other hand, it results in the dependence of the sensitivity of moisture measurements to the amount of water in the material. The relative permittivity of water bonded in a monomolecular layer is approximately 3.1, but for further layers it increases relatively fast. Therefore, the dependence of relative permittivity on moisture content is generally characterized by a more or less gradual change at the transition from a monomolecular to a polymolecular layer. Consequently, the methods of moisture measurements based on the determination of changes of relative permittivity have lower sensitivity in the range of low moistures where their application is rather limited.

The principle of TDR device consists in launching of electromagnetic waves and the amplitude measurement of the reflections of waves together with the time intervals between launching the waves and detecting the reflections. The fundamental element in any TDR equipment used for the determination of moisture content in porous materials is a device to observe the electromagnetic pulse echo in time domain. The method application originates from the application of electric cable tester. The measuring device usually consists of four main components: a step or needle pulse generator, a coaxial cable wave guide, a sampler and an oscilloscope to register or visualize the trace of echo.

The pulse generator produces the electromagnetic wave that propagates through the measured medium. The Fourier transform of an electrical pulse consists of sine waves covering a large frequency range but dependent on the shape of pulse. The highest frequency present in the pulse depends on its slew rate. This means that step pulse and needle pulse can be used equivalently if their rise time is comparable.

A very important part of TDR equipment is the probes. Rods of the probes are the signal conductors. There are a lot of probe constructions available for TDR measurements. They generally differ in shape, material and number of rods but general idea is that TDR probe is an extension of the coaxial cable with specified geometry. The TDR probe itself is conductively connected to the coaxial cable in such a way that the cable is open ended and the probe forms this open end. In principle, the coaxial cable and the probe differ not only in the shape but also in a type of dielectric material. While the cable has usually polyethylene as a dielectric, the measured material serves as a dielectric of the probe. Thus, the cable dielectric is nearly ideal but the measured moist material usually contains dissolved salts and therefore conducting current appears. This is, however, not disturbing the measurement because of the high frequency of the pulse.
The sampler detects the electromagnetic waves launched by the pulse generator and transmitted through the coaxial cable and TDR probe system. TDR meter consists of two main components, a high precision timing device and a high precision voltmeter. When the electromagnetic waves launched by

the generator are detected by the sampler, the sampler measures the voltage between the shield and the conductor at a certain time interval. The set of data obtained consists of voltage as a function of time when the transmitted pulse echo comes back to the device. The coaxial cable connects the step-pulse generator and the sampler. The shield of the coaxial cable is connected to earth and its electric potential is 0 V. The electromagnetic waves produced by the step- or needle-pulse generator are launched into the coaxial cable with a voltage drop of several tenths of a volt between the conductor and the shield.

The evaluation of data obtained by a tester is based on the following basic principles. Any change of impedance in the cable-probe system causes a partial or total reflection of the pulse. Therefore, one reflection will be on the cable/probe interface, where the dielectric is suddenly changed, and therefore the impedance must also be changed, while the second reflection is on the open end of the probe, where the impedance tends towards free space impedance and the wave is reflected in phase.

Reflected pulses can be either in phase with the incident pulse, which happens in the case when the electromagnetic waves pass an increase in impedance, or in counter phase, when a decrease of impedance is met.

Time/velocity of pulse propagation depends on the apparent relative permittivity of the porous material, which can be expressed using the formula

$$\varepsilon_r = \left(\frac{ct_p}{2L} \right)^2 , \tag{1}$$

where ε is the complex relative permittivity of the porous medium, c the velocity of light ($3 \cdot 10^8$ m/s), t_p the time of pulse propagation along the probe rods measured by TDR meter and L the length of the sensor's rod inserted into a measured porous medium.

Complex relative permittivity of porous medium consists of the real part ε_r' and imaginary part ε_r'',

$$\varepsilon_r = \varepsilon_r' + \varepsilon_r'' . \tag{2}$$

Both parts of the complex relative permittivity depend on applied measuring frequency. From Figure 1 it is evident that imaginary part of the complex relative permittivity can be in case of TDR measurement neglected and the real part is more or less constant.

Knowing the relative permittivity of the studied material we can estimate water content in a medium in a few of possible ways for example using empirical calibration, homogenization techniques and empirical conversion functions.

Complex relative permittivity exhibits also temperature dependence which can be described according to [CRC, 2002] by equation

$$\varepsilon = 249.21 - 0.79069 \cdot T + 0.00027997 \cdot T^2 \quad (273 < \mathrm{T\ (K)} < 373). \tag{3}$$

Therefore, in practical application of TDR technique for moisture measurement especially in situ temperature compensation has to be done.

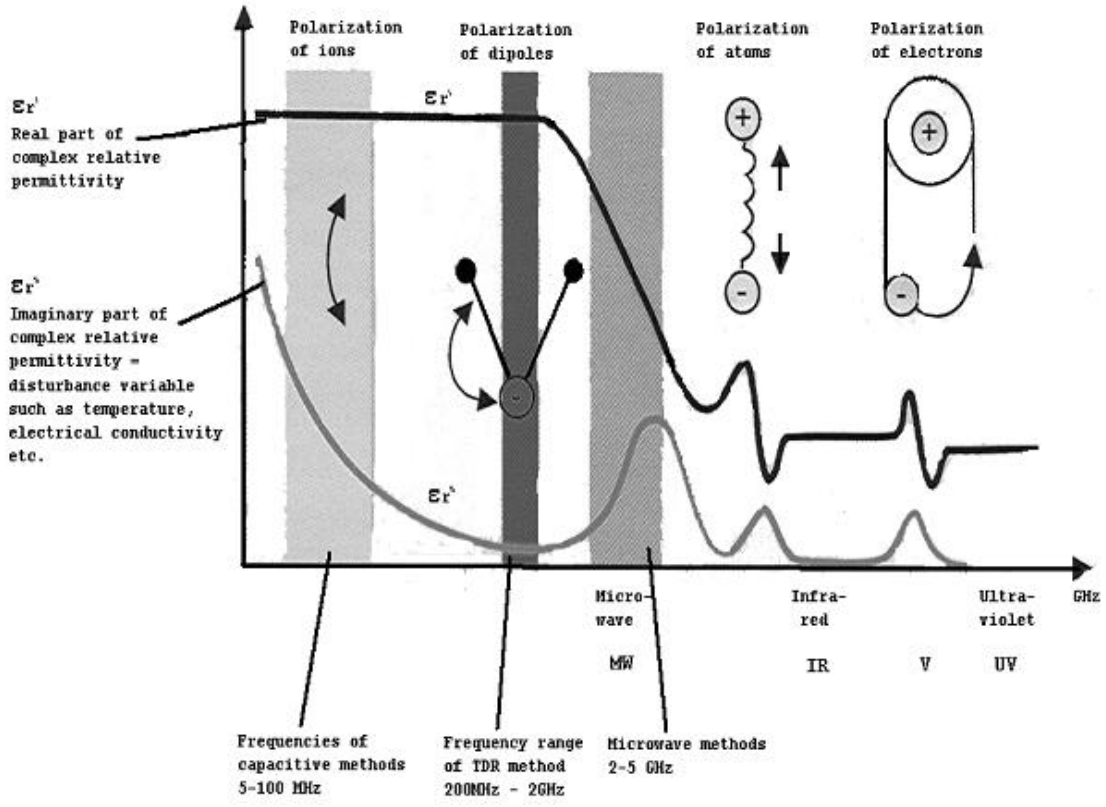

Figure 1. Illustration of complex relative permittivity dependence on frequency.

3 MEASURING TECHNOLOGY, MATERIALS AND SAMPLES

For the TDR measurements in this paper, the cable tester LOM/RS/6/mps produced by Easy Test which is based on the TDR technology with $\sin^2$-like needle pulse having rise-time of about 200 ps, was employed. It is computer aided instrument [Malicki & Skierucha, 1989] originally designed for measurements of soil moisture. The built-in computer serves for controlling TDR needle-pulse circuitry action, recording TDR voltage versus time traces, and calculating the pulse propagation time along particular TDR probe rods and the relative permittivity of measured material.

A two-rod miniprobe LP/ms (Easy Test) was used for the determination of moisture content that was designed by Malicki et al. [Malicki *et al.*, 1992]. The sensor is made of two 53 mm long parallel stainless steel rods, having 0.8 mm in diameter and separated by 5 mm. The sphere of sensor's influence was determined with the help of a simple experiment. The probe was fixed in the beaker and during the measurement, there was added water step by step. From the measured data (relative permittivity in dependence on water level) there was found out that the sphere of influence creates the cylinder having diameter about 7 mm and height about 60 mm, circumference around the rods of sensor. The accuracy of moisture content reading given by producer is ± 2% of displayed water content.

The measuring technology can be divided into three basic steps; probe calibration, sample arrangement and probes placing, data evaluation and determination of moisture content. The probe calibration was done for every probe using the known dielectric constants of water and benzene (see Pavlík *et al.*, 2006, for details).

The moisture measurements were done on the AAC samples provided by Polish producer PPH FAELBED Inc.. Three different types of AAC based materials were studied. Nominally, AAC 500,

AAC 600 and AAC 700 having different densities and porosities were tested. The experiment was done on samples having dimensions of 40 x 40 x 100 mm. At first, two parallel holes having the same dimensions as the sensor rods were bored into each sample. Then, the sensors were placed into the samples and sealed by silicon gel. The samples were partially saturated by water and insulated to prevent water evaporation. The relative permittivity of wet samples was then continuously monitored until the measured values reached the constant value. Then, the experiment was interrupted, sensors removed from the samples and moisture content in the samples was determined using gravimetric method. In this way, the empirical calibration curve of particular measured materials was accessed that in future work can be used for evaluation of measured relative permittivity data.

4 EXPERIMENTAL RESULTS

The obtained results (see Figure 2) clearly document the dependence of relative permittivity of the studied materials on moisture content. The empirical calibration curves have more or less exponential shape for all studied materials. We can observe relatively similar results in the range of lower moisture contents whereas for higher moisture contents (typically from 30%) the effect of different densities plays an important role. However, for rough estimate of moisture content of AAC the results can be considered similar and no extra calibration for every AAC material is supposed to be done.

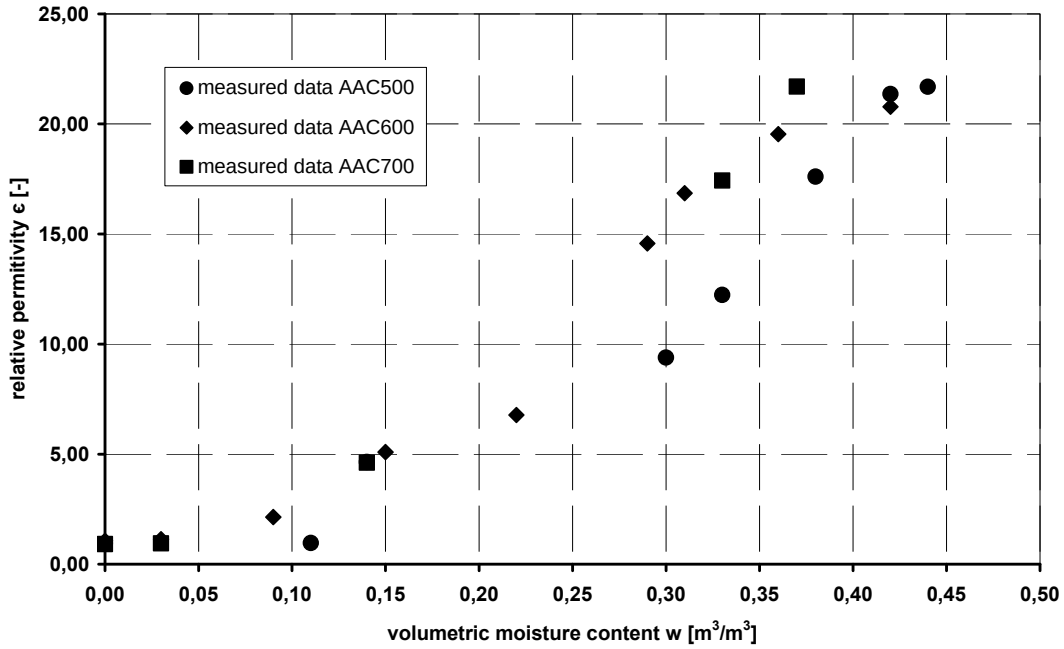

Figure 2. Empirical calibration curves of the measured AAC materials.

5 CONCLUSIONS

From the point of view of the applicability of TDR methodology for moisture measurement of building materials on AAC basis, the experiment presented in this paper has clearly shown a good perspective of the TDR method for such type of measurements. The obtained results can find use for example in long term monitoring of moisture content in AAC structures which can contribute to the accurate assessment of hygric function of building structures and in consequence to the higher durability and service life of AAC structures. The results can also be used for the determination of hygric parameters of tested materials, particularly moisture diffusivity and water absorption coefficient. It should also be noted that the TDR method has a high potential not only in laboratory

measurements, but it also makes possible long term monitoring of moisture content in situ, directly on building site.

Durability Properties of High Performance Concrete Containing Alternative Silicate Binders

Eva Mňahončáková [1]
Pavla Rovnaníková [2]
Robert Černý [3]

T 11

ABSTRACT

Alternative silicate binders such as fly ash, ground granulated blast furnace slag, silica fume and metakaolin/calcined clay have a high potential to replace a part of Portland cement in concrete due to the generally recognized necessity to decrease the amount of carbon dioxide in atmosphere. Fly ash, ground granulated blast furnace slag and silica fume are waste materials. Metakaolin is produced by thermal decomposition of kaolin without production of CO_2. Main durability properties, namely moisture and heat transport and storage parameters, of high performance concrete belong to the most critical parameters in designing and using complex reliability based models for service life prediction of concrete structures. In this paper, durability properties of high performance concrete containing two selected alternative silicate binders, namely metakaolin and ground granulated blast furnace slag, are studied. Moisture diffusivity is determined by a method utilizing the results of water sorptivity measurement, water vapor diffusion permeability is measured by the cup method. Thermal conductivity and specific heat capacity are measured by an impulse technique. The experimental results indicate that the chosen composition of the two studied concrete mixtures can ensure both sufficiently high compressive strength and reasonable resistance against water transport which makes good prerequisites for the achievement of high durability.

1 INTRODUCTION

The progressive building materials development improves their quality and utility value. In order to achieve better material properties, besides the new technologies also specific admixtures are employed. The accurate admixture dosage and technological conditions observation can improve the material parameters like strength and durability. Most frequently, such admixtures as silica fume, ground granulated blast furnace slag, metakaolin, fly ash or flue cinder are used in concrete production.

Traditional concrete was characterized essentially by its compressive strength. Therefore, when first high performance concretes (HPC) appeared they were supposed to be considered as just high strength concretes (HSC). However, within the last several decades this basic view was changed substantially. In the new HPCs some other properties such as water and salt transport and storage parameters, freeze-thaw resistance or abrasion resistance began to gain higher importance and in some cases they even became decisive for the solutions made in the design process. As these parameters depend more or less on the porosity of a material, the reduced porosity became the main characteristic of HPC. Despite the gradual shift in the HPC design and application philosophy towards a generally recognized necessity to measure a wider scale of HPC parameters the mechanical properties still remain the far most frequent parameters investigated in the research work being done on HPC.

We will give only a few examples of the investigations done during the last couple of years. Donza et al. [2002] measured the compressive strength and the elasticity modulus of HPC depending on the aggregate fineness and realized that granite crushed sand appeared as the most advantageous. Gao et al. [2001] found that the compressive strength of HPC was improved after using superfine mineral powder of phosphoric slag. Beshr et al. [2003] reported the positive effect of the coarse aggregate quality on the compressive strength, split tensile strength and modulus of elasticity of HPC. The effect of silica fume on the mechanical properties was reviewed in an extensive way by Chung [2002].

Water and water vapor transport and storage properties of HPC were not yet in the center of interest of most researchers until now although they possess a very high predicative potential concerning the HPC quality. So, only couple of references was found in common sources within the last years. Jooss and Reinhardt [2002] measured water permeability and water vapor diffusion coefficient of five HPC mixtures with the compressive strength of 86-93 MPa and found both the transport coefficients to decrease several times compared to the reference B35 concrete. Nilsson [2002] determined desorption isotherms and hygroscopic moisture diffusion coefficients of twenty HPC mixtures and realized that moisture diffusion coefficient was not only several times lower but also much less moisture dependent for HPC than for normal concrete. Sun et al. [2001] measured the relative water permeation coefficient of several HPC with expansive agents and hybrid fibers and found that the impermeability resulted from the combined use of both admixtures. Khan [2003] determined the sorptivity of several HPC incorporating fly ash and microsilica prepared with different water/binder ratios and found the incorporation of 8-12 % of microsilica as cement replacement as the optimum value.

In this paper, measurements of basic moisture and heat transport and storage parameters of two different HPCs, the first with groundgranulated blast furnace slag admixture and the second with metakaolin admixture, are presented.

2 MATERIALS

Two different types of concrete, namely the high performance concrete containing ground granulated blast furnace slag and the same material with metakaolin, were studied. Table 1 presents the composition of the studied concrete mixtures.

Table 1. The composition of concrete mixtures [kgm^{-3}].

Component	Type of concrete mixture	
	BM	BS
CEM I 42.5 Mokrá	440	440
aggregates 0-4 mm	812	812
aggregates 4-8 mm	910	910
plasticizer Mapei Dynamon SX	5.3	5.3
metakaolin MEFISTO	44	-
ground granulated blast furnace slag Štramberk	-	44
water	188	188

3 EXPERIMENTAL METHODS

3.1 Basic Physical Properties

Among the basic properties, the bulk density, matrix density and open porosity were measured. Each sample was dried in a drier to remove majority of the physically bound water. After that the samples were placed into the desiccator with deaired water. During three hours air was evacuated with vacuum pump from the desiccator. The specimen was then kept under water not less than 24 hours.

From the mass of the dry sample m_d, the mass of water saturated sample m_w, and the mass of the immersed water saturated sample m_a, the volume V of the sample was determined from the equation

$$V = \frac{m_w - m_a}{\rho_l}, \tag{1}$$

where ρ_l is the density of water.

The open porosity ψ_0 [m^{3}m^{-3}], the bulk density ρ [kgm^{-3}] and the matrix density ρ_m [kgm^{-3}] were calculated according to the equations

$$\psi_0 = \frac{m_w - m_d}{V\rho_l} \tag{2}$$

$$\rho = \frac{m_d}{V} \tag{3}$$

$$\rho_{mat} = \frac{m_d}{V(1-\Psi_0)} \tag{4}$$

The samples for determination of basic properties had the size of 50 x 50 x 20 mm.

3.2 Compressive Strength

The compressive strength was determined using the standard 500 kN testing device. It was calculated as the ratio of the measured ultimate force and the load area.

3.3 Water Vapor Transport Properties

The common cup method was used in the measurements of water vapor transport parameters [Roels et al. 2004]. The specimens were water and vapor proof insulated by epoxy resin on all lateral sides, put into the cup and sealed by technical plasticine. The impermeability of the plasticine sealing was achieved by heating it first for better workability and subsequent cooling that resulted in its hardening. Two different experiments were done. In the first one (the dry cup method), the sealed cup containing silica gel (the equilibrium relative humidity above the desiccant was 5 %) was placed in a controlled climatic chamber with 30% relative humidity and weighed periodically. In the second one (the wet cup method), the cup containing saturated K_2SO_4 solution (the equilibrium relative humidity above the solution was 97.8 %) was placed in a controlled climatic chamber with 30 % relative humidity. The measurements were done at 25±1°C for a period of two weeks. Steady state values of mass gain or loss were determined by linear regression for the last five readings.

The water vapor diffusion permeability δ was calculated from the measured data according to the equation

$$\delta = \frac{\Delta m \cdot d}{S \cdot \tau \cdot \Delta p_p}, \tag{5}$$

where δ is the water vapor diffusion permeability [s], Δm the amount of water vapor diffused through the sample [kg], d the sample thickness [m], S the specimen surface [m^2], τ the period of time corresponding to the transport of mass of water vapor Δm [s], Δp_p the difference between partial water vapor pressure in the air under and above specific specimen surface [Pa].

In an analogous way, the water vapor diffusion coefficient D was calculated as

$$D = \frac{\Delta m \cdot d \cdot R \cdot T}{S \cdot \tau \cdot M \cdot \Delta p_p}, \tag{6}$$

where D is the water vapor diffusion coefficient [m^2s^{-1}], R the universal gas constant, M the molar mass of water, T the absolute temperature [K].

On the basis of the diffusion coefficient D, the water vapor diffusion resistance factor μ was determined,

$$\mu = \frac{D_a}{D}, \tag{7}$$

where D_a is the diffusion coefficient of water vapor in the air.

The samples for determination of water vapor transport properties were cylindrical, with the diameter of 110 mm and height of 20 mm.

3.4 Water Transport Properties

The water sorptivity A and apparent moisture diffusivity D_w were measured using a water suction experiment [Kumaran, 1994]. For the determination of water sorptivity a common experimental setup was chosen. The specimen was water and vapor-proof insulated on four lateral sides and the face side was immersed 2 mm in the water. Constant water level in the tank was achieved by a Mariotte bottle with two capillary tubes. One of them, inside diameter 2 mm, was ducked under the water level, second one, inside diameter 5 mm, was above water level. The automatic scale allowed recording the increase of mass. The known water flux into the specimen during the suction process was then

employed to the determination of water sorptivity. The samples were tested in constant temperature conditions.

The water absorption coefficient A [kgm^{-2}s$^{-1/2}$] was then calculated using the formula

$$i = A \cdot \sqrt{t}\,, \tag{8}$$

where i is the cumulative water absorption [kg/m^2], t is the time from the beginning of the suction experiment.

For the calculation of apparent moisture diffusivity, the following approximate relation was employed

$$D_w \approx \left(\frac{A}{w_c} \right)^2 \tag{9}$$

where w_c is the saturated moisture content [kgm^{-3}].

The samples for determination of water transport properties had the dimensions of 50 x 50 x 20 mm.

3.5 Thermal Properties

The thermal conductivity as the main parameter of heat transport and the specific heat capacity as the main parameter of heat storage were determined using the commercial device ISOMET 2104 (Applied Precision, Ltd.). ISOMET 2104 is a multifunctional instrument for measuring thermal conductivity, thermal diffusivity, and volumetric heat capacity. It is equipped with various types of optional probes, needle probes are for porous, fibrous or soft materials, and surface probes are suitable for hard materials. The measurement is based on the analysis of the temperature response of the analyzed material to heat flow impulses. The heat flow is induced by electrical heating using a resistor heater having a direct thermal contact with the surface of the sample. The measurements in this paper were done in dependence on moisture content. The samples for determination of thermal properties had a size of 70 x 70 x 70 mm.

4 EXPERIMENTAL RESULTS AND DISCUSSION

4.1 Basic Physical Properties

The basic properties of studied HPCs are shown in Table 2. BM containing metakaolin achieved higher porosity and thus lower bulk density compared to BS containing ground granulated blast furnace slag. So, the voids in the cement matrix in BS were filled more successfully than in BM.

Table 2. Basic physical properties of studied HPCs.

HPC	ρ [kg m^{-3}]	ρ_m [kg m^{-3}]	Ψ_0 [%]
BM	2370	2706	12.4
BS	2398	2674	10.3

4.2 Compressive Strength

Table 3 shows the compressive strength of the studied HPCs after 28 days. The results were very similar for both materials. The differences were within the error range of the experimental method.

Table 3. Mechanical properties of studied HPCs.

HPC	Compressive strength [MPa]
BM	84.0
BS	83.3

4.3 Water Vapor Transport Properties

The water vapor transport parameters of the studied HPCs are shown in Table 4. The measured data revealed basic information that the values of water vapor diffusion coefficient corresponding to the lower values of relative humidity (5/30 %) were always lower than those for higher relative humidity values (97/30 %). This is in accordance with the previous measurements on many other materials including concrete [Kumaran 1996]. The main reason for this finding is coupling of water vapor transport with liquid water transport in a material with higher relative humidity where the capillary condensation takes place in a much higher extent than in the range of lower relative humidity [Černý and Rovnaníková 2002]

Comparing the data measured for the two studied HPCs, we can see that the values of water vapor diffusion coefficient of BM was in the both ranges of higher and lower relative humidity higher than for BS. This is in a general agreement with the open porosity data in Table 2 as it is quite obvious that a material with higher porosity should transport water vapor faster than a material with lower porosity.

Table 4. Water vapor transport properties of studied HPCs.

HPC	*5/30%*			*97/30%*		
	δ [s]	D [m^2s^{-1}]	μ [-]	δ [s]	D [m^2s^{-1}]	μ [-]
BM	1.11E-11	1.53E-06	16.87	2.27E-11	3.12E-06	7.47
BS	9.82E-12	1.35E-06	17.27	1.67E-11	2.30E-06	10.08

Table 5. Water transport properties of studied HPCs.

HPC	A [kg $m^{-2}s^{-1/2}$]	D_w [m^2 s^{-1}]
BM	0.0080	4.03E-09
BS	0.0076	5.64E-09

The results of measurements of water transport parameters are presented in Table 5. The comparison of water absorption coefficients showed that the material BM with higher porosity transported liquid water slightly faster than the material BS. Differences in the intensity of water transport in both materials are illustrated in more detail in Fig.1 where an example of the course of water absorption is presented. The lower value of apparent moisture diffusivity of BM in Table 5 is clearly due to the higher open porosity of the material and thus its higher saturated moisture content. This indicates the possible shortages in estimating the moisture diffusivity using Eq. [9]. The more laborous and for concrete much more time consuming way of determination of moisture diffusivity using inverse analysis of moisture profiles [Černý and Rovnaníková 2002] should apparently be given precedence in such cases.

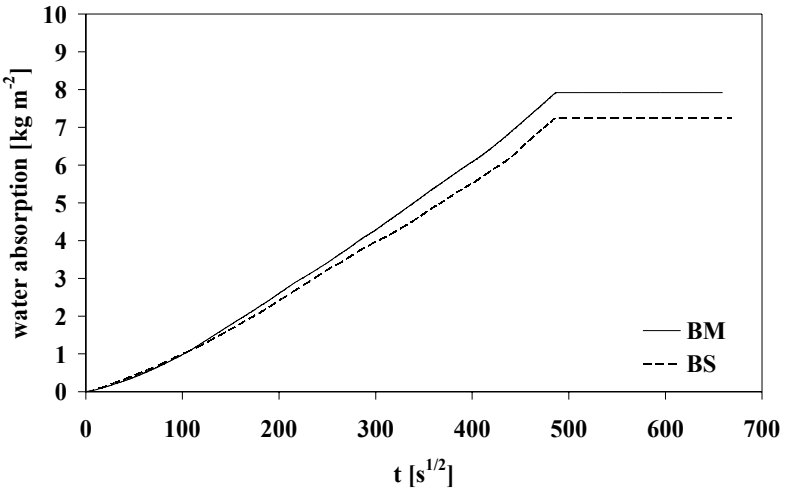

Figure 1. Water absorption of studied HPCs.

4.4 Thermal Properties

The thermal parameters data in Table 6 show that the material BS had systematically higher values of thermal conductivity than BM in the whole range of moisture content analyzed but the differences were relatively low, up to 10%. This is in a qualitative agreement with the open porosity data in Table 2. The specific heat capacity of BM was slightly higher than of BS in the whole range of moisture content. Some small discrepancies were observed for BS where the specific heat capacity in some cases decreased with increasing moisture content. However, this was apparently an experimental uncertainty which was within the error range of the measuring method of ±10%. The thermal diffusivity of BM was very similar to that of BS in whole the moisture range except for the dry state where for BM it was about 10% lower. This reflects the changes in thermal conductivity and specific heat capacity data.

Table 6. Thermal properties of studied HPCs.

HPC	*w* [kgkg^{-1}]	λ [Wm^{-1}K^{-1}]	*c* [Jkg^{-1}K^{-1}]	*a* [m^{2}s^{-1}]
BM	0.000	1.57	727	0.90
BM	0.037	1.84	734	1.06
BM	0.040	1.98	742	1.13
BM	0.047	2.08	761	1.15
BS	0.000	1.71	683	1.04
BS	0.034	1.94	743	1.09
BS	0.038	2.00	727	1.10
BS	0.042	2.13	719	1.13

5 CONCLUSIONS

The results of the experimental work presented in the paper indicated that both metakaolin and ground granulated blast furnace slag were materials having good perspectives as partial cement replacement in future use. The compressive strength of HPCs with either metakaolin or ground granulated blast furnace slag in the amount of only 10% of the mass of cement in the mixture was after 28 days higher than 80 MPa which with the CEM I 42.5 type of cement was a very good result. The water and heat

transport properties of both studied concretes were found to meet reasonably the basic requirements necessary to achieve such a durability which is expected for HPC.

Multidisciplinary Collaborations for a Qualitative Systemization towards a Durable Structure

Shohre Shahnoori [1]
Liek Voorbij [2]

T 11

ABSTRACT

Optimization in order to ensure efficiency plays a major role in the construction industry. However, efficiency has a very broad definition, even in the defined area of the pragmatic construction. The context of this study is an efficient building system in a seismic desert area in which declining the vulnerability of the structure to increase the safety of the inhabitants, in earthquakes is the main goal. Sustainability, however, is the key issue to elaborate the system.

With such complex constraints, materialization of the structure is very sensitive. It has to deal with the earthquake resonance effects as well as the desert climatic conditions. Compared with some other industries technology transfer had slow adoption in construction industry. Nevertheless, it can revolutionize the ways to find solutions for the long lasting construction problems. In this study with a collaborative knowledge from different discipline, modern technology will be implemented in the materialization of a qualitative structure. For this, the data collection and laboratory tests were consequences of the design conceptions.

1 INTRODUCTION

Material selection and optimization in design and construction is a major issue (Ashby, 2005). However, extra consideration is required when this selection and construction is going to happen for a context with additional constrains such as seismicity and desert climatic conditions (Shahnoori et al. 2007). Engineers from various fields work on this particular subject concentrating on different aspects. Conventionally, safety and economy are always the most important principle aspects. However environmental considerations also became of high concerns (Brundtland, 1987) to designers (e.g. engineers), scientists and authorities (Troyer, 1990). Durability of buildings including the building materials, as an essential part of construction, can be defined as a common issue between these three essential aspects (i.e. safety, economy, and sustainability). Because durability of building materials will, first, improve the life safety for inhabitants. Secondly, it enhances the economical aspects with more efficiency (relatively) over time, requiring less repair and replacement (Newman et al., 2003). Besides, using durable materials in the building, relatively saves more natural resources of being distracted for raw materials (Yu, et al. 2006). Moreover, eco- costs relate to both the environment and the economy, that decline by using durable materials (Hendriks, et a. , 2002). Implementing durable materials, in fact, assists the material minimization on a long term (Groot, 2005) to ensure an eco-efficient system for a sustainable construction. For this, Vogtlander et al. (2004) takes also the Virtual Pollution prevention costs into the account. These are the required costs to reduce the emissions of the production process to a sustainable level.

The main context of the research is reconstruction after a destructive earthquake. Therefore for a sustainable reconstruction, this study, focuses on materialization of houses seeking for more durability. Durably materializing houses is very effective. Because, earthquakes happen in large numbers and in various places on the planet. Table number 1.1 shows the high rate of earthquakes occurrence in the world since 1900. This table indirectly emphasizes/ensures the efficiency of application of strong durable materials. However, the statistics are only about earthquakes with a magnitude of 5 and more, which are called strong earthquakes (CERCESJ, 2006).

Table 1. Magnitude- average annually (The data was collected from the USGS and wikipedia)

Date / Magnitude	1900-20	1920-40	1940-60	1960-80	1980-2000	2000-2007	Total

For building collapse as the main consequence of large earthquakes, causing huge economic and social impacts, lacking systemization and material qualification were identified as two important items (Shahnoori, 2005). A very important part of systemization for such a purpose in a seismic area is also materialization (Booth et al., 2006). The former research proved that a concrete composite as the main base for materializing structures in many seismic cities is a good alternative (Shahnoori et al., 2007). Concrete, being a very flexible material, has the potential to be combined with a large variety of materials for upgrading its mechanical properties (Li, 2003). This material has a good compression strength while it is weak in tension. Thus, normally the efforts in the structural design aim at enhancing the tension (Macdonald, 2003). For which using reinforcement materials that are good at tension such as stainless steel, in this composite, are conventions. Besides, concrete is a brittle material, which causes it to include cracks. But in the normal situation these cracks are not counted as serious problem (Markovic, 2006). However, for a seismic design they can cause consequent problems. The main problem resulting in a huge scale death toll and sever injuries in earthquakes is de-fragmentation of construction materials. Therefore, a strong material that can not easily be segmented (that is the case in the bricks and other similar materials especially with weak mortars) is a

good alternative. A qualified concrete composite with an appropriate performance is conditionally a good solution. There are two conditions to be met: first, being affordable. Secondly, declining the chance of propagation of cracks to a bigger or larger size, resulting in serious structural problems (Marcovich, 2006). This study concentrates on investigating the possible options to meet these requirements by using fiber reinforced concrete.

2. APPROACH AND METHODOLOGY

This study is part of a wider research on reconstructing the houses in seismic desert cities. The focus of this study lies in materialization of the structure, which is related to the work presented in this piece. The aim of the total study is improvement of the durability of an appropriate concrete composite for such a situation and at the same time declining the vulnerability of the inhabitants. For that developing a durable concrete aiming at improving the ductility of the composition is required. For that two models were materialized with a time difference of about 2 years, using the earth-casting technique for molding the composite (i.e. figure. 2.1.and 2.2.).

Figure 2.1

Figure 2.2

Models are based on Portland cement and aggregates as a conventional concrete in the scale of 1:25, thus the thickness of the shell structures were 8 mm for each. Different reinforcement materials in various typology and geometry were used to make a shell structure of reinforced concrete. The characteristics of these fibers are shown in table 2. Fibers were mainly divided in two groups of woven and individuals; the individuals were mixed in the composite. However the woven fibers were positioned in the middle of the walls.

Table 2. typology, geometry, and time of use of reinforcement materials in the concrete composite

Typology / Fibers	Short fibers	Long & straight	Woven fibers
E-glass	4.5 mm First period	50 mm Second period	50 mm wide, First and second
Carbon	-	-	60 mm wide, Second period
Aramid	-	-	50 mm wide, Second
Poly Propylene	-	-	First and second
Natural fibers	-	30-120 First &second	-

The models were built in the indoor climate and curing for the concrete was done also in such an environment. W/C ratio was about 1/3, fibers in the woven type were locally positioned. Two main task were necessary before the observation, including first the sample preparation, and second, making the thinsections. These processes were done as the specimens were made by cuting the samples, stabilzation through vacuum impregnation, and then cutting them into sections (25-30 µm) by DBT Diamond Roller and preparation by Grinder/86. By Gluing the HELP glass to flatten, resin impregnation, then gluing the object glass to pulish and hardening them under the UV-light, the specimens of about 0.5 mm were cut, grind and pulished. Observation, investigate, and analyzing the

composite on micro scale to investigate the interactions were assisted by the Polarized ligh and the UV-fluorescence.

3. RESULTS

The basic composite matrix (liquid phase) with E-glass, carbon fibers, aramid, and poly propylene were similar therefore the differences were related to the various effects of different fibers. Table 3 shows a comparison of density for the different reinforcing materials used in the composite in addition to some other mechanical properties involved in the durability.

Table 3. comparison of some mechanical properties of reinforcement materials used in the composite

Property reinforcement	Density (g/cm^2)	Strength (MPa)	Young modulus (GPa)	Elongation (%)
Stainless steel fibers	7.8	480-2240	189-210	05-3.5
E-glass	2.5	2500-3500	70-75	2.5
Carbon	1.4	2500-5500	220-700	1.4-1.8
Aramid	1.4	3000-4000	85-135	3.3-3.7
Poly Propylene	0.9	27.6-41.4	7	20
Natural fibers	1.5	80-840	9-22	2.0-2.5

Main results from the tests related to this study are as:
- There was an adhesion problem between the cement matrix and the natural fibers (Figure 3.1. &2)
- The cement is more porous around the bio-fibers
- In the end of the bio-fibers the cement particle does not go through (too big to go, i.e. Figure 3.1.)

Figure 3.1. a, and **b** the bio fibers, and **c**, glass fibers for comparison

- Distribution of the glass fibers is not homogenous in all the specimens (i.e. Figure 3.2).
- In the samples from the second model a good adhesion was observed between the carbon and Aramid fibers and the matrix
- Long glass fibers show a better bond with the matrix
- Around the glass fibers in the older version, alkaline problem is observable while in the samples from the model number 2 this was not seen
- The polypropylene fibers have a better bonding with the cement matrix even in the older version they do not show particular problems
- The matrix in the second model is more homogenous (from the mix), however the interface structure between the matrix with the expanded clay, fibers and the bulk still shows problems including the pullout, and unbundling.

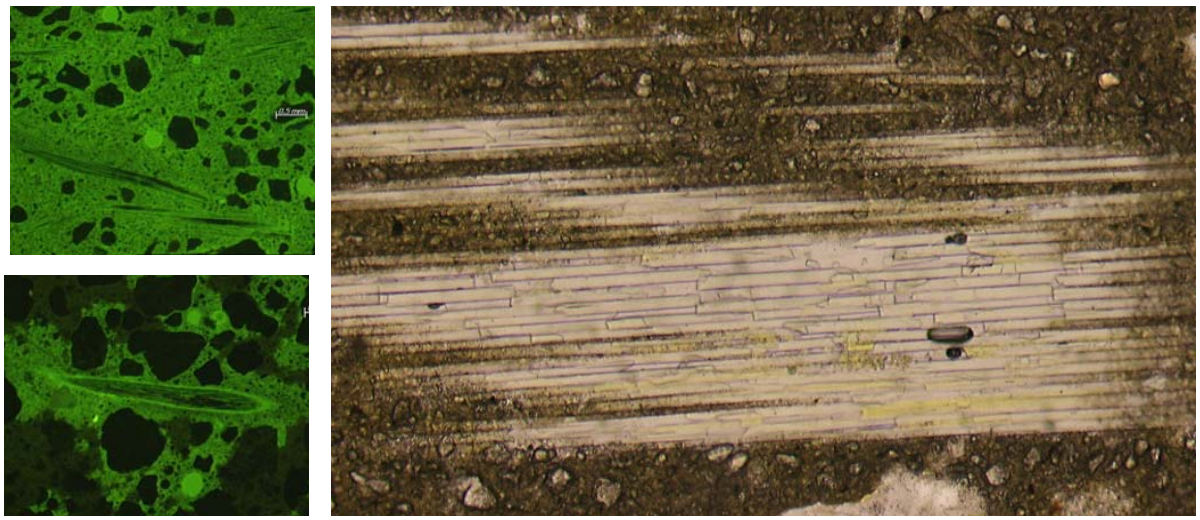

Figure 3.2. a, **b**, and **c** the glass fibers and the concrete matrix

4. DISCUSSION

Reinforcing materials that are weaker in tension than in compression with fibers to achieve better properties is not new. For example in Aqur Quf (i.e. near Baghdad) straw was used to strengthening the sun-baked bricks in about 3500 (Bentur et al. 2007). However, from 1900 with the invention of Hadscheck process asbestos cement was the first widely used manufactured composite (Bentur et al. 2007). This is called the first version of modern fiber reinforced composites. Since 1960 polymers have been used as reinforcement for concrete which was accompanied by further application of the reinforced concrete system (Dolan et al., 1999). Although since then the application of these fibers had an ordinary progression, recently it has been developed revolutionary.

An example of the latest version of these advanced technology is Engineered Cementitious Composite (ECC). This concrete is a very progressed version of a ductile concrete while it is 40% lighter in weight (Li, 2005). The economical efficiency of this composite lies in its long life, so, with a better bonding achieved by micro scale fibers acting like ligament as it is much more durable than the conventional concrete (SNR & ECSS, 2005). Nevertheless the application of such an material in a seismic desert city requires more research.

Predicting the durability of concrete is difficult because so many items (e.g. compressive strength and permeation properties) are involved (Jones et al. 2002). The observation for durability in this study is not based only on the reactions insides one time modeling but it includes also model with about 1.5 year time difference. Some effects such as alkali pollutions are more obvious in the samples from the older model, but most of the problems were generally similar.

As a biodegradable and renewable source, bio-fibers, recently attracted many scientists. One might expect that these fibers are the most sustainable solution for fiber reinforced concrete. For example these kind of fibers (that are industrially produced and implemented) have been used as filters for air and water or bio-fiber geo-textiles in the form of a mat. Annually about 4 billion tons bio fibers is being produced world wide. 60% comes from agriculture and 40% from forests. (Svennerstedt, 2002). Many building products that are made of these fibers are highly applicable and desired (e.g. door panels). The basic structure of bio fibers consists of cellulose, hemi-cellulose, and lignin. The cellulose molecules consist of glucose units linked together in long chain while hemi-cellulose are polysaccharides bonded together in branching chain. Lignin, a three dimensional polymer with an amorphous structure (Olesen, 2001), is the compound that gives rigidity to the plant. For which pectin is the glue to hold them together (Svennerstedt, 2002). The relative high strength and low density and the heat, sound, and electrical insulation ability are of other main advantages of these fibers. However,

they are prone to water absorption and many of them are hygroscopic, thus the water absorption is high (due to the cohesion of hydrogen by hydrogen molecules to groups of hydroxyl in cellulose in cell-wall polymers). Problem is that reactive organic chemicals are tied to the cell-wall hydroxyl groups of cellulose, hemi-cellulose and lignin (Svennerstedt, 2002). Although this problem can be decreased and controlled by some methods (e.g. acetylation and heat treatments), it needs extra improvements and costs. These extra costs lower the applicability in building.

Additionally, the nature of such fibers causes them to have a big range of variety in diameter, length, and shape/geometry, which makes it much more difficult to create a reliable concrete with them compared to the industrially produced fibers such as glass fibers. This size problem needs extra attention and costs during the production process, but the quality is affected in either situation. Another problem that comes from the nature of such fibers is the low fire resistance. With temperatures above 200 ºC most of natural fibers ignite, thus for the exposed structural application this should be taken into the account. Moreover, bio-fibers can not be basically counted as durable (i.e. in the concrete composites for building products), because of destructive effect of alkaline pore solution on them. Especially in a long time as Swamy (1990) reported the lignin content may influence the hydration of the cement composite matrix. The decomposition of the fibers takes place more rapidly at high temperature (Gram et al. 1984). Thus, making a durable strong concrete structure by using bio-fibers, for improving some mechanical properties such as tensile strength, needs much more research and extra considerations. Although John et al. (1990) proved that producing load bearing bio fiber concrete is possible, and although Brazilian (RILEM & CIB, 1990) proved that by changing the concrete matrix prolongation of the durability of bio-fiber concrete is possible, the mentioned consequences prevent generalization of this use of bio-fibers for a durable concrete composite at least for a load bearing shell structure.

For the application of bio fibers in a seismic desert area it needs to be mentioned that even though the water absorption might not cause to much problems the availability of these fibers in these areas is low. Furthermore because of the long term and other construction problems with the use of these fibers they are not suitable for application in seismic areas.

From the results of the test samples the longer glass fibers showed a better bonding and better matrix-fiber interface structure than the shorter fibers, specially in the samples taken from the younger model. This might be caused by the higher need to water for the shorter fibers. Although Benmokrane et all (1999) proved that the fiber glass applied in the Juffre bridge worked well, the durability of structures is a time dependant item. Particularly for this bridge the fiber optic sensors were installed for the long and short term control to investigate future problems. These first applications had a great effect on the implementation of the glass fibers for reinforcing the concrete for such structures. However, for structural application, in seismic desert areas it would be the aim to replace steel bars wit glass fiber reinforcements. Alsayed et al. (1999) tested this application for a column, which showed that such a replacement in columns reduces their capacity by about 13% when subjected to monotonic-concentric loading (Alsayed et al., 1999). The axial capacity of the columns containing Glass fibers ties was 10% lower than those containing an equal volume of steel ties. However, for ductility and crack prevention, which is a very important goal of this study, Sato et al. (1999) proved that the prevention of propagation of cracks improved, based on the finding that the crack spacing decreased as the reinforcement ratio increased. In the test results of this study, no crack was reported in the samples of high ratio glass fiber reinforced composite. Nevertheless, it is not certain that glass fiber reinforcement will be suitable for the seismic desert application. This will require further study.

The ductility of the concrete reinforced with fibers such as glass fiber, carbon, and aramid increase was similar to the test done by Sato et al. (1999). Sato et al. (1999) showed that the effect to improve strength is the biggest in carbon fibers while aramid improves the ductility. For the shear strength carbon fibers are more effective than the aramid (Sato et al., 1999).

Intensive fiber pull-out indicates a fairly weak matrix/fiber interface bonding of the composite. Suzuki et al (1992) states that this prominent behavior of fiber pull-out is very significant for attaining high fracture energy (γρο). As it occurred in the work of Suzuki et al (1992), the few fragments of broken matrices imply the absence of chemical bonding at the interface between the matrix and the fibers in the older samples. The individually pull-out of the fibers and no observation of fiber bundles is different from the dominant mixed mode pullout of individual fibers and fiber bundles in the carbon fiber. Similar to carbon fiber the bonding is stronger in polypropylene fibers than the glass fibers. The alkali problem, which was observed in the matrix in the edges of the glass fibers is less than the problem caused by the high porosity of the matrix around the bio-fibers. This problem is not generally observable for the polypropylene fibers. Thus, for some mechanical properties such as strength, glass fibers have priority to the polypropylene fibers, but the propylene fibers similar to the carbon fibers showed a better bundling in these tests. Although carbon and aramid fibers can be mentioned as creating durable composite, the affordability is a subject for the general application of such materials.

5. SUMMARY AND CONCLUSION

Bio fibers are naturally lacking durability, and thus to implement them in a liquid like concrete which may even be exposed to the water after the hardening, needs extra costs and attentions. With interaction of extra risk possibility, and regarding the current applied techniques, this is not a good alternative to be used in a concrete composite for load bearing structures in seismic areas yet. However, desert climate creates two contradictories. First, because of dry-ness of a dry desert, it is a good option, (as water creates the most crucial problems for such fibers) but, secondly, for the same reason growing such fibers in a large scale does no seem feasible in the desert.

In the concrete as a composite with brittle ceramic matrix, the problems associated with the process of fiber pullout are much more complex than that in a monolithic material. However, as fibers generally prevented cracks and crack propagation and increased the ductility, appropriately using a fiber reinforced concrete composite is a good solution to decrease the vulnerability of the inhabitants of houses in seismic areas. With all of these, polymers showed better comprehensive characteristics, however further research for the most suitable polymer to be mixed in the composite is required.

Concrete Crack Width under Combined Reinforcement Corrosion and Applied Loads

Chun-Qing Li [1]
Shangtong Yang [2]
T K Ho [3]

T 11

ABSTRACT

Concrete crack width is a parameter of the most practical significance for the design and assessment of reinforced concrete structures. Practical experience and observations suggest that corrosion affected reinforced concrete structures are more prone to cracking than other forms of structural deterioration. The situation is exacerbated when the applied loads add additional radial pressure to that induced by corrosion expansion. It is well known that concrete cracking incurs considerable costs of repairs and inconvenience to the public due to interruptions. This gives rise to the need for thorough examination of concrete cracking under both reinforcement corrosion and applied loads so as to achieve cost-effectiveness in maintaining the serviceability of concrete structures.

This paper attempts to derive a model for concrete crack width under the combined pressure of corrosion expansion and applied loads. A recently developed corrosion model will be used to determine the corrosion volume. The concrete fracture mechanics will be employed in the derivation whereby cracks are modelled as smeared cracks and concrete be quasi-brittle. With the values of the basic variables of the model taken form literature review, a worked example is presented for illustration. A merit of the derived model is that it is directly related to design variables used by practical engineers. The paper concludes that the model presented herein can be used to estimate concrete crack width under the combined effects of reinforcement corrosion and applied loads with reasonable accuracy.

1. INTRODUCTION

Corrosion of reinforcement in concrete has been identified as one of the most predominant factors for the deterioration of reinforced concrete structures [Bhargava et al. 2006]. The corrosion products occupy much greater volume than the original steel. When steel corrosion develops, the corrosion products first accumulate at the steel surface and try to fill the closest voids. After that the corrosion products exert expansive pressure to the surrounding concrete as the corrosion continues. This expansive pressure could induce tensile stresses in the concrete whose tensile strength is usually very low which leads to longitudinal cracking of concrete. This situation will be exacerbated when applied loads introduce additional radial forces to the surrounding concrete due to the bond action between the concrete and reinforcement. The bond depends primarily upon mechanical action which through ribs of deformed bars imposes radial stress components to the concrete. As a result, there are more cracks on the surface of concrete, incurring considerable costs of repairs and inconvenience to the public due to interruptions [Li et al. 2006].

Considerable studies have been carried out on corrosion-induced concrete cracking [Dagher and Kulendran 1992; Liu and Weyers 1998] and on loading-induced concrete cracking [Colotti and Spadea 2004; Goto 1971; Tepfers 1979]. Liu and Weyers [1998] examine the time from corrosion initiation to cracking of the cover concrete both theoretically and experimentally and developed a model to calculate the critical amount of rust products. Li et al. [2006] establish an analytical model for corrosion-induced crack width which gives quantitative relationships between the critical factors affecting cracking and crack width. Ueda et al. [1998] use finite element methods to examine the factors that affect corrosion-induced cracking in concrete and find that the tensile strength and creep of the concrete are important factors. Tepfers [1979] conduct a research on the cracking resistance of the cover concrete without considering the corrosion effect and obtain the stresses in concrete for an elastic stage, a plastic stage and an elastic stage with internal ring cracks. Goto [1971] presents the results of experiments on the characteristics of internal cracks, secondary cracks and longitudinal cracks around tensile reinforcing bars, and points out the longitudinal cracks are more probable when primary crack spacing is near the maximum. The review of research literature (see references) shows that there is little research focusing on both corrosion and loading effects on concrete cracking.

This paper attempts to investigate the combined effects of both loading and corrosion on concrete cracking and to develop an analytical model for crack width. In this study, both effects are examined on three different stages – no cracking, partly cracked, and completely cracked based on which three different mechanisms are taken into account for both effects together. Fracture mechanics is employed for the analysis of stress and strain in the cracked concrete where isotropic property is no longer applicable. The developed model can be used as a tool to assess the serviceability of corrosion affected concrete infrastructure.

2. FORMULATION OF THE PROBLEM

Although considerable research has been undertaken on corrosion-induced, or loading-induced concrete cracking, little work has been conducted directly on corrosion-induced crack width over time [Li et al. 2006], and almost no research is carried out on both corrosion and loading induced crack width as a function of time.

Concrete with embedded reinforcing bar can be modelled as a thick-wall cylinder [Bažant 1979; Pantazopoulou and Papoulia 2001; Tepfers 1979] where elastic mechanics [Timoshenko and Goodier 1970] and fracture mechanics [Bažant and Jirasek 2002; Noll 1972] are employed to analyse the stress distribution. This is shown in Fig. 1 (a), where D is the diameter of reinforcement bar, d_0 is the thickness of the annular layer of concrete pores at the interface between the bar and concrete and C is the concrete cover. $P(t)$ is the expansive pressure at the interface between the rust band and concrete, and it consists of two parts: $P_1(t)$ induced by corrosion and P_2 induced by loading.

$$P(t) = P_1(t) + P_2 \tag{1}$$

Under the expansive pressure, the concrete cylinder undergoes three phases in terms of cracking: 1) no cracking; 2) partially cracked; 3) completely cracked.

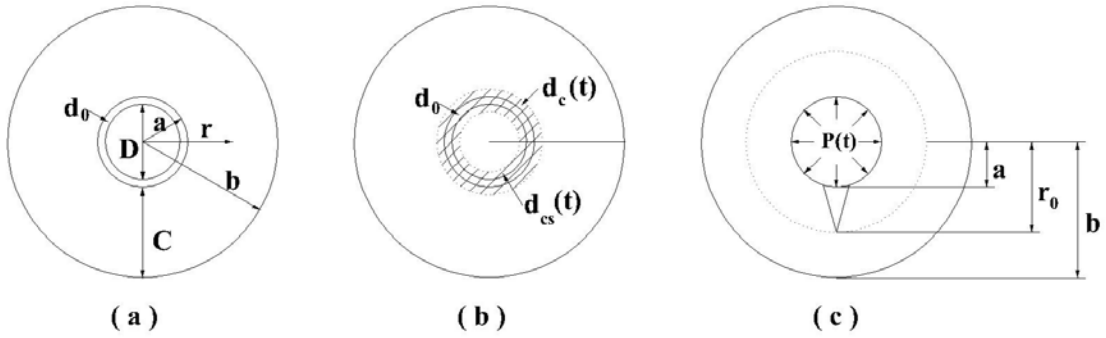

Figure 1. Schematic of corrosion-induced concrete cracking process

2.1 Effect of Corrosion Products

As shown in Fig. 1 (b), $d_c(t)$ is the thickness of the band of rust which is formed after the corrosion products fill in the full layer of concrete pores, $d_{cs}(t)$ is the thickness of corroded steel. Usually d_0 is constant once concrete has hardened. The inner and outer radii of the thick-wall cylinder are $a = D/2 + d_0$ and $b = C + D/2 + d_0$. As steel corrodes, the corrosion products first fill in the pore band of d_0, which does not cause stresses in the concrete cylinder. After that, as the corrosion propagates in the concrete cylinder, a ring of corrosion products forms, the thickness of which as mentioned above, is $d_c(t)$. According to Liu and Weyers [1998], $d_s(t)$ is the sum of d_0 and $d_c(t)$, and can be determined as

$$d_s(t) = \frac{W_{rust}(t)}{\pi D}\left(\frac{1}{\rho_{rust}} - \frac{\alpha_{rust}}{\rho_{st}}\right) \tag{2}$$

where α_{rust} is a coefficient related to the type of corrosion products, ρ_{rust} is the density of corrosion products, ρ_{st} is the density of steel, and $W_{rust}(t)$ is the mass of corrosion products. Then $d_c(t)$ can be obtained from

$$d_c(t) = d_s(t) - d_0 \tag{3}$$

It is assumed in this paper that $d_c(t)$ is the displacement of the concrete cylinder caused by corrosion only.

In Figure 1, $d_{cs}(t)$ can be expressed in terms of $W_{rust}(t)$ as

$$d_{cs}(t) = \frac{\alpha_{rust} W_{rust}(t)}{\rho_{st}} \tag{4}$$

According to Li et al. [2006] and Liu and Weyers [1998], $W_{rust}(t)$ can be expressed as

$$W_{rust}(t) = \sqrt{2\int_0^t 0.105(1/\alpha_{rust})\pi D i_{corr}(t)dt} \tag{5}$$

2.2 Effect of Applied Loads

This paper only concerns load-induced longitudinal cracks which are due to radial component of the bond forces between deformed rebar and surrounding concrete as schematically shown in Fig. 2.

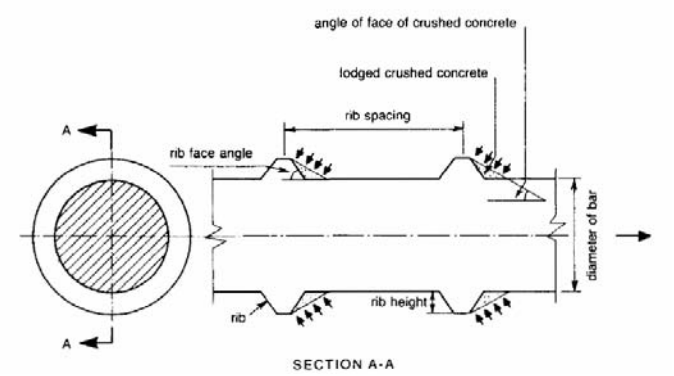

Figure 2. The mechanical interaction [Tepfers 1979]

The radial pressure to concrete can be calculated from Tepfers [1979]

$$P_2 = \frac{D}{4}\frac{d\sigma_s}{dx}\tan\theta \tag{6}$$

where σ_s is the steel stress under loads, x indicates different position over the length of the rebar, and θ is the angle between the bond force and the axis.

For a simply supported reinforced concrete beam subject to distributed load with magnitude ω, from theory of concrete structure, σ_s can be determined as follows

$$\sigma_s = \frac{M(x)}{A_s(h_0 - \frac{f_y A_s}{2\alpha_1 f_c b})} = \frac{\frac{\omega L}{2}x - \frac{\omega x^2}{2}}{A_s(h_0 - \frac{f_y A_s}{2\alpha_1 f_c b})} \tag{7}$$

where L is the length of the beam, f_y is the tensile strength of the reinforcement, f_c is the compressive strength of the concrete, A_s is the area of the reinforcement in the concrete, h_0 is the effective height and b is the width of the concrete beam.

It follows that P_2 can be expressed as

$$P_2 = \frac{D}{4}\frac{\frac{\omega L}{2} - \omega x}{A_s(h_0 - \frac{f_y A_s}{2\alpha_1 f_c b})}\tan\theta \tag{8}$$

3. DERIVATION OF CRACK WIDTH

At no-cracking stage, the concrete cylinder can be considered to be elastically isotropic so that the theory of elasticity can be employed to determine the radial stress $\sigma_r(r)$ and tangential stress $\sigma_\theta(r)$ at any point (r) in the cylinder. According to [Timoshenko and Goodier 1970], the radial and tangential stresses can be expressed as

$$\sigma_r(r)=\frac{E_{ef}}{1-\upsilon_c^2}\left[(1+\upsilon_c)c_1-\frac{(1-\upsilon_c)c_2}{r^2}\right] \tag{9}$$

$$\sigma_\theta(r)=\frac{E_{ef}}{1-\upsilon_c^2}\left[(1+\upsilon_c)c_1+\frac{(1-\upsilon_c)c_2}{r^2}\right] \tag{10}$$

At the partially cracked stage, the concrete cylinder is divided into two coaxial cylinders: inner cracked and outer uncracked ones. For the outer uncracked concrete cylinder, the theory of elasticity still applies. For the inner cracked one, however, fracture mechanics is employed to determine the stress distribution by assuming that the cracks are smeared and uniformly distributed on the circumference of the cracked cylinder [Pantazopoulou and Papoulia 2001]. To account for this, a tangential stiffness reduction factor α (<1) is introduced.

For the outer uncracked concrete, the stress components are

$$\sigma_r(r)=\frac{E_{ef}}{1-\upsilon_c^2}\left[(1+\upsilon_c)c_3-\frac{(1-\upsilon_c)c_4}{r^2}\right] \tag{11}$$

$$\sigma_\theta(r)=\frac{E_{ef}}{1-\upsilon_c^2}\left[(1+\upsilon_c)c_3+\frac{(1-\upsilon_c)c_4}{r^2}\right] \tag{12}$$

For the inner cracked concrete the radial and tangential stresses are

$$\sigma_r(r)=\frac{\sqrt{\alpha}E_{ef}}{1-\upsilon_c^2}\left[c_5(1+\upsilon_c)r^{(\sqrt{\alpha}-1)}-c_6(1-\upsilon_c)r^{(-\sqrt{\alpha}-1)}\right] \tag{13}$$

$$\sigma_\theta(r)=\frac{\alpha E_{ef}}{1-\upsilon_c^2}\left[c_5(1+\upsilon_c)r^{(\sqrt{\alpha}-1)}+c_6(1-\upsilon_c)r^{(-\sqrt{\alpha}-1)}\right] \tag{14}$$

At the completely cracked stage, the governing equation for the concrete cylinder is the same as that of inner cracked part for the partially cracked stage with different boundary conditions. Thus, the stress components are as follows

$$\sigma_r(r)=\frac{\sqrt{\alpha}E_{ef}}{1-\upsilon_c^2}\left[c_7(1+\upsilon_c)r^{(\sqrt{\alpha}-1)}-c_8(1-\upsilon_c)r^{(-\sqrt{\alpha}-1)}\right] \tag{15}$$

$$\sigma_\theta(r)=\frac{\alpha E_{ef}}{1-\upsilon_c^2}\left[c_7(1+\upsilon_c)r^{(\sqrt{\alpha}-1)}+c_8(1-\upsilon_c)r^{(-\sqrt{\alpha}-1)}\right] \tag{16}$$

In the above equations, C_1 - C_8 are coefficients of differential equations to be determined based on initial and boundary conditions which cannot be described in details here due to page limit.

Before corrosion initiates, there is only applied load induced pressure P_2, under which the concrete cylinder could be either not cracked or partially cracked. Completely cracked case can be designed out. This needs to be checked before corrosion induced pressure is considered.

Assuming under P_2 at t=0 the concrete cylinder has no cracking, apply $\sigma_r(a) = -P_2$ and $\sigma_r(b) = 0$ (see Fig 1) as the boundary conditions, the stresses components could be obtained

$$\sigma_r(r) = \frac{a^2 P_2}{b^2 - a^2}(1 - \frac{b^2}{r^2}) \tag{17}$$

$$\sigma_\theta(r) = \frac{a^2 P_2}{b^2 - a^2}(1 + \frac{b^2}{r^2}) \tag{18}$$

If $\sigma_\theta(a) < f_t$, it means no cracking for concrete cylinder at t=0,
If $\sigma_\theta(a) \geq f_t$ and $\sigma_\theta(b) < f_t$, it means partially cracked for concrete cylinder at t=0.

When there is no cracking, applying $u(a) = d_c(t)$ and $\sigma_r(b) = 0$ as the boundary conditions, the corrosion-induced radial stress at $r = a$ could be found as

$$\frac{E_{ef} d_c(t)}{a(\frac{a^2 + b^2}{a^2 - b^2} - \upsilon_c)}.$$

Then applying

$$\sigma_r(a) = \frac{E_{ef} d_c(t)}{a(\frac{a^2 + b^2}{a^2 - b^2} - \upsilon_c)} - P_2$$

and

$$\sigma_r(b) = 0$$

as new boundary conditions, the radial and tangential stresses at any point (r) under the combined effect can be obtained. The same methodology applied to the second phase and third phase is employed to determine all the coefficients. Finally, the solution to crack width is

$$w_c = 2\pi b\left[c_7 b^{(\sqrt{\alpha}-1)} + c_8 b^{(-\sqrt{\alpha}-1)} - \frac{f_t}{E_{ef}}\right]$$

$$= \frac{4\pi d_s(t)}{(1-\upsilon_c)(a/b)^{\sqrt{\alpha}} + (1+\upsilon_c)(b/a)^{\sqrt{\alpha}}} + \frac{4\pi a P_2}{E_{ef}\sqrt{\alpha}((b/a)^{\sqrt{\alpha}} - (a/b)^{\sqrt{\alpha}})} - \frac{2\pi b f_t}{E_{ef}} \tag{19}$$

When the concrete is partially cracked before corrosion starts, the initial cracking time $t_1 = 0$. The concrete cylinder undergoes from the phase of partially cracking and the stresses expressions of (11) to (14) are applicable. Under these two scenarios the coefficients of differential equations are the same. It needs to be checked, however, at the very beginning, which scenario occurs and analyse for the correct phase.

4. WORKED EXAMPLE

To demonstrate the application of the derived model, a numerical example is carried out using the values of basic variables in Table 1. In this case, a reinforced concrete beam with the dimension 100 x

200 x 3000 (length) mm is used. The beam is subjected to a uniformly distributed load of 2e4 N/m and is (assumed) located in a marine environment which inevitably causes reinforcement corrosion in the beam and eventually concrete cracking. Under this situation, equation (19) can be used to estimate the crack width. Firstly, computer program written in MATLAB is developed for all the computation for different phases as described above. The program is run 1001 times for a 10 years service life with a time increment of 0.01 year. The value of crack width is obtained once the stiffness reduction factor α is determined in each run. The results for the crack width, the expansive pressure and the tangential stiff reduction factor are presented as function of time in Fig.3.

Table 1. Values of some basic variables

Symbol	Values
α_1	0.85
h_0	163mm
f_y	400MPa
A_s	226 mm^2
b	120mm
C	31mm
D	12mm
d_0	12.5μm
f_t	5.725 MPa
α_{rust}	0.57
ρ_{rust}	3600 kg/m^3

As can be seen in Fig 3, the crack width increases with time as well as the displacement of concrete cylinder at r=a. At time t=0, the expansive pressure is caused by applied loads only; therefore the pressure keeps constant until corrosion induces the additional pressure. At about 2 years, the concrete surface cracks leading to an abrupt increase in crack width, accompanied with sudden decreases in the tangential stiffness reduction factor α and expansive pressure P. The sudden decreases in the expansive pressure and α indicate that the consistency in deriving the crack width based on both isotropic, elastic concrete and anisotropic, quasi-brittle concrete. At nearly 3 years, the tangential stiffness reduction factor α approaches zero which means almost no tangential stress in concrete from then.

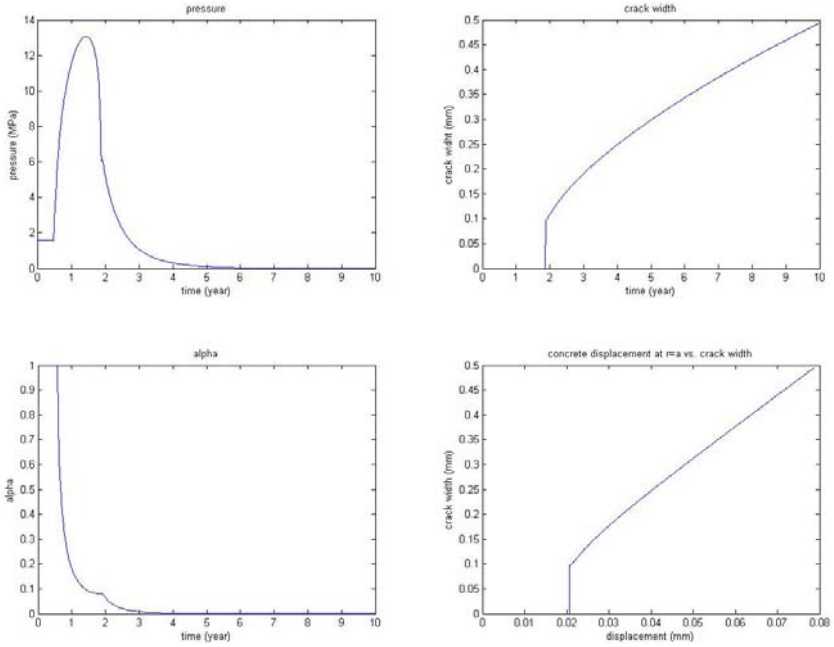

Figure 3. Relationships between some important factors and time

5. CONCLUSIONS

An analytical model for concrete crack width under both reinforcement corrosion and applied loads has been derived based on a combination of elastic mechanics and fracture mechanics. The model is directly related to the causal factors of corrosion rate and applied load, as well as the concrete geometry and properties. Due to page limit, details of the derivation of the solution to the differential equations cannot be presented. A worked example is given and the numerical results seem to be quite reasonable to reflect the engineering reality. It can be concluded that the model derived in the paper can serve as a useful tool for engineers, operators and asset managers in decision-making with regard to the serviceability of corroded concrete structures.

T 11

ABSTRACT

Concrete in sewage and wastewater treatment plants are deteriorated by sulfuric acid. To prevent this deterioration, some coutermeasures are taken. The use of mineral admixtures such as blast furnace slag, fly ash and silica fume is one of the countermeasures. In this study, the effect of mineral admixturs on resistance of cement hydrates to sulfuric acid attack was investigated.

Cement paste and mortar specimens were prepared with different water cement ratios. A part of cement was replaced with blast furnace slag, fly ash and silica fume. After curing, the specimens were immersed in sulfuric acid solutions of pH=1.0 and 2.0. To simulate a circumstance of sewage, some specimens were immersed in flowing sulfuric acid solution. The erosion depths and mass losses of the specimens were measured. For some specimens, the calcium hydroxide contents were determined before and after immersion.

As a result, specimens containing silica fume showed much better resistance to sulfuric acid attack than those containing blast furnace slag and fly ash. Specimens containing three mineral admixtures of blast furnace slag, fly ash and silica fume also showed good resistance. The flow of the solution accelerated the erosion of specimens immersed in sulfuric acid solution of pH=2.0.

1 INTRODUCTION

Concrete structures in sewage and wastewater treatment plants are severely damaged by sulfuric acid attack. Generally some kind of resin material is coated on the concrete surface when severe acid attack is expected against the concrete. But this coating is effective only if there is no defect such as a pinhole. Otherwise concrete deterioration will be developed from the surrounding of a pinhole. To prevent such deterioration, it is demanded that concrete itself has the resistance to sulfuric acid solution in some extent. The use of mineral admixtures such as blast furnace slag, fly ash and silica fume will be one of the countermeasures against the concrete deterioration due to acid attack because calcium hydroxide which reacts with sulfuric acid to produce gypsum is consumed by hydration of blast furnace slag and pozzolanic reaction of fly ash and silica fume.

Recently the design method of a concrete structure has been shifting to the performance-based design method. If a concrete is placed under a circumstance where its deterioration is supposed, the deteroiration prediction will be demanded in the design stage. In this study, the effect of mineral admixtures on resistance of cement hydrates to sulfuric acid attack was investigated to establish an estimation method for predicting deterioration of cement hydrates containing mineral admixtures due to sulfuric acid attack.

2 EXPERIMENTAL PROCEDURES

2.1 Materials

Ordinary portland cement, blast furnace slag, fly ash and silica fume were used as binding material. The physical and chemical properties of these materials are shown in Table 1. Silicious sand was used as fine aggregate. In Japan, a new type of acid resistant cement has been developed [Kawai *et al.* 2007]. This cement is composed of 20% of ordinary portland cement, 30% of blast furnace slag, 30% of fly ash and 20% of silica fume. In this study, this cement was also used as binding material.

Table 1. Physical and chemical properties of binding materials used in this study

Binding material	*Chemical component* [%]							
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	Na_2O	K_2O
Ordinary portland cement	20.41	5.18	3.17	64.25	2.06	2.16	0.4	0.39
Blast furnace slag	33.86	14.92	0.29	42.24	6.09	0.23	0.36	0.65
Fly ash	57.8	29.1	3.9	3.2	1.1	0.3	0.49	0.46
Silica fume	96.3	---	---	0.3	0.6	0.2	---	---

Binding material	*Chemical component* [%]			*Density* [g/cm^3]	*Blaine specific surface area* [cm^2/g]
	TiO_2	P_2O_5	MnO		
Ordinary portland cement	0.24	0.69	0.06	3.15	3 460
Blast furnace slag	0.65	0.01	0.34	3.05	3 950
Fly ash	1.67	0.04	0.01	2.28	3 900
Silica fume	---	---	---	2.22	---

2.2 Specimens

Cement paste specimens with a water binding material ratio of 0.35 and mortar specimens with a water binding material ratio of 0.40 were prepared. Both cement paste and mortar specimens are prisms of 40 mm x 40 mm x 160 mm in size. Specimens were demolded 24 hours after casting and cured in water at 20 ^{o}C for given periods. The mix proportions of cement paste and mortar specimens are shown in Tables 2 and 3, respectively.

Table 2. Mix proportions of ccement paste specimens

Mark	*W/B*	*Mass ratio of binding materials*			
		Ordinary portland cement	*Blast furnace slag*	*Fly ash*	*Silica fume*
OPC	0.35	100	--	--	--

2.3 Immersion Test

After cured in water for 8 weeks, cement paste specimens were cut into 40 mm x 40 mm x 40 mm in size and immersed in sulfuric acid solution with a pH value of 1.0. Mortar specimens were cut into 40 mm x 40 mm x 80 mm in size and four sides of mortar specimens were sealed with an acid-resistant resin so that sulfuric acid solution penetrated into the specimens one-dimensionally only from both ends of the specimens. After that the mortar specimens were immersed in sulfuric acid solution with pH values of 1.0 and 2.0. Before immersion, all surfaces of these specimens were ground with a grinder since calcium leaching during the water curing was suspected in the vicinity of the surfaces.

For mortar specimens, some were immersed in flowing sulfuric acid solution to simulate a circumstance of an actual sewage [Kawai *et al.* 2005] and the deterioration of them was compared with that of specimens statically immersed in sulfuric acid solution. The flow was generated by circulating the solution with a pump.

The mass losses of cement paste specimens and the erosion depths of mortar specimens were measured at given periods. The value of pH of the solution was continously measured with a pH meter to hold it constant by adding sulfuric acid.

3 RESULTS AND DISCUSSIONS

3.1 Immersion Test of Cement Paste Specimens

Calcium hydroxide contents of cement paste specimens at the age of 28 days are shown in Fig. 1. The calcium hydroxide contents of the specimens containing blast furnace slag (BFS30) and silica fume (SF20) decrease more than the replacement percentage of the mineral admixture, compared with the calcium hydroxide content of the specimen using ordinary portland cement (OPC). Hydration of blast furnace slag and pozzolanic reaction of silica fume consume calcium hydroxide while pozzolanic reaction of fly ash does not proceed. It is found that the specimen using acid resistant cement (ARC) remains very few calcium hydroxide contents.

Figure 2 shows the calcium hydroxide amount consumed by each mineral admixture which was calculated from the calcium hydroxide contents of cement paste specimens at the age of 56 days. A very large amount of calcium hydroxide is consumed by silica fume compared with blast furnace slag

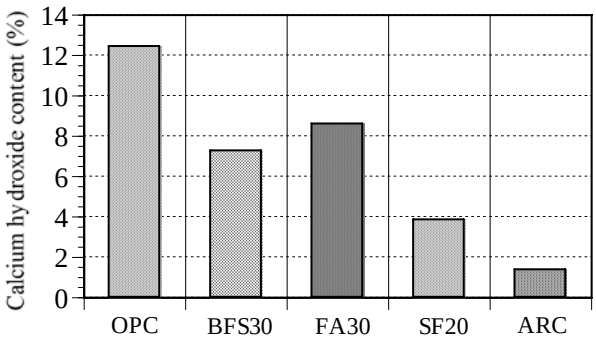

Figure 1. Calcium hydroxide content of each cement paste specimen at the age of 28 days

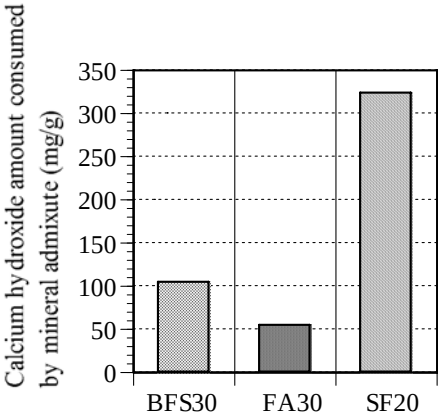

Figure 2. Calcium hydroxide amount consumed by each mineral admixture for 56 day curing

and fly ash. From this result, it is suitable to replace ordinary portland cement with silica fume in order to consume calcium hydroxide in the cement paste and improve the resistance of cement hydrates to sulfuric acid. The addition of silica fume, however, may reduce the consistency of cement paste. Therefore the addition of an appropriate amount of blast furnace slag or fly ash in addition to silica fume could be needed to keep the consistency of cement paste and improve the resistance of cement paste to sulfuric acid.

Changes in the mass loss of each specimen immersed in sulfuric acid solution of pH=1.0 are shown in Fig. 3. For BFS30, FA30, SF20 and ARC, the larger the calcium hydroxide content, the larger the mass gain of the specimen. The change in the mass of the specimen depends upon the remaining calcium hydroxide content. Therefore the addition of blast furnace slag instead of fly ash in addition to silica fume will be better from the result of the mass change.

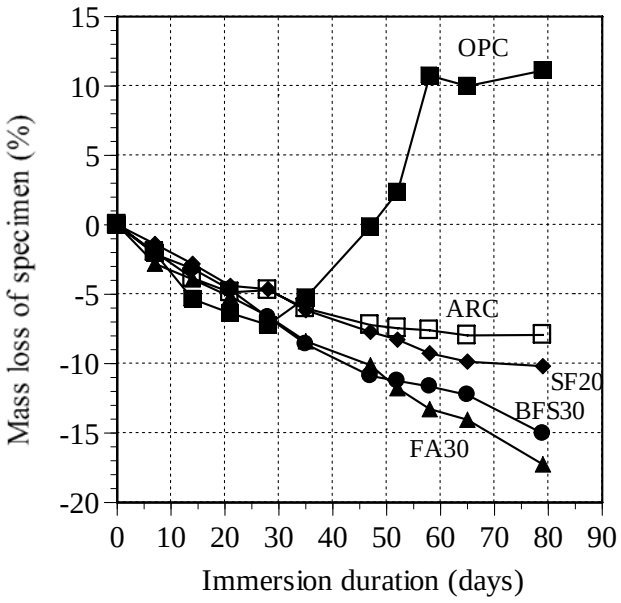

Figure 3. Mass loss of each cement paste specimen immersed in H_2SO_4 solution of pH=1.0

Photograghs of cement paste specimens immersed for 79 and 116 days in sulfuric acid solution of pH=1.0 are shown in Figs 4 and 5, respectively.

For the specimens using ordinary portland cement (OPC), gypsum was precipitated on the surfaces and removed. As a result, the size of the specimen reduced (Fig.5 (a)). On the other hand, for the

(a) OPC

(b) BFS30

(c) FA30

(d) SF20

(e) ARC

(d) SF20

(e) ARC

Figure 5. Photographs of specimens immersed for 116 days in H_2SO_4 solution of pH=1.0

specimens using blast furnace slag and fly ash (BFS30, FA30), gypsum was precipitated on the surfaces but remained there. Gypsum layers were formed on the surfaces of the specimens and cracks which will be caused by swelling of gypsum production can be seen around the corners of the

specimens (Fig. 5 (b), (c)). It is thought that the gypsum layer for FA30 is gray because it contains fly ash particles together with gypsum. Comparing with gypsum produced in OPC, gypsum produced in BFS30 and FA30 should have higher cohesiveness which leads to control of acid penetration into a specimen. Little deterioration can be seen apparently for the specimens using silica fume and acid resistant cement (SF20, ARC) although some alternation is observed around the surfaces (Fig. 5 (d), (e)). This alternation, however, was so strong that there was no separation.

3.2 Immersion Test of Mortar Specimens

Erosion depths of mortar specimens immersed in flowing and static sulfuric acid solution with pH values of 1.0 and 2.0 are shown in Figs 6 and 7, respectively.

For specimens immersed in sulfuric acid solution of pH=1.0, the erosion depths of the specimens using ordinary portland cement, blast furnace slag and acid resistant cement differed largely, while the difference of the specimens immersed in flowing and static sulfuric acid solution was small. The specimens using acid resistant cement show good resistance to sulfuric acid solution and the addition of blast furnace slag also improves the resistance to sulfuric acid solution.

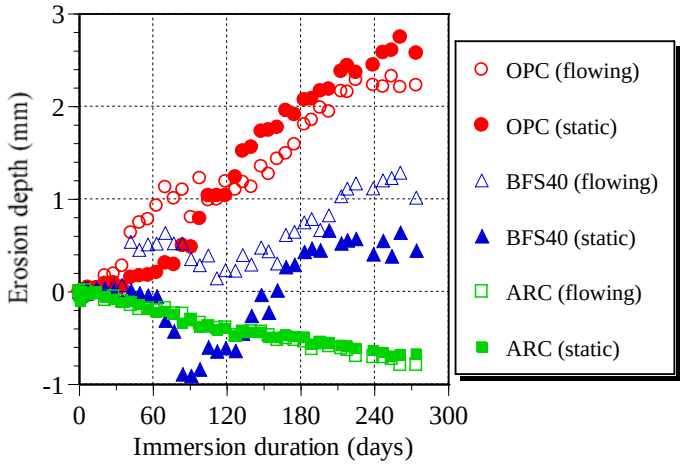

Figure 6. Changes in erosion depth of each mortar specimen immersed in H_2SO_4 solution of pH=1.0

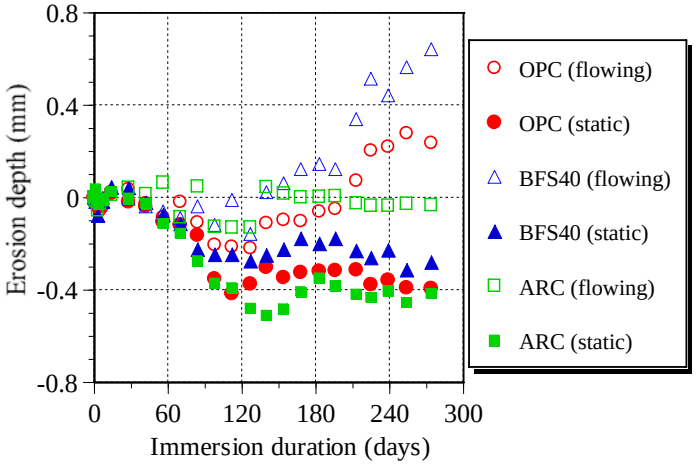

Figure 7. Changes in erosion depth of each mortar specimen immersed in H_2SO_4 solution of pH=2.0

For specimens immersed in sulfuric acid solution of pH=2.0, the erosion depths of the specimens immersed in flowing and static sulfuric acid solution differed significantly in every binding material. Since the acid attack at pH=2.0 is weaker than at pH=1.0, the production of gypsum by calcium

hydroxide and sulfuric acid is slow enough to remove the product by the shearing force of the flow in flowing sulfuric acid solution. It can be said that the shearing force of the flow accelerates the erosion of the specimen.

Mass losses of mortar specimens immersed in flowing and static sulfuric acid solution with pH values of 1.0 and 2.0 are shown in Figs 8 and 9, respectively.

The results do not wholly correspond to the results for the erosion depths. For instance, the erosion depths of the specimens for OPC and BFS40 immersed in flowing sulfuric acid solution are largely different in Fig. 6 but the mass losses of both specimens are almost same in Fig. 8. This will be because the specimen for BFS40 was not eroded very much but the microstructure near the surfaces became porous. Such microstructural change could be reflected to the mass losses.

Comparing the results between pH=1.0 and pH=2.0, the specimens for OPC immersed statically in sulfuric acid solution show very different tendency, which can be seen also in the results for the erosion depth. This will explain that the reaction rate of calcium hydroxide and sulfuric acid is quite different at pH=1.0 and pH=2.0.

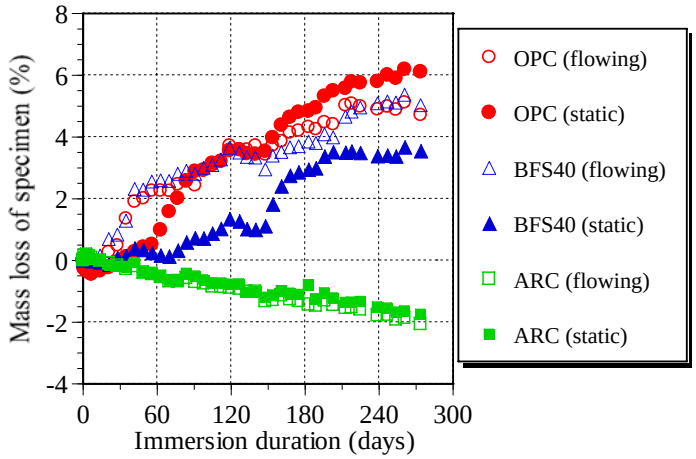

Figure 8. Changes in mass loss of each mortar specimen immersed in H_2SO_4 solution of pH=1.0

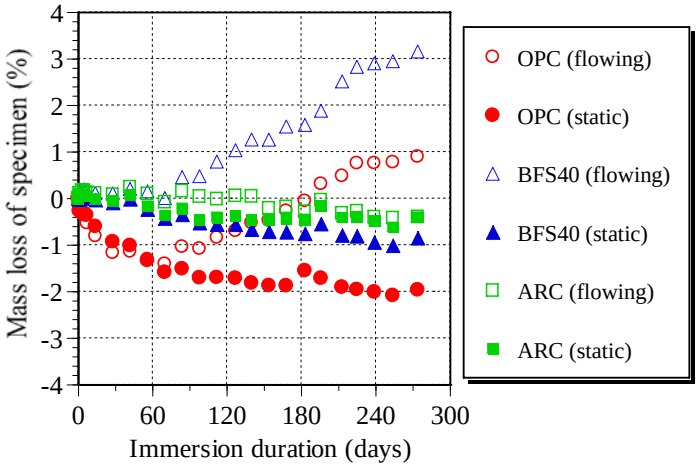

Figure 9. Changes in mass loss of each mortar specimen immersed in H_2SO_4 solution of pH=2.0

4 CONCLUSIONS

In this study, the effect of mineral admixtures on resistance of cement hydrates to sulfuric acid attack was investigated. As a result, the following conclusions can be drawn.

1. Coment paste specimens containing silica fume showed good resistance to sulfuric acid attack compared with specimens containing blast furnace slag and fly ash. Cement paste specimens containing three mineral admixtures of blast furnace slag, fly ash and silica fume also showed good resistance to sulfuric acid attack.

2. When mortar specimens were immersed in sulfuric acid solution of pH=1.0 and pH=2.0, changes in erosion depths and mass losses were different in the value of pH for specimens containing no mineral admixture and blast furnace slag. Specimens containing three mineral admixtures of blast furnace slag, fly ash and silica fume showed very little changes in both erosion depths and mass losses.

3. When mortar specimens were immersed in flowing sulfuric acid solution at pH=2.0, the erosion of the specimens was accelerated compared with specimens immersed statically in sulfuric acid solution.

Corrosion Resistance of GGBS Concrete

M. Hulusi Ozkul [1]
Unal Anil Dogan [2]
Ali Raif Saglam [3]
Nazmiye Parlak [4]

T11

ABSTRACT

Owing to the fact that corrosion of steel is the key concern of service life of reinforced concrete structures, researchers have been dealing with this subject for many years. Pozzolanic materials, most of which are by products of industries, are widely used in concrete production, especially to increase the durability properties. Fly ash, ground granulated blast furnace slag (GGBS) and silica fume are the most common pozzolans together with natural pozzolans used in concrete technology.

In this experimental research, resistance to chloride induced corrosion of reinforcing steel bars embedded in GGBS concrete has been studied. Two classes of concrete have been prepared; such as C25 and C35 at two different binder ratios. Cement in the concrete was replaced with GGBS at the ratios of 30%, 50% and 70%. Lollipop specimens with steel bars located in the center were prepared and stored in 1M NaCl solution for corrosion testing. Two levels of continuous potential difference, i.e. 6V and 12V, were applied to accelerate the corrosion and corrosion rate, corrosion potential and resistivity of concrete were monitored by using the linear polarization method. Efficiency factor of GGBS on corrosion initiation and threshold chloride concentration are calculated. Test results showed that higher the GGBS content in concrete lower the chloride diffusion and longer the corrosion initiation time.

1 INTRODUCTION

It is well known that the most common cause of deterioration of reinforced concrete structures is corrosion of reinforcing bars. Under normal conditions, high alkalinity of concrete keeps the embedded steel passive; however corrosion may initiate due to either carbonation of cover, or chloride attack or both. Permeation of such aggressive substances through concrete cover controls the time to corrosion onset.

Sustainability of construction industry can only be achieved by using supreme amount of pozzolanic material replacements in concrete [Mehta 1997]. Pozzolanic materials improve the impermeability by both filling and pozzolanic effects, the latter occurs between pozzolans and $Ca(OH)_2$, generated during the hydration of C_3S and C_2S components of cement, to form calcium silicate hydrate (C-S-H). Hence, utilization of mineral admixtures in concrete mitigates the heat of hydration, improves the durability, recycles the waste products and reduces the cost.

Fly ash and GGBS are widely employed in concrete production. In the production of GGBS, grinding is needed, however, the energy requirement for grinding is only 25% of that of clinker production [Song & Saraswathy 2006]. Neville [1993] denoted that the content of GGBS must be at least 50% by mass of the total cementitious material, and preferably 60-70% to be effective. In order to maintain a significant influence in reducing reinforcement corrosion, more than 40% of cement in concrete should be replaced by GGBS [Mangat & Molloy 1991]. Aldea *et al.* [2000] reported an increase on compressive strength up to 25% slag replacement and a decrease above this level, and concretes with 50% slag replacement had compressive strength similar to control mixture. However, increasing slag replacement continuously improved microstructural properties and decreased chloride penetrability. In another study [Thomas & Bamforth 1999], it is estimated that diffusion coefficients for slag or fly ash concretes decrease to one or two order of magnitude than similar grade Portland cement concrete during 100-year service life. Robins *et al.* [1992] obtained lower permeability values for slag concretes just in case of water curing under hot climate conditions. In a more recent study, significant improvements in corrosion rate, corrosion potential and carbonation depths of slag added concretes were reported compared to those of plain concrete having similar compressive strength [Pal *et al.* 2002]. Leng *et al.* [2000] found 50% reduction in the coefficient of chloride permeability, provided 30% of cement is replaced with GGBS.

2 EXPERIMENTAL

2.1 Materials

Concretes were cast by using CEM I 42.5 cement. The aggregates were composed of crushed stone II, crushed stone I, crushed stone sand and natural sand, with the specific weights of 2.70, 2.70, 2.66, 2.59 kg/dm^3 and in the percentages of 0.25;0.25;0.25;0.25, respectively. Physical and chemical properties of cement and GGBS are presented in Table 1.

In order to observe the effect of concrete quality on the corrosion behavior of embedded steel bars, two water/cement ratios of 0.65 and 0.49 were tested. A lignin based water reducer was employed in the dosages of 0.7% and 1.2% (as wt. percentage of cement) for high and low water/cement ratios, respectively. Mixture propotions of concretes are given in Table 2. Cubes of 150x150x150 mm specimens were cast for compression tests and lollipop cylinders of ϕ100x200 mm specimens containing a ϕ10 steel bar located in the center for corrosion tests were cast. Prior to casting concrete, steel bars were cleaned by a metal brush and partially coated with an epoxy based coating as shown in Figure 1. Thus, the exposed area of each steel was equal to 31.4 cm^2. Two sets of lollipop specimens were prepared for each batch. Following demoulding the specimens, uncoated parts of the steel bars of the lollipop specimens were

coated with vaseline to avoid corrosion and specimens were partially immersed in a water tank for 28 days for curing.

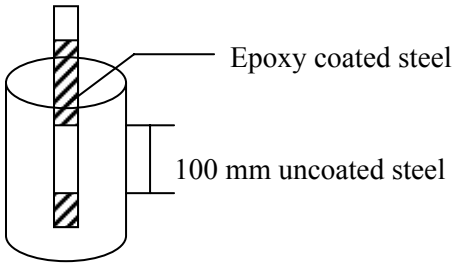

Figure 1. Lollipop specimens

2.2 Methods

The corrosion in rebars was electrically accelerated by using a 6-volt direct current to find out the time to corrosion initiation and 12-volt direct current to observe crack propogation. Each exposing cycle consist of keeping the lollipop specimens in 1M NaCl solution for 24 hours, followed by 48 hours of drying in air (Fig. 2a). All the specimens were monitored by the Gecor 8 corrosion ratemeter (Fig. 2b) which can perform in accordance with linear polarization method and can also measure half-cell potential and resistivity, at the end of each cycle. Chloride profiles of specimens for corrosion initiaton were measured at the end of acceleration.

Figure 2. a) Accelerated corrosion test setup, **b)** Gecor 8 corrosion ratemeter

3 TEST RESULTS AND DISCUSSION

Compressive cube strengths of concretes with and without GGBS are demonstrated in Figure 3. For both type of concrete classes, increasing amount of GGBS exhibited reduced 7-day to 28-day compressive strength ratios. This ratio decreased from 0.80 to 0.28 for C25 and from 0.82 to 0.21 for C35 grade concretes, which can be attributed to the lower hydration reaction rate of GGBS at early ages.

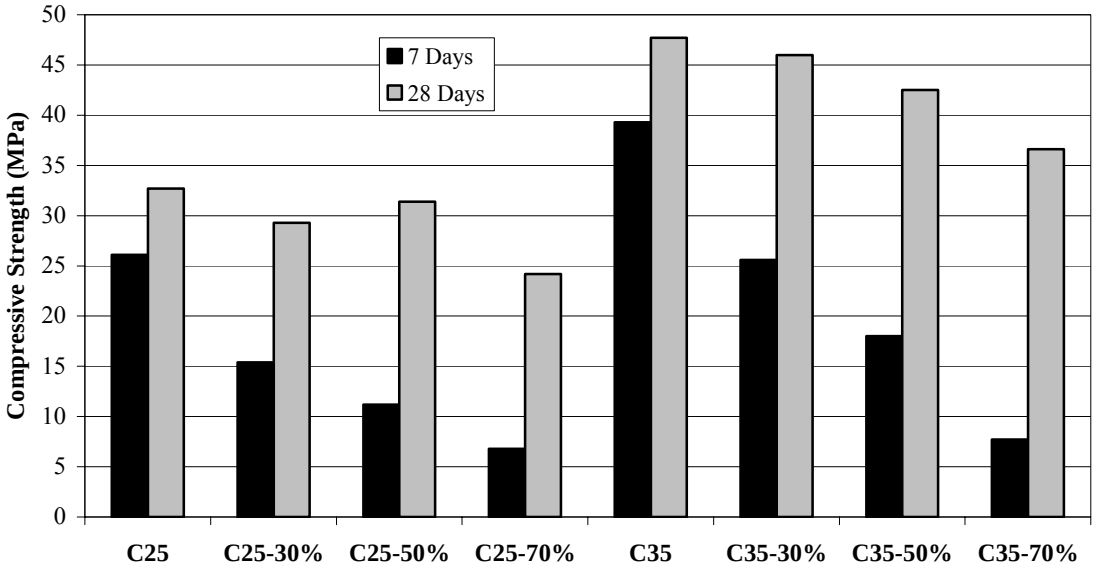

Figure 3. Compressive cube strengths of concretes

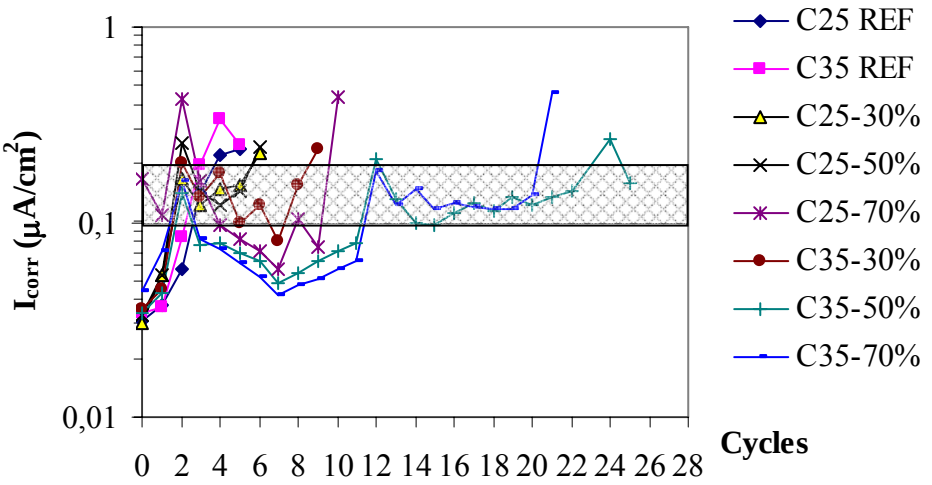

Figure 4. Corrosion rate measurements of lollipop specimens subjected to 6V potential difference.

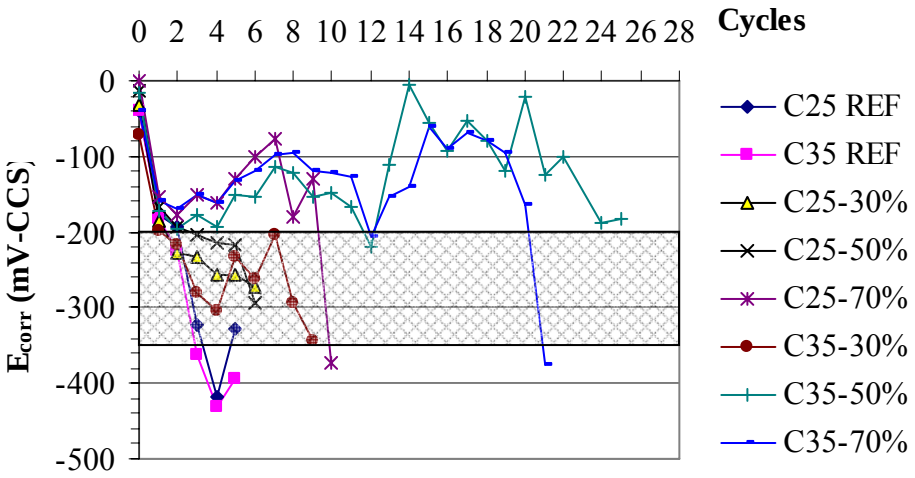

Figure 5. Corrosion potential measurements of lollipop specimens subjected to 6V potential difference.

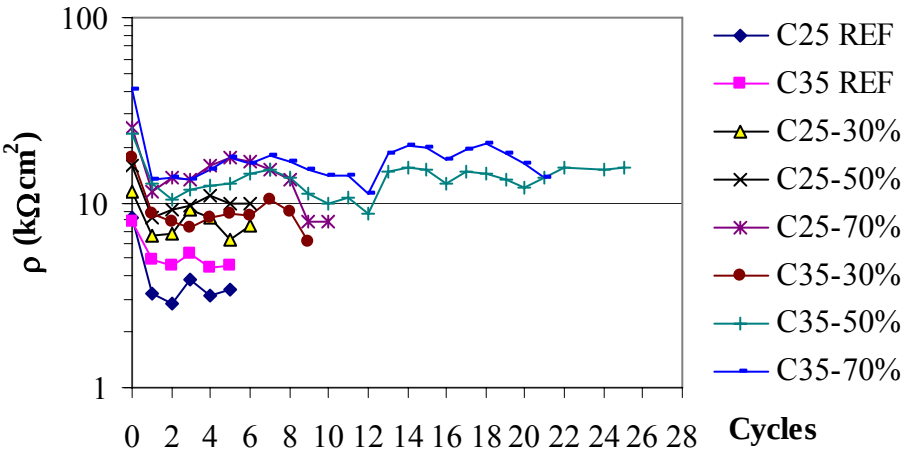

Figure 6. Resistivity measurements of lollipop specimens subjected to 6V potential difference.

In order to determine the corrosion initiation time of the lollipop specimens, corrosion rate (I_{corr}), corrosion potential (E_{corr}) and resistivity (ρ) tests were carried out under a potential difference of 6V

and the results are shown in Figures 4-6, respectively. Critical zones for I_{corr} and E_{corr} values are shaded in these figures and tests were finalized when the I_{corr} values exceeded the critical zones. Test results exhibited that for the 70% GGBS replaced specimens of C25 grade concretes, the longest corrosion initiation times were obtained and those of 30% and 50% replaced specimens followed them. No difference was seen between the performances of 30% and 50% replacement levels for C25. On the other hand, for C35 concretes, the best performance belongs to the specimens of 50% GGBS replacement instead of 70% replaced ones, showing a kind of optimum GGBS replacement ratio. The tests of E_{corr} supported the results of I_{corr}, as can be seen in Figures 4 and 5.

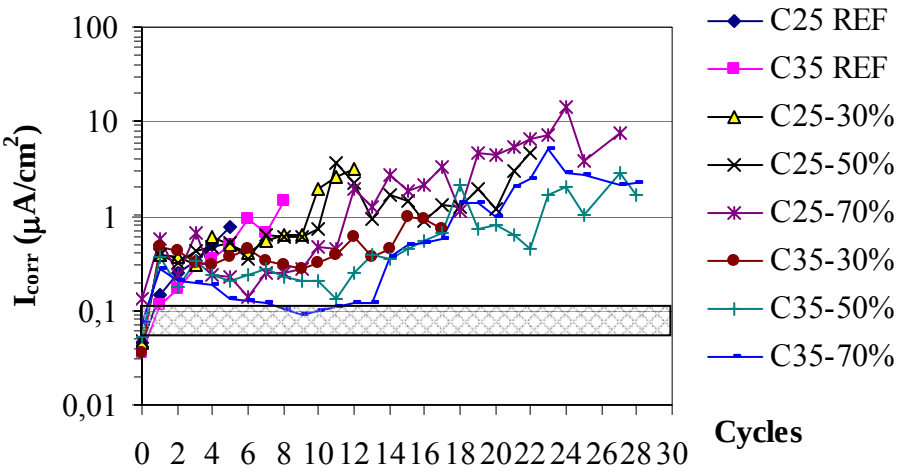

Figure 7. Corrosion rate measurements of lollipop specimens subjected to 12V potential difference.

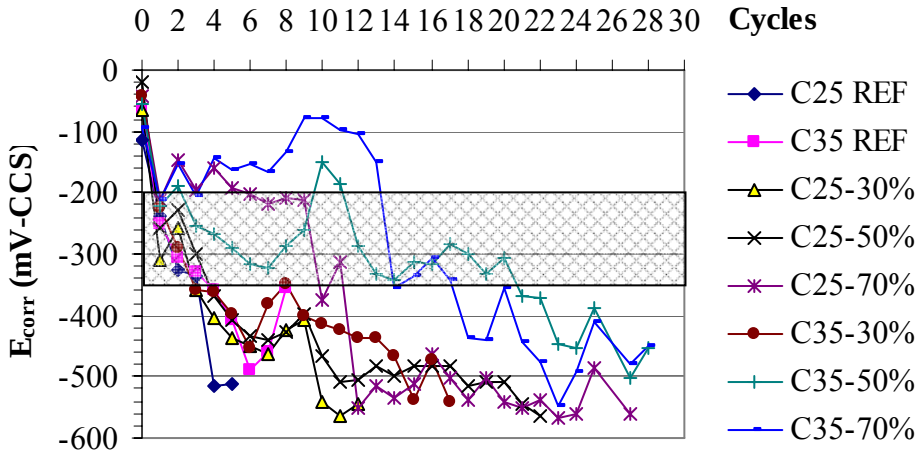

Figure 8. Corrosion potential measurements of lollipop specimens subjected to 12V potential difference.

In the corrosion data obtained from the specimens subjected to 12V potential difference (Figures 7-9) no cracks were seen below the corrosion rate of 1µA/cm^2 and above the corrosion potential of -500 mV (vs. CCS). Besides, resistivity values were seen as the main indicator on failure of concrete cover, particularly after corrosion onset. Concretes with higher resistivities, as a function of binder composition, cracked at elevating corrosion rates. Increasing slag content prevented crack formation even at very high corrosion rates and at very low corrosion potentials for longer periods. In other words, for 45 mm concrete cover (for lollipop specimens), C25 grade specimens with GGBS contents of 0, 30%, 50% and 70% cracked at corrosion rates of 0.78 µA/cm^2, 3.19 µA/cm^2, 4.54 µA/cm^2 and 7.58 µA/cm^2, respectively. At the end of 28 cycles, no cracks have been observed yet on the C35-50% and C35-70% specimens.

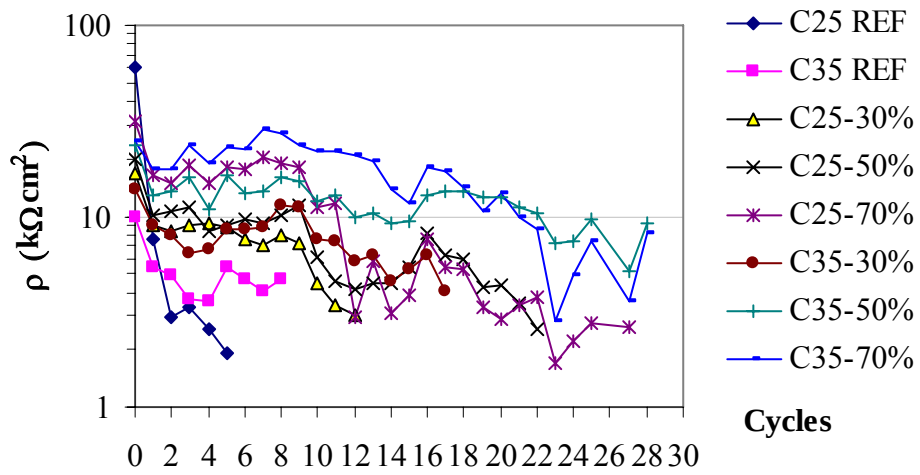

Figure 9. Resistivity measurements of lollipop specimens subjected to 12V potential difference.

Figure 10 demonstrates the number of cycles needed for corrosion initiation (CI) and crack formation (CF) of all concretes. Apart from C35-50%, it can be concluded that higher the GGBS content longer the time to corrosion initiation and the time to crack formation.

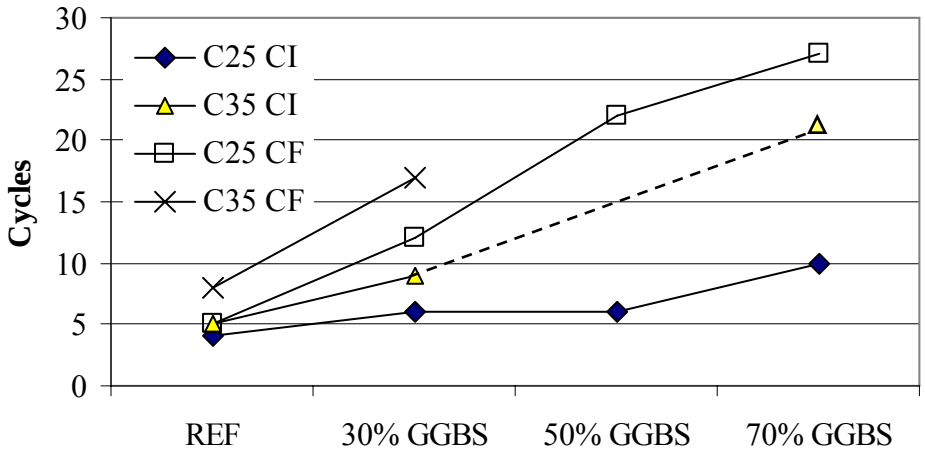

Figure 10. Number of cycles needed for corrosion initiation (CI) and crack formation (CF) of concretes

Chloride profiles of C25 coded concretes with the number of cycles for corrosion initiation are illustrated in Figure 11. Similar profiles of C35 were not shown, because corrosion has not initiated yet for high content slag added concretes at this grade. Figure 11 shows that, regardless of the number of cycles for corrosion onset, the higher the chloride content at peak values, the greater the binding capacity. Therefore, it can be deduced that ascending chloride binding capacity extends corrosion initiation period. Critical chloride concentration of reference concrete is higher than those of GGBS concretes, probably due to the consumption of hydroxide ions in pozzolanic reaction of slag.

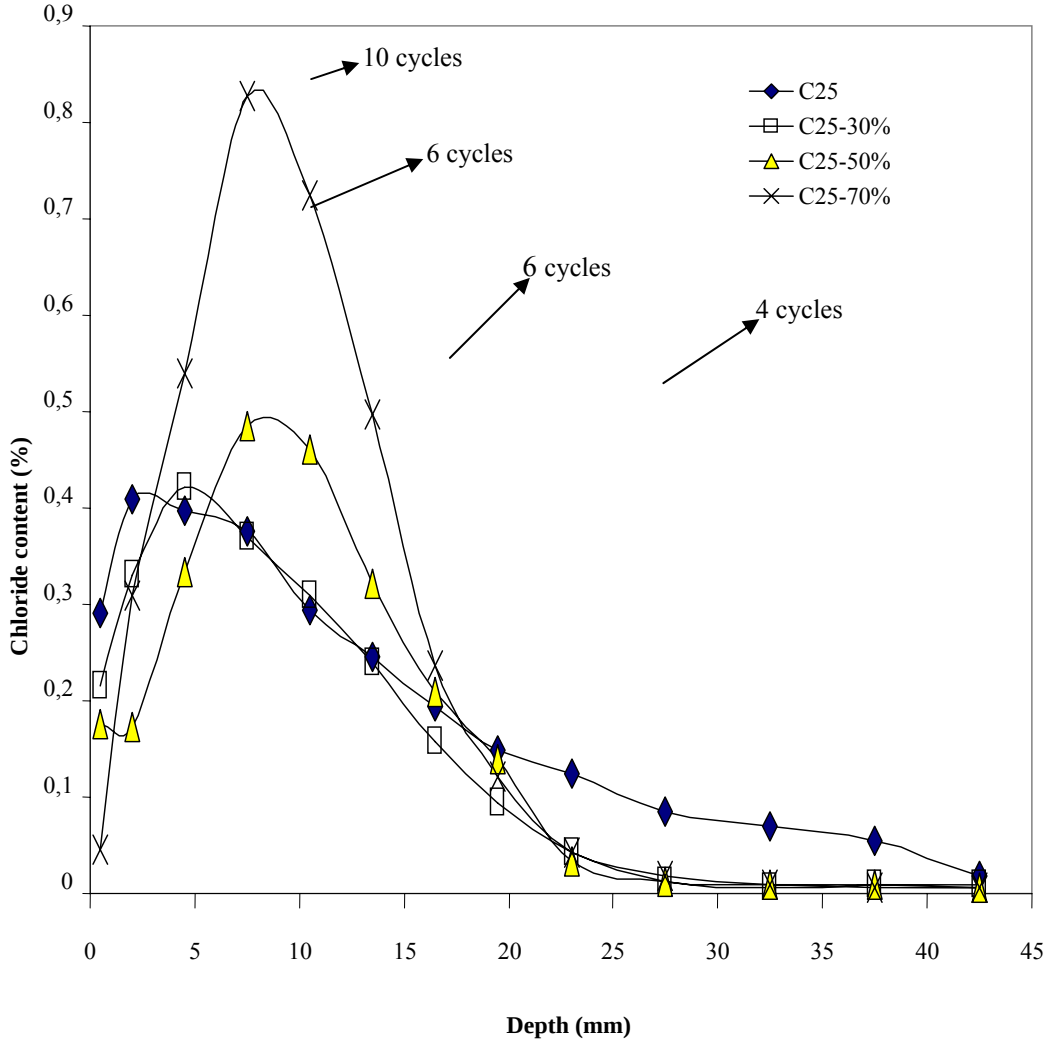

Figure 11. Chloride profiles of C25 coded concretes subjected to 6V potential difference.

4 CONCLUSION

In this paper, resistance of GGBS concrete against chloride-induced corrosion phenomenon with respect to migration test is studied. Significant reductions in compressive strength were obtained for high amount of slag replacement compared to OPC concretes. Besides, time to corrosion onset of C25 concretes containing %30, %50 and %70 GGBS, took 1.5, 1.5 and 2.5 times longer than that of plain concrete, respectively, while extention was 1.6, 4.2 and 5 times for C35 ones, in the same order.

More importantly, crack formation period, indicating the end of service life, for C25-30%, C25-50% and C25-70% concretes, extended 2.4, 4.4 and 5.4 times longer than that of OPC concrete, respectively.

Improvement in corrosion resistance of slag added concretes can be due to the chloride binding capacity of slag and affecting the resistivity by changing the pore solution chemistry. It can be concluded that usage of slag as cement replacement in concrete seems to be a good solution against chloride-induced corrosion, such as in marine environment.

Durability of Autoclaved Aerated Concrete

Berit Straube [1]
Peter Langer [2]
Andreas Stumm [3]

T 11

ABSTRACT

A main requirement of the "Construction Products Directive (CPD)" for buildings and building materials is their mechanical resistance and stability. A relevant part of the safety of components and buildings is their durability. The requirements for durability are affected by the economically useful life and the ambient conditions, such as physical- and chemical-environmental influences. The durability of cementious building materials is based on Calcium-Silicate-Hydrate phases (C-S-H), and is crucially defined by the formation of their mineral phases. The crystalline C-S-H phase, tobermorite, directly affects the mechanical properties of autoclaved aerated concrete (AAC). The formation of tobermorite is influenced by raw materials and process parameters. Well crystallised C-S-H phases in AAC must not be compared to the poorly crystallised C-S-H phases in normal concrete. C-S-H phases in normal concrete have a low ordered structure, with highly variable amounts of calcium, silicon and water, which lead to structural changes with increasing lifetime. In this study, the durability of AAC was investigated in order to assess the quality of AAC after long term application. Correlations between phase formation, mechanical properties and durability were proved with examples. AAC with well crystallised tobermorite is not substantially influenced by CO_2 under normal atmospheric conditions. Due to these results, it was conducted that AAC is durable and does not loose its function of stability during long term application.

1 INTRODUCTION

Autoclaved aerated concrete (AAC) is produced of natural inorganic raw materials such as sand, lime, cement, water and the rising agent aluminium.
AAC has an unique structure, formed by millions of small air pores, which leads to an optimum correlation between compressive strength and low materials weight. Moreover, air has a low thermal conductivity which makes AAC one of the best insulating building materials.
A requirement of the "Construction Products Directive (CPD)" for buildings and building materials is their mechanical resistance and stability. A relevant part of the safety of components and buildings is their durability. The requirements for durability are affected by the economically useful life and the ambient conditions such as physical- and chemical-environmental influences. Well crystallised C-S-H phases, like tobermorite in AAC, are resistant to carbonation and cannot be compared to the poorly crystallised C-S-H gels in ordinary concrete.

Poorly crystallised AAC contains so called C-S-H(I), which is from the structural point of view, between C-S-H gel and tobermorite (CaO/SiO_2 = 0.83). C-S-H(I) has highly variable amounts of calcium, silicon ($0.75 < CaO/SiO_2 < 1.5$) [Taylor 1964] and water, which easily leads to structural changes with increasing lifetime.

C-S-H(I) encourages the carbonation process in autoclaved aerated concrete like in ordinary concrete. Internal investigations assume, that the amount of C-S-H(I) directly influences the shrinkage.
In the production of AAC the formation C-S-H(I) has to be avoided. The addition of calcium sulphate, such as anhydrite and gypsum, improves the material, i.e. higher compressive strength and a intensified formation of better crystallised tobermorite. The tobermorite formation is intensified with lower shrinkage, and probably better resistance upon carbonation.

Additional calcium sulphate has been used in AAC production since 1967 [Clementi 1967]. The mechanisms are not completely understood.

In this study, the durability of AAC was investigated to assess the material properties of AAC during long term application using X-ray powder diffraction, carbon/sulphur-analysis and compressive strength testing. Correlations between phase formation, mechanical properties and durability were proved with model substances, drilling cores taken from buildings and stored AAC units.

2 EXPERIMENTAL

2.1 Sample Preparation

2.1.1 Model samples synthesis

Four model samples of AAC with the raw density of 440 kg/m^3 were produced (6 h at 190 °C) in lab sized moulds (10 litres) by using the usual method for the production of AAC [RILEM 1993]. The recipes are shown in Table 1. The content of calcium sulphate ($CaSO_4$ = anhydrite) was subsequently increased by substituting the non-reactive filler calcite ($CaCO_3$).

Eight AAC units (AU) with a bulk density 400 kg/m^3 from the identical production mixture were stored under a roof protected from rain. These materials were produced in 1980. Calcium sulphate was added to the mixture. The surface of the material was not protected by either mortar or paint.
These AAC units have been subsequently sampled and analysed for compressive strength after various time periods from the time of production (0 year) up to 26 years [Table 2].

Table 1. Recipes of the model mixes

sample	*quartz-sand* [% mass]	*CEM I 52.5 N* [% mass]	*lime* [% mass]	*anhydrite* [% mass]	*calcite-filler* [% mass]	*aluminium-powder* [% mass]	*water/solid ratio*
M0	58	15	15	0	12	0.05	0.65
M1	58	15	15	1	11	0.05	0.65
M3	58	15	15	3	9	0.05	0.65
M4	58	15	15	4	8	0.05	0.65

2.1.2 Drilling cores and stored AAC units

Four drilling cores (DC) were taken from four different buildings distributed over Germany [Table 2].

Table 2. Location and ages of taken cores.

sample	*age* [years]	*geographic region*
DC1	42	south-western Germany
DC2	37	central Germany
DC3	34	south-eastern Germany
DC4	28	eastern Germany
AU	0,1,2,3,5,8,13,26	southern Germany

2.2 Sample Characterisation

2.2.1 Sulphur analysis and qualitative phase analysis

The material was characterised in the centre of the drilling core [Fig. 1]. A Philips PW 1800 diffractometer with autosampler employing CuKα radiation and graphite secondary monochromator was used. Measurements were performed over a 4-60° 2Θ range, with a 0.02 2Θ step size and a exposure time of 1s/step. Automatic divergent slits were used to maintain an illuminated sample length of 10 mm. Qualitative analysis was performed by using Panalytical's High Score.

The samples were treated before measurement with isopropanol in a McCrone micronising mill. The milled material was prepared into a back loaded sample holder. Carbon/sulphur analysis was performed by the use of an Eltra CS 800 device. The results are given as SO_3 total from sulphate in the final product.

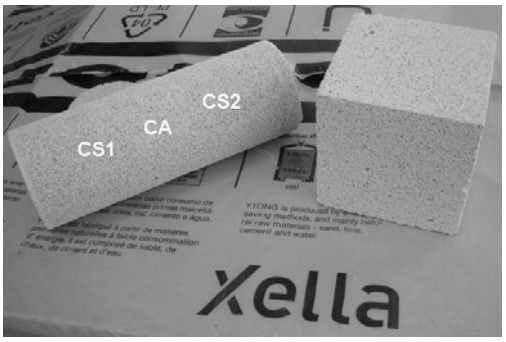

Figure 1. Photograph of a taken core sample (on the left) with the analysed areas CS1 = compressive strength 1, CS2 = compressive strength 2, CA = chemical sulphur analysis and qualitative phase analysis; (on the right) compressive strength testing cubes

2.2.2 Compressive strength testing

An universal hydraulic compressive strength testing device from Toni Technik was used. The compressive strength of the drilling cores was determined from two cylinders with a length and diameter of 75 mm [Fig. 1].

The compressive strength of both the model substances and the stored AAC units was measured on three cubes of the size 100 mm x 100 mm x 100 mm. The cubes were cut out from the base, mid and top of the AAC unit. In the lab samples they were taken from the base.

In this paper, the samples are compared with their compressive strength as well as with their so called A-value. The A-value represents a relative level of the strength of AAC.

The bigger the A-value the better the level of stability. The A-value depends on the raw density and the compressive strength and can be described as followed: A-value = CS / RD^2 x 0.016; with: CS = compressive strength [N/mm^2], RD = raw density [kg/dm^3], 0,016 = const. [Zürn 1997].

2.2.3 Determination of the shrinkage behaviour

According to RILEM [1993] water saturated specimens (40 mm x 40 mm x 160 mm) were dried at a temperature of 20 °C and a relative humidity of 43 % to the equilibrium moisture content, where the shortening of the specimens was recorded. The value of shrinkage in this paper is the complete change of the length from water saturated to equal moisture for this climate.
All tests were performed in a climate chamber (Feutron KPK 400.V).

3 RESULTS AND DISCUSSION

3.1 Model substances

The X-ray powder diffraction patterns of the model substances are shown in Fig. 2. The mineral phases are tobermorite, quartz, calcite and anhydrite. The peaks of tobermorite and anhydrite increase with increasing sulphate content [Fig. 2]. Calcite peaks gain intensity with decreasing calcite filler content. The AAC samples also show increasing compressive strength with increasing sulphate content. Finally, the measurement of the shortening shows decreasing shrinkage values with increasing amount of calcium sulphate.

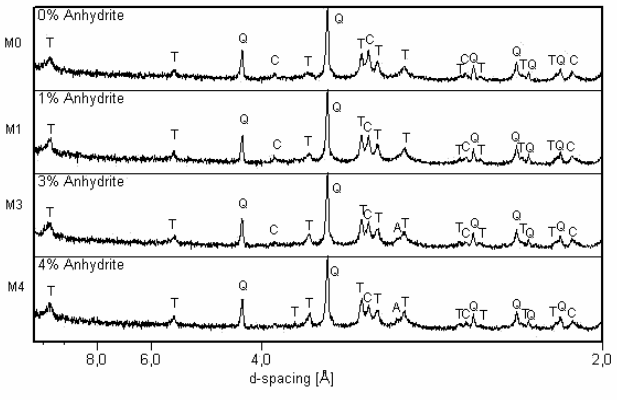

Figure 2. X-ray diffraction patterns of AAC with various amounts of sulphate. T = tobermorite, Q = quartz, C = calcite, A = anhydrite.

Table 3. Material properties of the model substances

Sample	*Anhydrite* [% mass*]	*SO_3* [% mass**]	*Raw density* [kg/m^3]	*Compressive strength* [N/mm^2]	*A-value* [a.u.]	*Shrinkage value* [mm/m]
M0	0	0.63	454	3.02	917	0.40
M1	1	0.91	440	3.45	1113	0.38
M3	3	1.99	441	3.80	1224	0.36
M4	4	2.29	433	3.90	1299	0.34

* of dry mix; ** of final product

3.2 Drilling Cores

The chemical analysis reveals, that sample DC1 has the highest amount of SO_3 (3.41 % mass), followed by DC2 (2.17 % mass), DC3 (1.98 % mass) and DC4 (0.89 % mass) [Table 4].

The compressive strength testing shows that sample C1 has the highest A-value (1104) followed by DC2 (1245), DC3 (972) and DC4 (686). The amount of sulphate determines the durability of the material, since the A-value increases with increasing amount SO_3 from sulphate. The compressive strength is less dependent from time than from the optimum mixture with its sulphate content. The samples (D1-D4) still fulfil the essential compressive strength values for building materials and buildings.

The X-ray diffraction analysis reveals in all samples tobermorite, quartz, anhydrite and calcite [Fig. 3]. Quartz is an residual product whereas anhydrite is a new formation. The amount of anhydrite increases parallel to the amount of SO_3. The intensity of calcite increases from sample DC1 to DC4. Low calcium sulphate content leads to an increasing formation of calcite, due to the higher CO_2 uptake [Fig. 3].

Table 4. Material's properties of the taken cores.

Sample	*Age* [years]	*Raw-density* [kg/m^3]	*Compressive strength* [N/mm^2]	*A-value* [a.u.]	*SO_3* [% mass*]
DC1	42	442	3,45	1104	3,41
DC2	37	496	4,90	1245	2,17
DC3	34	593	5,47	972	1,98
DC4	28	656	4,72	686	0,89

* of final product

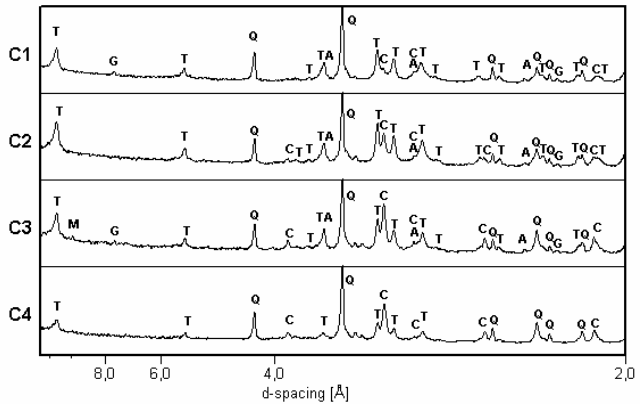

Figure 3. X-ray diffraction patterns of the 4 AAC drilling cores. T = tobermorite, Q = quartz, C = calcite, A = anhydrite, G = gypsum, M = muscovite.

3.2 Stored AAC units

Due to subsequent compressive strength testing, there is no detectable loss of compressive strength during the last 26 years of storage [Fig. 4]. The material did not loose its function of stability. AAC is durable, because it obviously has not changed its properties within 26 years.

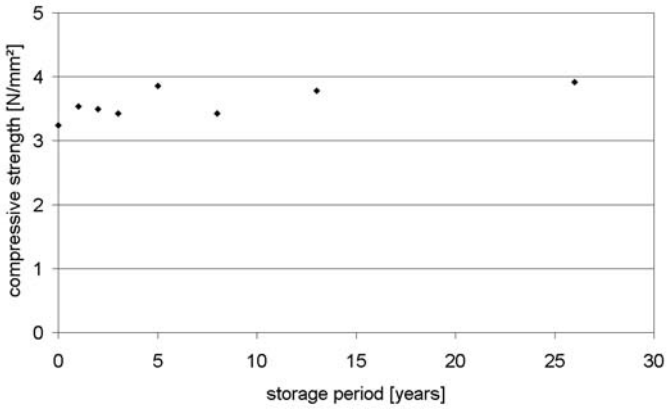

Figure 4. Compressive strength of sample AU after various storage periods.

4 CONCLUSIONS

Correlations between phase formation, mechanical properties and durability were proved with examples. The compressive strength testing reveals, that there is no loss of compressive strength over life time if calcium sulphate is used in the production of AAC. The addition of calcium sulphate leads to an intensified formation of the better crystallised C-S-H phase tobermorite.
AAC with well crystallised tobermorite is not substantially influenced by CO_2 under normal atmospheric conditions.
Due to these results, it was conducted that AAC is durable and does not loose its function of stability during long term application.

Prediction of Residual Stress Due to Early Age Behaviour of Massive Concrete Structures: On Site Experiments and Macroscopic Modelling

Jihad Zreiki [1]
Vincent Lamour [2]
Mohend Chaouche [3]
Micheline Moranville [4]

T 11

ABSTRACT

Early age behaviour of concrete is based on complex multi-physical and multiscale phenomena. The predication of both cracking risk and residual stresses in hardened concrete structures is still a challenging task. We propose in this paper a practical method to characterize in the construction site the material parameters and to identify a macroscopic model from simple tests. We propose for instance to use a restrained shrinkage ring test to identify a basic early age creep model based on a simple ageing visco-elastic Kelvin model. The strain data obtained from this test can be treated through an early age finite element incremental procedure such that the fitting parameters of the creep law can be quickly identified. The others properties of concrete have been measured at different ages (elastic properties, hydration kinetics, and coefficient of thermal expansion). From the identified early age model, we computed the temperature rise and the stress development in a non reinforced concrete stress for nuclear waste. The good agreement between in-situ measurement and predicted behaviour allowed us to validate our approach.

1 INTRODUCTION

Early age behaviour of concrete is based on complex multi-physical and multiscale phenomena. The predication of the cracking risk and the residual stresses in the hardened concrete structures is still a challenging task. The use of the restrained shrinkage ring test to identify a basic early age creep model is based on a simple ageing visco-elastic Kelvin model.
We propose in this article to identify a simple macroscopic model with a reduced number of parameters. First we model the total behaviour of the structure in various configurations, and then specimens of building site are used to accomplish the identification.
The behaviour of the concrete at early age is generally described as visco-elastic. The rheological models based on Kelvin chains are used to model this behaviour [De Schutter 1996] and [Bǎzant *et al.* 1997], or they are based on Maxwell chains to take into account the humidity or temperature effects [Bǎzant & Chern 1985] and [Bǎzant and *al.*2004]. However, others models have used the Burger model [Hauggaard et *al.* 1999] and [Bǎzant et *al.*2004]. In section 2 we begin with the model used to describe elastic modulus of concrete at early age, and then we proposed a model based on the hydration degree. Section 3 focuses on the basic creep's and the function of creep, and then we describe the hydration kinetic. After having exposed the behavioural model of concrete at early age and having identified its parameters, a comparison is done between real measurements and outputs of the numerical model are detailed in section 4 before concluding.
The stake of such tool is to limit the early age cracking risk in order to increase the durability of the prefabricated products of concrete and to determine of the residual stresses of fabrication.

2 EVOLUTION OF THE MODULE OF ELASTICITY

There are several models describing the evolution of the Young modulus. Some of them require more tests to reproduce the material behaviour. Researches have shown that models using the Apparent Setting time will be more robust against effects of insufficiency in amount of experimental data [Larson & Jonasson 2003]. Larson proposed a Linear Logarithmic Model (LLM) for the creep of concrete, in which the Young modulus is given by equation 1:

$$E(t_0) = E_{ref}.\beta_E(t_0) \tag{1}$$

Where: E_{ref} is a reference value, which here is chosen as the Young modulus at 28 days age, and $\beta_E(t_0)$ is a parameter expressed as:

$$\beta_E(t_0)\begin{cases} 0 & t_0 < t_s \\ b_1.\log(t_0/t_s) & t_s \le t_0 < t_s \\ b_1.\log(t_B/t_s)+b_2.\log(t_0/t_B) & t_B \le t_0 < 28j \\ 1 & t_0 \ge 28j \end{cases} \tag{2}$$

The traditional equations which describe the non-aging Young modulus, based on the compressive strength at age of 28 days, as in [Table 1], [Takács 2002].

Table 1. Formula for the Young modulus at age of 28 days.

Code	**Formula de E_c (MPa)**
CEP-FIP model code 1990	$E_c = 9980(f_{cm})^{1/3}$
Euro code 2	$E_c = 9500(f_{cm})^{1/3}$
ACI 318	$E_c = 4733(f_{cm})^{0.5}$

We find in ACI-209R-82 a recommendation for the prediction of creep and shrinkage, and they gave a relation for calculates the aging Young modulus [Rajeev *et al.* 2007] Equation 3.

$$E_c(t) = 0{,}04326\sqrt{\rho^3 . \mathrm{f}_{\mathrm{cm}}\left(\frac{t}{a+b.t}\right)} \tag{3}$$

Where: a, b: constants depend on cement type and treatment conditions; $E_c(t)$: The Young modulus of concrete at age t; ρ: The density of the concrete (kg/m^3).
The Young modulus given in CEB-FIP for a concrete of strength (12-80 MPa) at 28 days by the following form equation:

$$E_c(t_0) = E_c . \sqrt{\exp\left\{s\left(1-\sqrt{\frac{18}{t_0}}\right)\right\}} \tag{4}$$

Where: $E_c(t_0)$ The Young modulus of concrete at age t_0; c: Constant dependent on the type of cement.
In reality the Young modulus (E) of concrete evolves with time according to a chemical reaction of cement hydration [Ignacio & Bǎzant 1993] and [De Schutter 1999].
The Young modulus is given by De Schutter according to the degree of hydration for a concrete (CEM III/B 32.5) [De Schutter 1999].

$$E_0(\chi) = 37000.\left(\frac{\chi - 0.25}{1-0.25}\right)^{0.62} MPa \tag{5}$$

χ : The degree of hydration.
You can see a relation which depends on time, in which the Young modulus evolves in a potential way [Hauggaard *et al.* 1999].

$$E(t) = a.e^{-\left(\frac{b}{t}\right)^c} \tag{6}$$

Where a, b, c are parameters depend on material, and t is the equivalent time defined at temperature 20±C.
Byfor used to define the Young modulus as function of degree of hydration [Eduardo *et al.* 2004] like:

$$E(\xi) = E_\infty . \frac{1+1{,}37(f_{c,\infty})^{2{,}204}}{1+(f_c(\xi))^{2{,}204}}\left(\frac{f_c(\xi)}{f_{c,\infty}}\right) \tag{7}$$

$E_\infty = E(\xi = 1)$: The Young modulus at the end of hydration.

3 MACROSCOPIC MODEL OF CONCRETE AT EARLY AGE:

3.1 The creep's function:

The simplest and the oldest models of creep for concrete is the effective modulus method (EMM) [Bǎzant & Wittmann 1980], which consists only of a single linear elastic solution, as $E_{effective} = 1/J(t,t_0) = E(t_0)/(1+\phi(t,t_0))$, where J is the creep compliance function, t_0 is the age at loading, $E(t_0)$ is the initial Young modulus, and ϕ is the creep coefficient. The linear treatment of visco-elastic of ageing materials as the concrete can be characterised by the compliance function $J(t,t')$ or the relaxation function $R(t,t')$. $J(t,t')$ Presents the strain at time t caused by a constant

stress applied at the time t' [Ignacio & Bǎzant 1993]. For a stress different of 1, the strains are calculated by the following equation:

$$\varepsilon(t) = \Delta\sigma.J(t,t') \tag{8}$$

For $t = t_0$, we have $J(t_0,t_0) = 1/E(t_0)$. By applying the principle of superposition, we find the equation of Volterra which constitute the law of linear visco-elastic behaviour of aging material:

$$\gamma(t) = \int_{t'=0}^{t} J(t,t')d\sigma(t') \tag{9}$$

The use of Dirichlet series to expresser the function of creep $J(t,t')$, and the integral of the equation give more effective differential equations for the numerical solutions:

$$J(t,t') = \frac{1}{E_0(t')} + \sum_{\mu=1}^{n} \frac{1}{E_\mu(t)}\left(1 - e^{\frac{-E_\mu}{\eta_\mu}(t-t')}\right) \tag{10}$$

$J(t,t') = q_1 + C(t,t')$ Where q_1 is the instantaneous elastic strain. The equation of creep can be written like a sum of exponentials (i.e., Dirichlet series). It is possible to convert the equation (9) to linear differential equations. These equations can be simulated well by rheological models like Kelvin or Maxwell chains with an aging spring $E_\mu(t)$ and aging dashpot $\eta_\mu(t)$ [Ignacio & Bǎzant 1993]. There are several possibilities of arranging the spring and the dashpot, but it is shown that the behaviour of creep generally can be described by Maxwell or Kelvin chains [Bǎzant & Santosh 1989].
If we consider only one element of the chains of Kelvin (μ=1) 'Fig 1', we can write the differential equation:

$$E_1(\chi)\gamma + \eta_1(\chi)\dot{\gamma} = \sigma \tag{11}$$

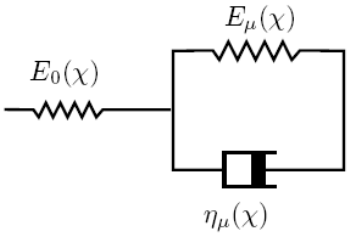

Figure1. The Rheological model of Kelvin

3.2 Thermal model:

We can write the equation of heat describing the thermal transfers in concrete at early age:

$$C(\chi)\frac{\partial T}{\partial t} = div(k(w,\chi).grad(T) + Q_{hy}(\chi) - Q_{ev}(\chi) \tag{12}$$

Where C and K are the thermal capacity and conductivity, Q_{hy} the heat provided by the hydration, Q_{ev} the waste heat by evaporation in skin in the event of fast unmoulding in conditions of extreme drying.

3.3 Hydration kinetic:

With simplicity the kinetics of hydration of cement can be modelled by an equivalent chemical affinity according to Arrhenius's law:

$$A(\chi) = \dot{\chi} = \widetilde{A}(\chi).\exp\left(\frac{-E_a}{RT}\right) \tag{13}$$

With: $\widetilde{A}(\chi)$ the chimical affinity equivalent standardized given for an isothermal reation of hydration.

The evolution and the heat of hydration of concrete can be followed by a quasi-adiabatic test on insulated cylindrical. We can determine the equivalent endogenous affinity and the evolution of the reaction advancement degree for various thermal paths.

We consider that the advancement of hydration reaction is stabilized at 28 days ($\chi = Q/Q_{28d} \approx 1$) 'Fig.2'.

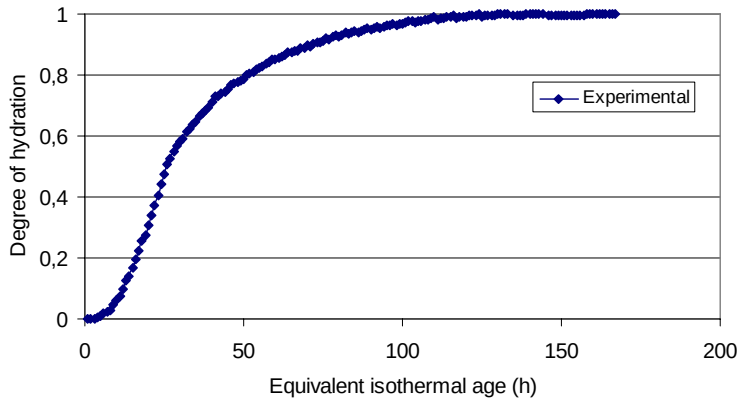

Figure 2. Evolution of degree of advance of reaction (activation energy = 46 KJ/mol)

3.4 Mechanic model:

We used a mechanical model based on the deformation partition principle:

$$\dot{\varepsilon} = \dot{\varepsilon}_e + \dot{\varepsilon}_c + \dot{\varepsilon}_T + \dot{\varepsilon}_{Sh} \tag{15}$$

With: $\dot{\varepsilon}_T = \alpha.\dot{T}$ the thermal deformation, α the thermal dilation coefficient; $\dot{\varepsilon}_{Sh}$ the shrinkage's deformation, $\dot{\varepsilon}_e$ elastic deformation, $\dot{\varepsilon}_c$ creep's deformation equation (11).

4 IDENTIFICATION OF MODELE

4.1 Used Concrete

We used to identify the model a self compression fibred concrete with a low heat of hydration, the composition of this concrete is presented in the Table 2

4.1 Mechanical proprieties

To identify the creep model, we propose a shrinkage ring test. In fact the ring test is a simple test by which we measure the visco-elastic deformation in a ring of concrete. The geometry of the ring is presented in the 'Fig.3'.

Table 2. Formulation of concrete (W/C = 0.35).

Materials	*Concrete fractions* [Kg/m^3]
Cement CEM V / A (S-V) 42.5 N CE PM ES CP1	454
Silica fume	45
Calcareous sand 0/4mm	984
Calcareous aggregate	672
Affective water	173
Superplasticizer	5.2
Fibre (L30mm, Ø0,6mm)	85

The section of the brass ring: 2*7cm, the section of concrete: 7*7cm, the outside diameter of concrete: 64 cm, and the inside diameter: 50cm, the inside diameter of ring: 46 cm. We measure orthoradial deformation by four gauges presented in 'Fig.5'. The rheological diagram of the ring test is represented on 'Fig 4' [Lamour & *al* 2007]. The result of the ring test allows us to determine the parameters of the creep model by an explicit diagram of integration. 'Fig 5'

Figure 3. The ring test

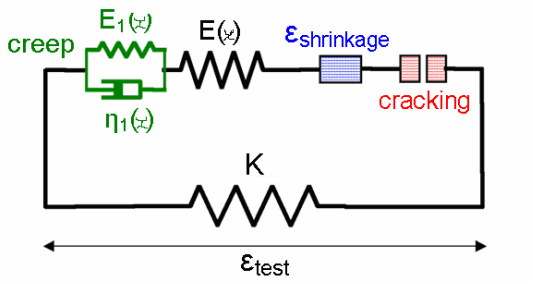

Figure 4. Simplified 1D parallel model for the ring test.

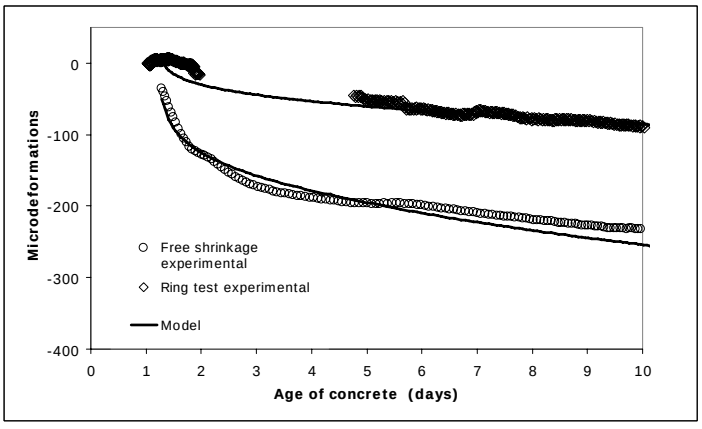

Figure 5. Simplified 1D parallel model for the ring test

The evolution of the elastic modulus was measured on specimen (7*7*28 cm) by using the Ultrasound velocity measurement, where transversal wave velocities were measured, the elastic modulus (E) was determined by using wave propagation theory in homogeneous bodies.
We propose for fitting elastic modulus a model (see eq.5)based on χ (hydration degre) like the model proposed by [De Schutter G. 1999].

$$\left\{ E(\chi) = E_{\max}\left(\frac{\chi - \chi_0}{\chi_{\max} - \chi_0} \right)^b \right\} \tag{16}$$

Where : χ the hdration degre; $\chi_{\max} \approx 1$ the hydration degree at end of test; $\chi_0 = 0.25$ the hydration degree at unmoulding, $E_{\max} = 35GPa$ the elastic modulus at fin of essais, b = 0.5 coefficient . The experimental resalting and modele proposed showen in 'Fig 6 '

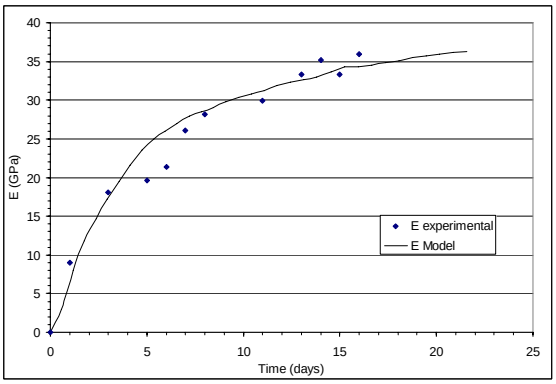

Figure 6. Elastic modulus

5 CALCULUS OF THE RESIDUAL CONSTRAINT ON REAL STRUCTURE

The studies structure corresponds to a piece of fibres massive concrete none armed including four reservations 'fig 7'. The measurement of the deformation and temperature is automated via an autonomous power station of acquisition.

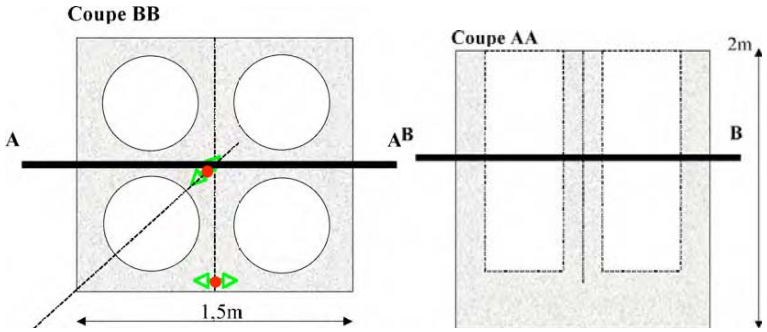

Figure 7. The piece of concrete with two vibrating cord sensor installation (red and green)

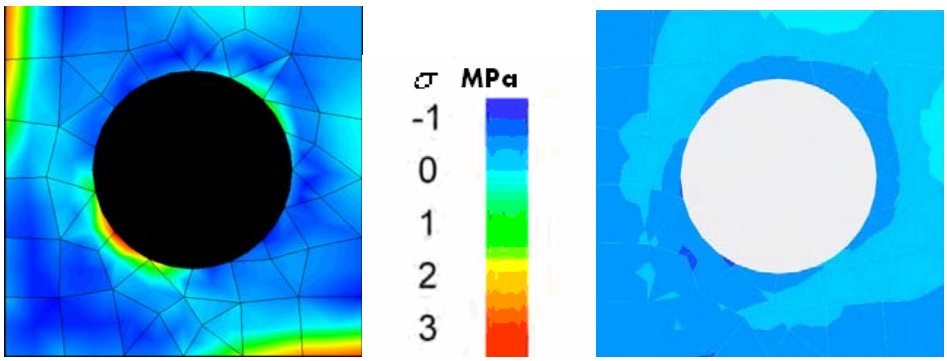
The model is implanted in code of element finis (CAST3M) developed by [CEA-France], the resolution of problem is done in an iterative way: for each step of time corresponding to an increment of the advance of the reaction of hydration in each element [Lamour & *al* 2007]. The deformations are calculated from an identified model on specimen, moreover the modelling of structure makes it possible to evaluate the mechanical constraints generated in the structure 'Fig 8'. We verify in particular that the generated constraints are lower than resistances in traction of the concrete.



a) At peak of heat (40 h) b) Residual stresses après cooling

Figure 8. Simulated cartography of the principal stress in a quarter of the piece
(The blue zones are a compression zones, the orange zones represent the zones at the risk with respect to cracking at early age).

6 CONCLUSIONS

We proposed in this paper a practical method to characterize the material parameters in the construction site and to identify a macroscopic model from simple tests. We proposed for instance to use the restrained shrinkage ring test to identify a basic early age creep model based on a simple ageing visco-elastic Kelvin model.

Model identification of elastic modulus based on hydration degree has given good resultants. The identification of creep's deformation was done by a rheological model in using the ring test.
This model makes it possible to quantify the risk of cracking and to evaluate the residual stresses of manufacture by taking into account the clean creep identified by the ring test.

Repair & Rehabilitation of Initially cracked RCC Beams by CFRP

Liaqat. A. Qureshi [1]
Imran A. Bukhari [2]
Kamran A. Qureshi [3]

T 11

ABSTRACT

This paper presents the comparison of different repairing techniques commonly used for cracked RCC beams. Six RCC beams (each 3 meter x 225 mm x 300 mm) designed as under-reinforced beams were cast, cured and tested by two-point loading. One beam was loaded up to failure and treated as "Control Beam". Its failure load was noted and deflections were continuously measured by deflection gauges installed at middle and quarter points. Other beams were loaded up to ¾ th of the failure load of control beam. The five cracked beams were repaired by using different ratios of "Carbon Fiber Reinforced Polymers (CFRP) strips". When repair process was over, all five beams were tested again and loaded up to their ultimate load. Again deflections were noted and overall performance of beams was analyzed.

It was noted that the ratio of "Carbon Fiber Reinforced Polymers (CFRP) strips" used will affect the load carrying capacity of the beam and will lead to decreased deflection and increased brittleness of the beams. All patterns used were found to be able to restore or enhance the structural capacity of cracked sections.

1 INTRODUCTION

A devastating earthquake, measuring 7.6 on the Richter scale, hit the northern part of Pakistan on the morning of 8th October, 2005. With the death toll of about 90 thousands and injuries in the same range, it is a catastrophe on a scale never before seen in this region. The earthquake also resulted in destruction of all types of buildings and other infrastructure. The buildings which survived are also suffering from severe major cracks. The rehabilitation and repair of cracks in order to make the structure safe for human use is a major problem. To restore their structural capacity, retrofitting and/or strengthening are badly needed. There are different techniques available for retrofitting and strengthening of initially cracked reinforced concrete beams reported in literature. In this research, laboratory investigation regarding use of carbon fiber reinforced polymers to strengthen a given structure or part of it to restore its serviceability and strength is discussed.

Studies have shown that fiber reinforced plates (FRP) increase the strength of flexural members significantly. CFRP has a high strength to weight ratio, favorable fatigue behavior and excellent resistance to electrochemical corrosion to make it practically suited for structural application [Clarke and Waldron 1996]. A study conducted by Alfarabi et al.[1994] showed that, although the FRP increase the failure loads, most of the beams strengthened by FRP started the failure at the curtailment zones of the plates. The epoxy used to laminate the plate at the soffit of flexural members only failed at loads much higher than the required level [El-Mihimly & Tedesco 2000]. Similar study also found that the failure modes for repaired structures may change from ductile to brittle [Arduni et al. 1997]. The probability of this change depends largely on the percentage of FRP being used, the location of FRP and the presence of shear reinforcement in the existing structures. Toong and Li [2000] investigated the effect of using carbon fibre reinforced polymer (CFRP) plates to strengthen one-way spanning slab to increase the flexural capacity with particular emphasis on the cracking behavior at working load. All the CFRP strengthened specimens exhibited large increase in load carrying capacity ranging from 60% to 140% [Wauud & Jaafar 2005].

In this research work CFRP plates were applied at the soffits of initially cracked RCC beams in different proportions in order to observe their strengthening effect as compared to control beam which was loaded up to its failure load. Furthermore this study focuses on the serviceability, strength and ductility performance for each of the CFRP ratio used to ascertain their potential application in initially cracked reinforced beams.

2 EXPERIMENTAL PROGRAM

In order to investigate the effect of repair by using various patterns of CFRP, on the structural response of initially cracked RCC beams, a total of six full-scale RCC beams were cast, cured and tested. All beams were designed by ultimate strength method as under-reinforced and having dimensions 3 meter x 225 mm x 300 mm and singly reinforced by 3 # 4 bars, without using shear reinforcement. All specimens were tested under two pint loading. One beam, designated by C1, was loaded up to failure and named as “Control Beam”. Its failure load was noted and during loading, deflections were measured by deflection gauges installed at middle and quarter points. Other beams were loaded up to ¾ th of the failure load of control beam. Subsequently, the load was removed and specimens removed from the testing frame, so that repairs may be carried out.

Five beams were retrofitted by using different amounts of CFRP and when repair process was over, these were again tested by the same loading arrangement till failure and deflections noted. The response of each of the five retrofitted specimens in terms of deflection, stiffness, cracking load, ultimate load, and failure pattern was analyzed

2.1 Materials Used in the Beams

2.1.1 Cement
Ordinary Portland Cement (TYPE 1) was used.

2.1.2 Fine Aggregate
Sand from Lawrencepur (Pakistan), free from deleterious substances was used. Gradation of sand was carried out in accordance with ASTM Standards. Fineness Modulus was found as 2.62.

2.1.3 Coarse Aggregate
Coarse Aggregate consisted of clear, hard, strong, sound and uncoated crushed stones quarried from Margala Hills, best source of aggregate in Pakistan near Islamabad. These were free from deleterious amount of soft, friable, thin elongated or laminated pieces. Gradation of coarse aggregates was carried out in accordance with ASTM Standards.

2.1.4 Water
Water fit for drinking, as proved by water quality tests, was used in concrete work.

2.1.5 Formwork
Steel formwork (moulds) was used for casting beams.

2.1.6 Size of Beams
All beams were identical in X-section, length and materials:

Cross-section of beams = 225mm x 300 mm
Length of beams = 3 meter

2.1.7 Reinforcement
Deformed steel of grade 40 for 3 # 4 bars was used as main reinforcement. # 4 stirrups were used @100 mm c/c up to 0.7 meter from each end.

2.1.8 Concrete Mix. Design
Concrete Mix. Proportion 1:2:4 (by weight) was used. Water cement ratio was kept as 0.50 and slump was measured as 38 mm (average). Average cube crushing strength at 28 days was achieved as 4258 psi.

2.2 Materials for Retrofitting

2.2.1 Sika Carbudur Laminates
Type used was **S812**, 80 mm wide and 1.2 mm in thickness with cross sectional area of 96 mm^2, Black color, having base of carbon fiber reinforced with an epoxy matrix. Fiber volumetric content is greater than 68%. Main properties for this type as provided by manufacturer are as under:

Shelf life	Unlimited (no exposure to direct sunshine)
E-Modulus	> 165,000 N/mm^2
Tensile strength	> 28,000 N/mm^2
Mean value of Tensile strength at break	> 3, 050 N/mm^2
Elongation at break	> 1.7 %
Density	1.5 g/cm^3

2.2.2 Sikadur-30 Adhesive
For bonding Sika Carbudur laminates on the prepared substrate of beams, Sikadur-30 adhesive was used. It has following properties as per manufacturer technical data:

Appearance	Component A:	White paste
	Component B:	Black paste
	Component A + B:	Light grey after mixing
Mix. Ratio	A : B = 3 : 1	(Parts by weight)
Density	1.5 Kg/lit	(A + B)
Pot life	40 minutes	(at 35°C)
Open time	30 minutes	(at 35°C)
Shrinkage	0.04 %	

Static E-Modulus	12,800 N/mm^2	
Adhesive Strength	Concrete failure	(4 N/mm^2)
Shear Strength	Concrete failure	(15 N/mm^2)
Coefficient of expansion	9 x 10^{-4} per ^{o}C	(-10^{o}C to + 40^{o}C)

2.2.3 Colma Cleaner
The behavior of concrete elements strengthened or retrofitted with Sika Cabudur Laminates is highly dependent on a sound concrete substrate and proper preparation and profiling of the concrete surface. Surfaces of the beams were grinded and smoothened with the help of hand grinder and cleaned with Colma Cleaner before applying adhesive over the surface of Sika Cabudur laminates.

2.3 Strengthening of Beams

Five beams were retrofitted at their soffits as under:

- **Two Beams** - One S812 laminate was bonded in the center along the length of beams as shown in Fig. 1.
- **Two Beams** - One 1.5 meter piece of S812 laminate was bonded in the centre over mid span, shown in Fig. 2.
- **One Beam** - Two S812 laminates were bonded in the center along the length of beams. The schematic diagram is shown in Fig. 3).

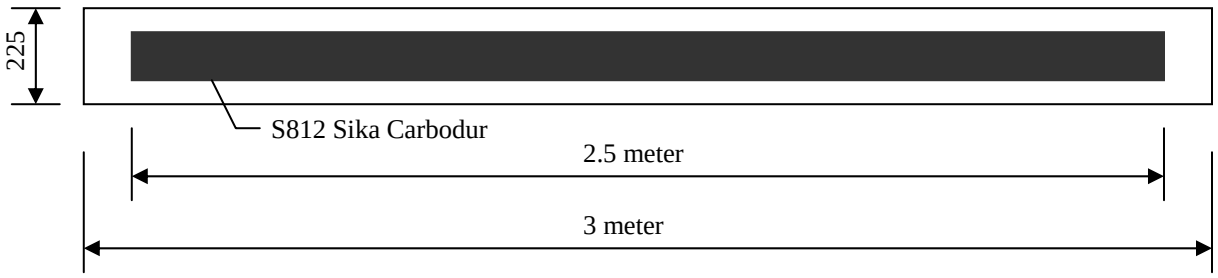

Figure 1. Strengthening by one strip of full beam length

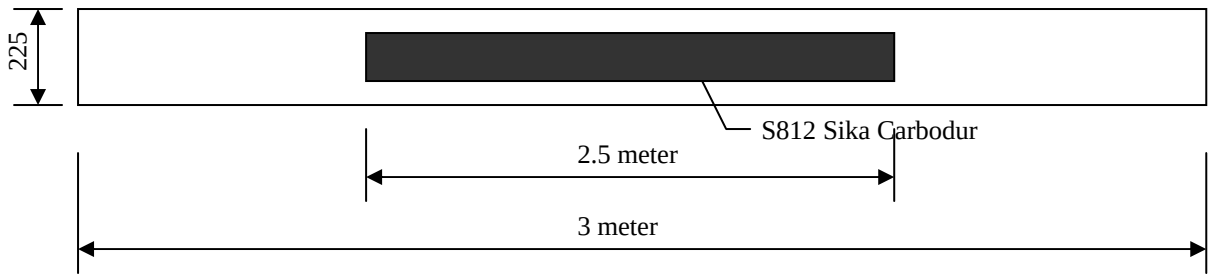

Figure 2. Strengthening by one strip of 1.5 m length.

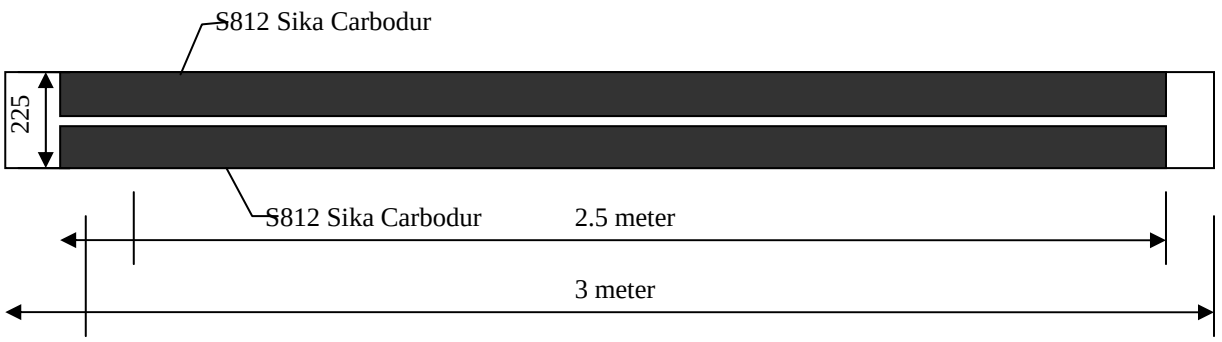

Figure 3. Strengthening by two strips of full beam length

2.4 Testing of Beams

First of all, beams were tested for flexural strength in a staining frame before strengthening. One dial gauge was installed at mid span to record the mid span deflection and two gauges were installed at quarter points to record deflection at those points. Two point loads were applied at the centre of beam and deflections recorded for each increment of load. One beam was tested up to failure and designated as control beam. Other beams were tested up to $3/4^{th}$ of failure load of control beam. These beams were then removed from the testing frame and strengthened with the help of CFRP strips as shown in figs 1 to 3. The strengthened beams were tested again up to ultimate load and deflections noted. The results of two beams, strengthened with one CFRP strip, are averaged as B1. Similarly average results of two beams strengthened with one 1.5 meter length of strip are designated as B2 and the results of beam strengthened by two CFRP strip are designated by B3.

3 RESULTS AND DISCUSSION

Figures 4 - 6 show load-deflections curves of B1, B2 and B3 before and after repair. The deflections recorded at mid-span are used in these curves. All results reflect less deflection after repair, which is an indication of non-ductile behavior of the beams. Also load-deflection curve of control beam shown in fig. 7 indicates high deflection at failure load. The decrease in deflection is more prominent at advanced stages of loading. Beams strengthened with two CFRP plates show least deflection at the highest ultimate load i.e., 275 KN, which reveals that these beams are more brittle as compared to control as well as other repaired beams. A comparison of ultimate loads, taken by control and repaired beams, is shown in figure 8.

In case of control beam, failure load was 200 KN. First crack appeared at 134 i.e., 67 % of the ultimate load. Crack pattern showed that failure mode was tension failure.

In case of B1, failure load of repaired beams was 210 KN, a little bit greater than that of control beam. First crack appeared at an average load of 114 KN i.e., 54 % of failure load. After strengthening, ultimate load bearing capacity increased by 5 %. Failure mode was CFRP plates end interfacial de-bonding.

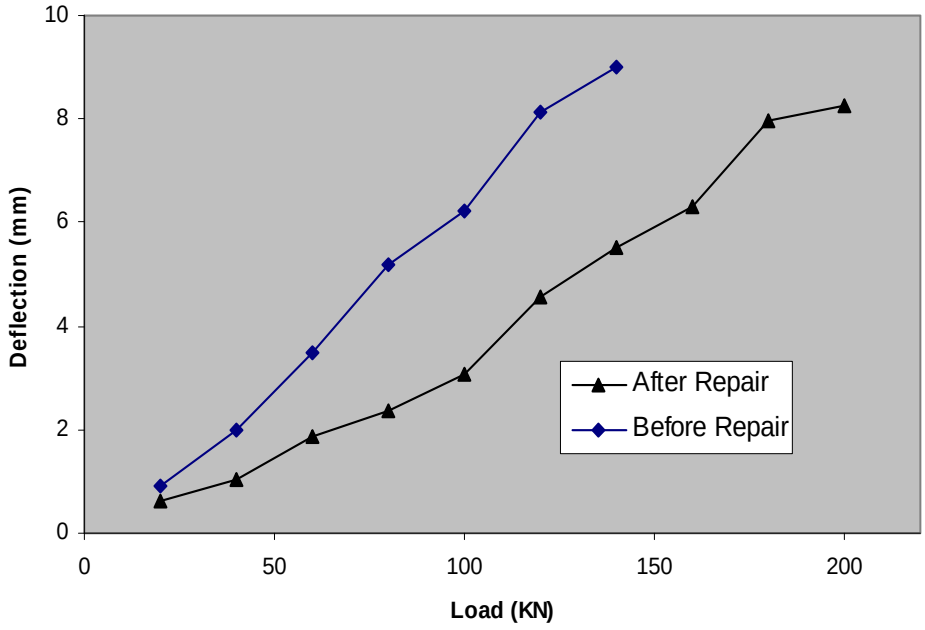

Figure 4. Load versus Deflection graph for B1.

In case of B2, beams failed at an average failure load of 180 KN. Ultimate load bearing capacity of repaired beams decreased by 10 % as compared to the control beam. Failure was flexural tension failure

near ends of CFRP laminates. Both tested beams failed in the same manner with CFRP plates intact with bottom.

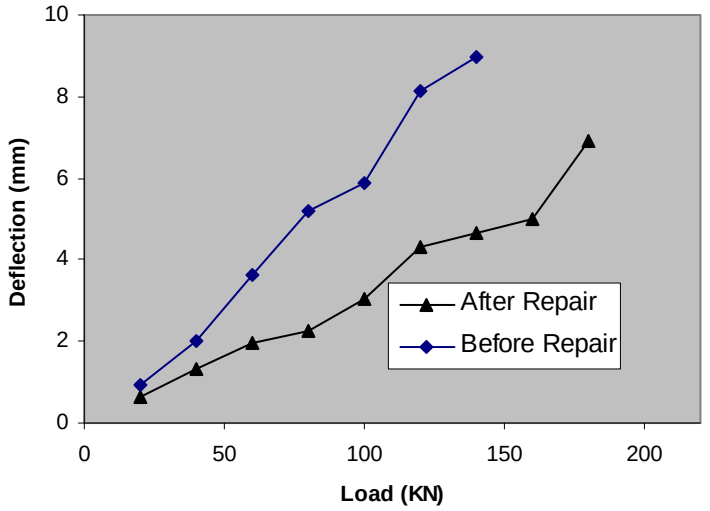

Figure 5. Load versus Deflection graph for B2.

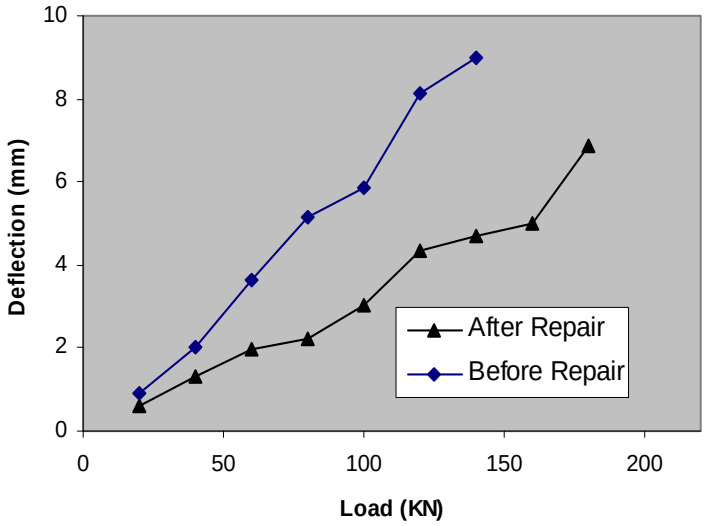

Figure 6. Load versus Deflection graph for B3

When two CFRP laminates of full beam's length were used for repair of cracked beams, more favorable results were found. Both beams failed at 275 KN load. Ultimate load bearing capacity increased by 138 % over the control beam. This ultimate bearing capacity is 31 % more than B1 and 53 % more than B2. Cracks started at load of 220 KN, which is 80 % of the ultimate failure load. Mode of failure involved the concrete cover separation (peeling off) along with laminate from one end.

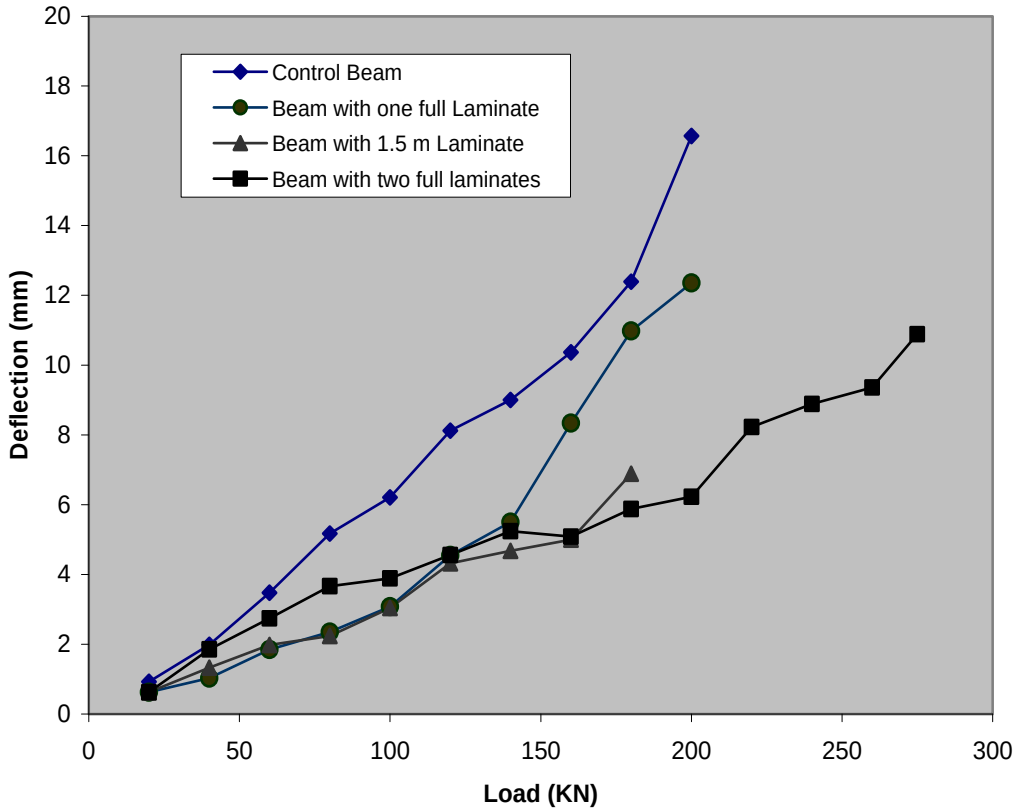

Figure 7. Comparison of Load versus Deflection graphs for strengthened beams and control beam.

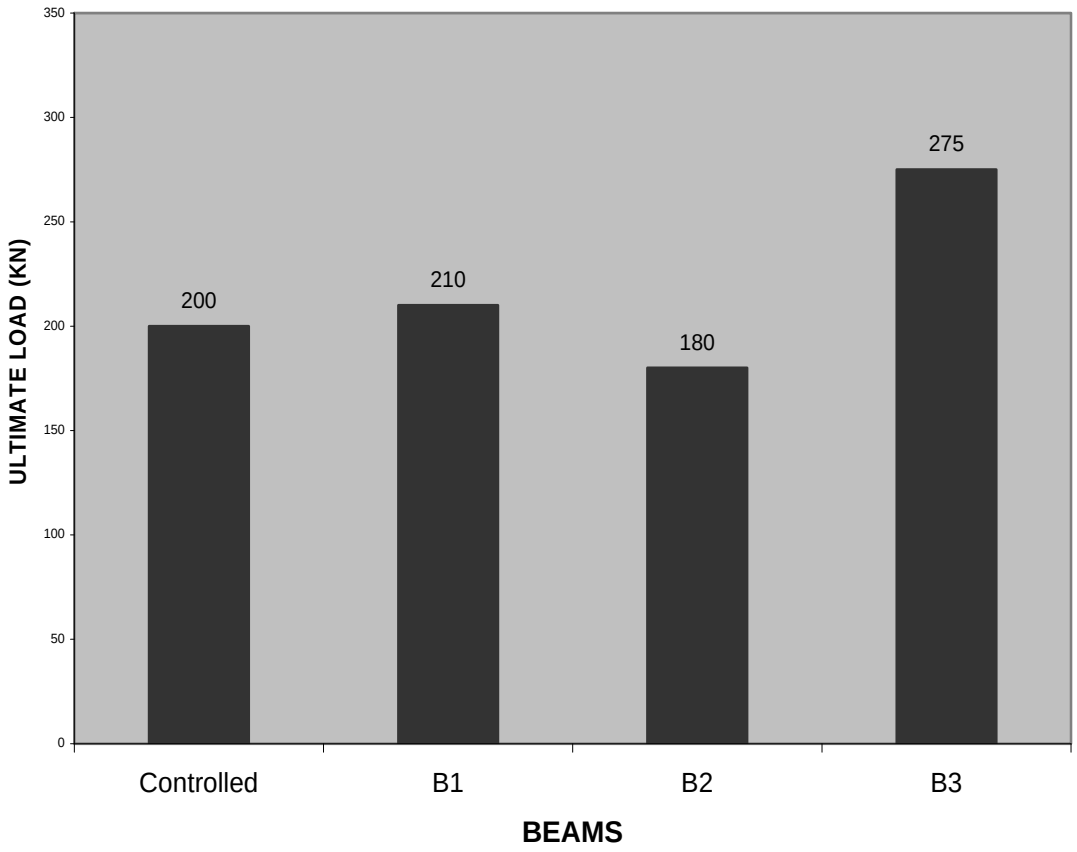

Figure 8. Comparison of ultimate loads taken by all beams

4 CONCLUSIONS

Based on this study, the following conclusions can be made:

- Strengthening of initially cracked RCC beams with externally bonded CFRP plates is effective and leads to increased load carrying capacity.
- The repaired beams had similar or higher cracking loads compared to the control beam.
- The deflection values of all the CFRP-strengthened tested beams are reduced.
- The retrofitted beams possess less ductility compared to the original beams before cracking. This is the result of the brittleness nature of the encountered failure modes of the retrofitted beams (concrete cover separation along with CFRP plates and de-bonding of CFRP plates from ends).
- In order to achieve full capacity of the laminate and to avoid brittle failure by de-bonding, special attention should be paid to provide adequate anchorage length for the fibers either longitudinally or transversely.
- Best results regarding ultimate failure load were achieved in case of two CFRP strips having lengths equal to full beam's length. On the other hand, the same is associated with high cost of CFRP strips used. This factor should be kept in mind while finally selecting this mode of repair.

T 11

ABSTRACT

The present study surveyed published data on chloride transport in concrete structures exposed to a marine environment for the duration ranging from 1 to 49 years. In particular, time-dependent characteristics of the diffusion coefficient (D) and surface chloride concentration (C_S) were extensively investigated for the prediction of the ingress of chlorides. As a result, it was found that both D and C_S are time dependent; D decreases and C_S increases with time. A build-up of the C_S was considered to solve the Fick's 2nd law and the time dependency of the D was applied to the solution for the chloride ingress, and then chloride profiles were comparably predicted, using both time dependent and time independent models. From the comparison, the chloride profiles calculated by the time dependent model are always higher than those by the time independent model. Consequently, the time dependent model predicts shorter service life which is the shorter time to corrosion initiation of rebar. It was found that decreased D with time is more influencing on the rate of chloride ingress than the increased C_S. It was also found that the conventional model, utilizing constant values of D and C_S may underestimate the rate of chloride transport and thus predict less risk of chloride-induced corrosion.

1 INTRODUCTION

The assessment of chloride-induced corrosion of steel embedment in concretes exposed to marine environments has received increasing attention, because of its widespread occurrence and high cost of repair. Corrosion of steel in concrete reduces the service life of concrete structures, and thus the service life should be predicted by comparison between the amount of chloride concentration at cover depth by chloride transport and chloride threshold value [Song et al. 2006a]. In the majority of previous studies on the service life prediction, a conservative chloride threshold value for corrosion initiation such as 0.2 or 0.4% by weight of cement has been used to predict the service life [Ann & Song 2007]. For chloride transport, the Fick's 2nd law is often used to predict chloride penetration in terms of diffusion [Collepardi et al. 1972], due to its convenient and easy calculation with constant values of the apparent diffusion coefficient (D) and surface chloride concentration (C_S), which are in fact dependent on concrete mix proportion and exposure condition to a salt environment (eg. submerged, tidal, splash and aerated zones in marine environments) [Song et al. 2007a]. The diffusivity decreasing with time due to development of the pore structure with time has been currently considered in assessing the rate of chloride transport [Thomas & Bentz 2000, Bamforth 1999]. Due to the hypothesis that chloride ions and surface concrete make a chemical equilibrium in the form of di-electric layer, the time dependency of the C_S has been intuitively ignored in conventional chloride transport model, so that a constant value of the C_S has been widely used in modeling chloride transport. Only when concrete structures are exposed to a marine atmospheric condition, a build-up of the C_S has been taken into account [Kassir & Ghosn 2002]. It was, however, observed in a survey on in-situ that a build-up of the C_S occurs, even when concretes are exposed to direct contact to seawater such as in tidal/splash zones [Uji et al. 1990].
The present study examined 6 concrete bridges located in the West Sea side of Korea exposed to tidal zone, where data on the D and C_S were obtained. These data were fitted as a function of time, and used in modelling to predict chloride profiles and the corrosion risk of concrete structures exposed to marine environments. The characteristic of a C_S build-up was considered in solving the Fick's 2nd law and the time dependency of the diffusivity was subsequently applied for the solution of the chloride ingress in concrete.

2 TIME DEPENDENCY OF CHLORIDE TRANSPORT

In this study, 6 concrete bridges exposed to marine environments were examined to assess the rate of chloride transport, depending on exposure duration. The bridges at ages ranging from 0.65 to 48.65 years were built in ordinary Portland cement (OPC) concrete as a binder. Concrete samples ground from surface concretes were obtained from a pier of the bridges in tidal zone at the time of tide down by drilling and grinding with 2 mm increments up to 50 mm. The chloride content of each sample was determined by acid soluble extraction in a nitric acid solution followed by potentiometric titration against silver nitrite. The chloride profiles at the time of sampling were also obtained. Then, the D, non-steady state diffusion in a semi-infinite medium, was determined for each specimen by fitting the error function solution to the Fick's second law, for.
Fig. 1 describes the D and C_S for target structures exposed to tidal zone. The best fit curves for the D are expressed as a power function of time, and for the C_S as a logarithm function of time. It is seen that the D decreased with exposure duration, despite their high deviation at exposure conditions, including different degrees of wave, weathering and presumably segregation of concrete in mixing. The D initially at 0.65 years ranged from 5.53×10^{-12} to 7.89×10^{-12} m^2/s and at 48.65 years from 4.47×10^{-12} to 5.55×10^{-12} m^2/s respectively. The C_S were also much affected by the exposure duration. The C_S ranged from 1.85 to 2.21% by weight of cement at 0.65 years and from 2.71 to 3.11% at 48.65 years respectively. These results were used to model chloride penetration considering its time dependency in terms of only diffusion in the present study.

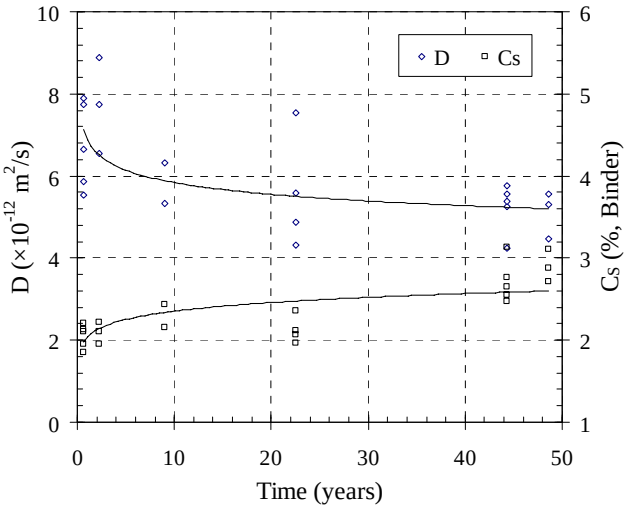

Figure 1. Time dependent change in the apparent diffusion coefficient and surface chloride

3 MODELLING OF CHLORIDE TRANSPORT

3.1 Time independent transport

The Fick's 2nd law is commonly used to describe chloride ion diffusion in concrete as given in Eq. 1, which is used for the time independent model. Theoretically, the D can be calculated by measuring the concentration of the C_S and the concentration of chloride ions $C(x, t)$ at the depth x and the exposure duration t.

$$C(x,t) = C_S(1 - erf\frac{x}{2\sqrt{Dt}}) \quad (1)$$

where, *erf* is an error function.

3.2 Time dependent diffusion coefficient

The diffusivity often decreases with time, as cement hydration proceeds to refine the concrete pore structure, thereby letting connectivity of the pores significantly decrease [Thomas & Bentz 2000]. A package program [Thomas & Bentz 2000] for service life prediction uses a model in determining the D in predicting a chloride profile as follows.

$$D(t) = D_R\left(\frac{t_R}{t}\right)^m \quad (2)$$

where, $D(t)$ is the diffusion coefficient at time t, D_R is the diffusion coefficient at reference time t_R (i.e. usually 28 days), and m is an age factor. This model is known to fit well for marine environments, as a change in the pore structure imposes a development of cement hydration [Bamforth 1999]. However, a direct application of this model for predicting the rate of chloride transport has a defect, that the historic change of the D for a given exposure duration is not considered, which may lead to an erroneous judgment on chloride ingresses and thus the risk of chloride-induced corrosion.
In this study, in order to remedy the defect by consedering hysteresis of the D, the mean value of the D for exposure duration to marine environments was used to predict a chloride profile. Thus, the mean D was calculated by integrating the definite D for a given exposure duration, and then by dividing the exposure duration, as given in Eq. 3.

$$D_m(t) = \frac{1}{t}\int_0^t D(\tau)\cdot d\tau \tag{3}$$

where $D_m(t)$ is the mean diffusion coefficient for the exposure duration, t. In this study, the time dependency of the D was expressed in the same power function as seen in Eq. 2. Thus the mean D can be obtained by substituting Eq. 2 into Eq. 3:

$$D_m(t) = \frac{D_R}{1-m}\left(\frac{t_R}{t}\right)^m \tag{4}$$

This equation is more useful to solve the Fick's 2nd law for a chloride profile, rather than a constant D, since both the time dependency and the hysteresis of the diffusivity are encompassed [Song et al. 2006b].

3.3 Time dependent surface chloride

A build-up of the C_S for concrete structures exposed to seawater was obviously observed in previous survey [Uji et al. 1990]. In this study, the time dependency of the C_S as well as the D is considered in solving the Fick's 2nd law, based on the in-situ data (Fig. 1). The time dependency of the C_S was observed as shown in Fig. 1. Hence, a build-up of the C_S was taken into account in calculating a chloride profile using the best fit of a change in the C_S with time [Song et al. 2006b] from the field data as Eq. 5.

$$C_S(t) = \alpha[\ln(\beta t + 1)] + k \tag{5}$$

Here, t is the time of exposure in years and α, β and k are constants obtained from in-situ environments as given in Fig. 1.
The chloride content, $C(x, t)$, at a given time t and a depth x, can be expressed with the time dependent C_S, by utilizing a heat conduction solution in solids [Carslaw & Jaeger 1959].

$$C(x,t) = \frac{2}{\sqrt{\pi}}\int_{\frac{x}{2\sqrt{Dt}}}^{\infty} C_S\left(t - \frac{x^2}{4D\omega^2}\right)\cdot e^{-\omega^2} d\omega \tag{6}$$

Eq. 6 was derived from the Fick's law by considering C_S variation with time while D remains constant. Although consideration of the time dependent D to solve the Fick's 2nd law could provide a more accurate prediction on the ingresses of chlorides, the calculation for the solution could be subject to an extreme complexity. Hence, the term D in the solution Eq. 6 was substituted by the time-varying D as Eq. 4, even it produce a marginal error. Thus, a final expression for the chloride transport can be written by the following equation.

$$C(x,t) = \frac{2}{\sqrt{\pi}}\int_{\frac{x}{2\sqrt{D_m(t)t}}}^{\infty} C_S\left(t - \frac{x^2}{4D_m(t)\omega^2}\right)\cdot e^{-\omega^2} d\omega \tag{7}$$

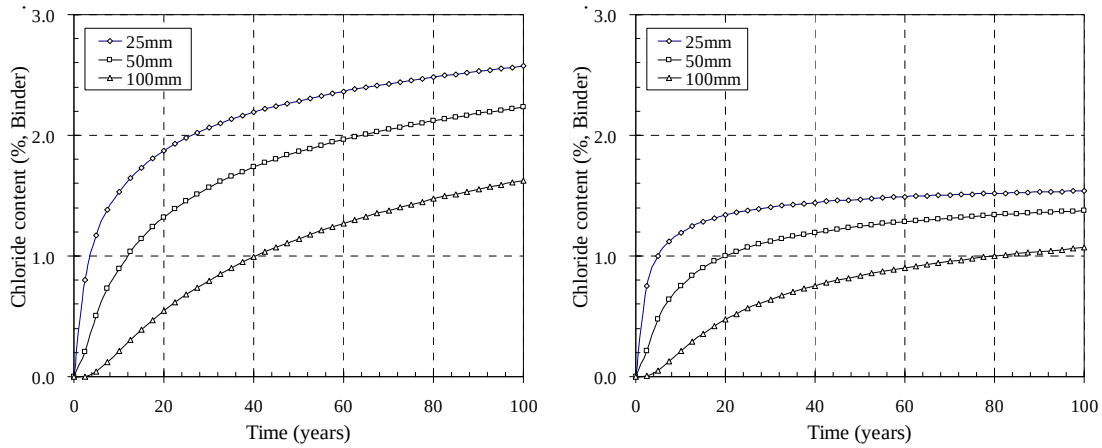
4 Results

4.1 Chloride penetration

The chloride penetration by both the time-dependent model and time-independent model at 25, 50, and 100 mm of concrete covers is calculated in Fig. 2. The chloride content was calculated with 2.5 years of the time interval. It is seen that the penetrated chloride ions calculated from the time dependent model is always higher than the time independent model. At an early age within 5-10 years, the penetration of chloride ions seems not to be affected by time dependency of chloride transport; there is no particular difference between the time-dependent model and the time- independent model.

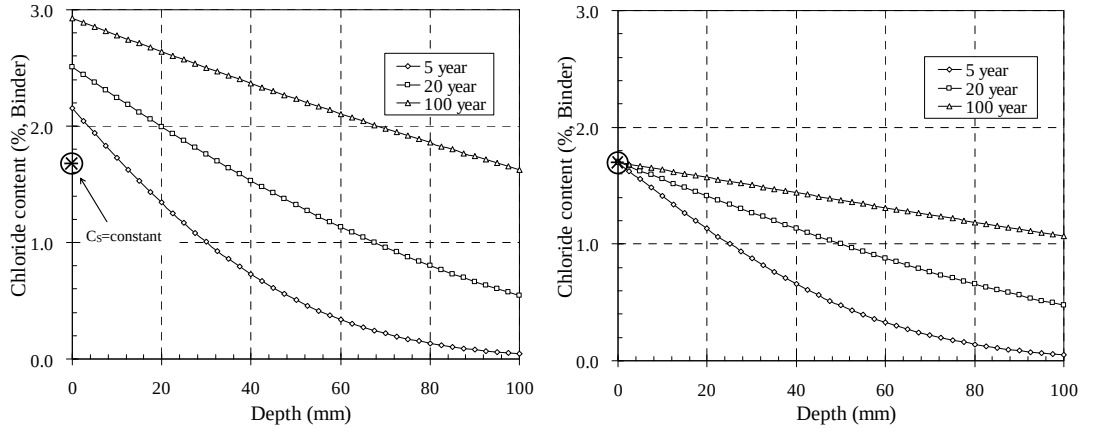
However, for chloride content penetrated through the depths of cover concrete, the time dependent model predicts higher chloride content than that by the time independent model. It can be seen that the influence of the increased C_S is very dominant for chloride penetration due to higher concentration gradient of chloride ions on the concrete surface. However, as the cover depth increases, the difference of penetration of chlorides between two models decreases, since the increased C_S is less influencing and only D governs the rate of chloride ingress.

The influence of the time dependency of C_S to chloride profiles is given in Fig. 3. The chloride profiles show up to the depth 100 mm of the concrete cover at 5, 20, and 100 years. The chloride ingresses by the time dependent model were always higher than those by the time independent model, and the chloride ingress increases much higher with time, presumably due to the higher C_S by time-dependent build-up of C_S. The concentration gradient of chloride ions on the surface concrete significantly increases with time and thus the higher level of chloride ingress at all depths occurs.



(a) Time dependent model (b) Time independent model

Figure 2. Penetration of chloride ions at different concrete cover depths



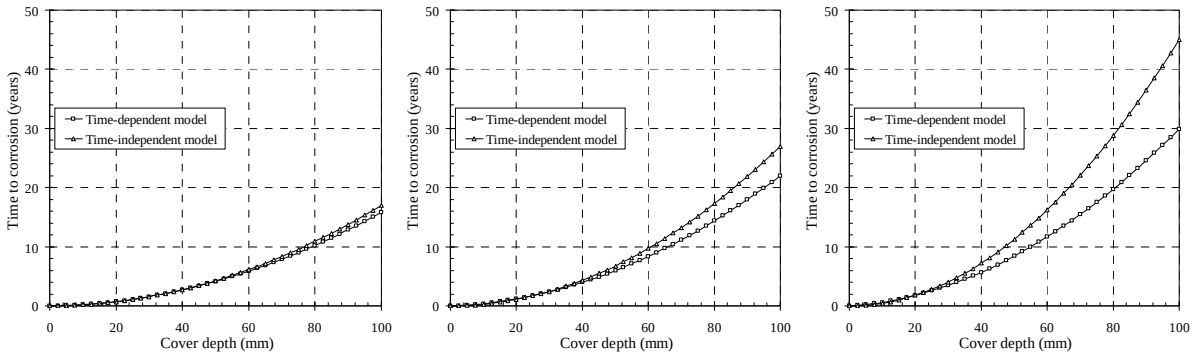
(a) Time dependent model (b) Time independent model

Figure 3. Chloride profiles with time

4.2 Time to corrosion

The time to corrosion, i.e. corrosion initiation, is calculated as in Fig. 4 with different chloride threshold level, C_{lim}, of 0.4%, 0.6%, and 0.8% by weight of binder, respectively. The concrete cover depth of up to 100 mm in a tidal zone is considered. It was found that the time dependent model predicts earlier corrosion initiation due to greater build-up of the C_S with time and relatively lower

decrease in the D. With 0.4% of C_{lim}, the difference in prediction of corrosion initiation by two models is negligible, whereas corrosion initiation predicted by time independent model is greater up to by about 50% than that by time dependent model for 0.8% of C_{lim}. It was also found that the defference by two models becomes large with a increase of C_{lim}.



(a) C_{lim} = 0.4 (%,binder) (b) C_{lim} = 0.6 (%,binder) (c) C_{lim} = 0.8 (%,binder)

5 DISCUSSION

5.1 Chloride transport

The chloride transport via capillary pores is dependent on volume fraction and connectivity of the pores inside concrete, and it can be depending on the W/C ratio, cement content, cement type, and use of secondary cementitious materials. For example, low W/C, good curing and use of pozzolanic materials result in the capillary pores being blocked with gel and reduced permeability to water containing aggressive ions such as chlorides. The reduction of the rate of chloride transport is also ascribed to the development of cement hydration. Cement matrix usually completes 85-90% of the hydration within 28-56 days after casting. The rest of hydration takes place in a very long term, ranging from a couple of years to decades. When cement hydration proceeds, the hydration products expand twice of the volume and thus may occupy the capillary pore or block the interconnected network. Thus, the rate of chloride transport could significantly decrease with time. This effect was once modelled using a computational technique [Garboczi & Bentz 1992], but the results was less conclusive, since only the change of geometry in the capillary pore network (i.e. volume fraction) with time was taken into account. In fact, the rate of chloride transport is much affected by other factors including chemistry between chloride ions and cement matrix [Ann et al. 2007], and physical condition of the interfacial zone between cement paste and aggregate, which are also attributed to the chloride ions' mobility. Hence, it seems to be necessary to further investigate the time dependency of the rate of chloride transport, considering the complexity of physical and chemical change in cement matrix.

A proportion of chloride ions present in concrete is chemically bound, primarily by tricalcium aluminate (C_3A) to form Friedel's salt. Recent studies have modelled the influence of binding on the penetration of chloride [Glass & Buenfeld 2000]. Glass & Buenfeld [2000] found that with increased chloride binding capacity, total chloride contents increase nearer the surface of the concrete, but decrease deeper in the concrete. An increase in the C_S is induced by the binding effect which allows the progressive build-up of higher total chloride content at increasing distances from the concrete surface. Chloride binding also reduces the content of free chloride within concrete and the concentration gradient at depth, because chloride binding removes chloride from the transport process [Song et al. 2007b]. It is notable that the content of bound chloride depends on the binding behaviour of cement matrix and the concentration of chloride source.

5.2 Corrosion of steel

A reduction of ionic diffusivity through concrete with time is beneficial in delaying the onset of chloride-induced corrosion and thus enhancing the corrosion free life of structures. However, a build-up of the C_S may mitigate the benefit of decreased diffusivity. It can be seen from the analytical results between two models that the increased C_S with time plays a more important role than the decreased D does in penetration of chloride ion. Pulverised fly ash (PFA), ground granular blast furnace slag (GGBS) or silica fume (SF) in concrete is effective in enhancing the resistance to chloride diffusion as compared with concrete with plain Portland cement as binder. The decrease in D for PFA, GGBS or SF concretes generally arises from (1) refinement of pore structure, and (2) increased binding capacity of GGBS [Luo et al. 2003]. These influences of concrete containing PFA and GGBS on the chloride diffusivity seem to continue for a long period of time. The D reduces more dramatically in concrete mixtures containing pozzolans showing their long-term hydration properties rather than in the OPC concrete [Bamforth 1999]. Even the structures investigated in the present study were built in OPC as binder, and then a reduction of diffusivity in concrete with time did not affect significantly to the diffusion resistivity, it is possible to delay the corrosion initiation of the structures by using the pozzolanic admixtures, such as PFA and GGBS, when considering time dependent characteristics.
The presence of moisture and oxygen are necessary for corrosion to proceed at a significant rate after initiation, so corrosion propagation is dependent on cathodic reaction in terms of oxygen and moisture, the estimates of corrosion rates may be given on the bases of oxygen pemeability [Andrade et al. 1989]. Concrete permeability depends largely on diameter, shape, and connectivity of pores. Pore volume in PFA concrete and SF concrete is rapidly reduced with time, permeability of 50% PFA concrete is approximately 50% less than that of OPC concrete [Day et al. 1985]. Therefore, pozzolanic materials give low permeability of oxygen and moisture inside concrete, and it results in delaying time to repair and/or mitigate corrosion development.

6 CONCLUSION

The conclusion of this study is as follows.

(1) Diffusion coefficient (D) of chloride ions in concrete obtained from in-situ marine environments decreased with time, whereas surface chloride concentration (C_S) increased. The D decreased dramatically for the first 20 years after exposure in marine environments and then still decreased but at a lower rate up to about 75% of the initial D, while the C_S highly increased up to by about 70% compared to the initial C_S.
(2) The chloride profiles were calculated by both the time dependent and independent models. The time dependent model predicted higher chloride ingress than the time independent model did and the chloride ingress increased with time at a much higher rate, since the decreased D with time is more influencing on the rate of chloride ingress than the increased C_S.
(3) Using the time dependent model, the time to corrosion initiation was predicted shorter than that by the time independent model, mainly due to a higher build-up of the C_S and relatively a lower fall of the D. It was found that the time independent model for chloride transport, which has been used for the prediction of service life, may underestimate the risk of chloride-induced corrosion in concrete structures.

Improvement of durability of RC column by transverse prestressing

Yasuji Shinohara[1]

T 11

ABSTRACT

Experiments and 3-D FEM analyses were performed on reinforced concrete columns laterally prestressed by high strength shear reinforcement to study the influence of the active confinement on shear crack behaviors and shear strength. Flexure-shear tests were performed on RC columns that were laterally prestressed (LPRC) and not prestressed (RC), respectively. The lateral prestress was introduced into concrete as follows: (1) the high strength transverse hoops were pretensioned to approximately 40-60% of the yield strength using the rigid steel molds and special jigs, (2) concrete was placed vertically into the steel molds and cured until the strength of the concrete increased sufficiently, and (3) the core concrete was laterally prestressed by removing the steel molds. All columns were designed to undergo shear failure before the longitudinal reinforcements yield. Six strain gauges were attached to each shear reinforcement (hoop), and the width of each shear crack near the shear reinforcement was measured by a digital microscope with a resolution of 0.01 mm three times during loading and two times during unloading. The results of the flexure-shear tests indicate that the shear capacity at first diagonal cracking is increased and the width values of shear cracks, especially their residual opening, are remarkably reduced by transverse prestressing. This reduction of the shear crack opening improves not only durability but also earthquake resistance.

FEM analysis can be used to evaluate the shear capacity at first cracking and the ultimate shear strength with a fair degree of precision. The FEM analysis using the smeared crack model cannot be used to evaluate a localized crack accurately, but can provide valuable information about the total damage in the overall depth of a specimen and about the effect of the active confinement on shear cracking by evaluating the intensity of confinement in the triaxial state of stress.

1 INTRODUCTION

Prestressing in concrete structures is generally performed to control flexural cracks by the arrangement of tendons in the axial direction of a given member. On the other hand, in an attempt to delay the onset of shear cracking and reduce the crack width, experimental studies have been conducted on reinforced concrete (RC) columns that have been laterally prestressed by high strength shear reinforcement [Watanabe *et al*. 2004]. The results of flexure-shear tests have indicated that transverse prestressing increases the shear capacity at first diagonal cracking (shear crack strength) and decreases remarkably the width of shear cracks, especially their residual opening. This reduction of the crack opening improves not only durability but also earthquake resistance.

The main purposes of the present study are (1) to investigate how transverse prestressing in RC columns affects the shear behavior with respect to the propagation of cracks and the triaxial state of stress, (2) to clarify the relationship between the width of a shear crack and the strain of a shear reinforcement, and (3) to determine the extent to which FEM analysis with a smeared crack model can evaluate the actual shear crack behavior.

2 OVERVIEW OF TEST AND ANALYSIS

2.1 Test Specimens and Analytical Models

The details of the test specimen and the finite element model are shown in Fig. 1. The specifications of the specimens are summarized in Table 1. Flexure-shear tests were performed on RC columns that were laterally prestressed (LPRC) and not prestressed (RC), respectively. The test specimens have a square cross section of 340 mm x 340 mm and a height of 900 mm. The specimens were designed to reach shear failure before the longitudinal reinforcements yield, in accordance with design guidelines of the Architectural Institute of Japan [1999]. For this reason, high strength steel bars (D22 in Fig. 1,

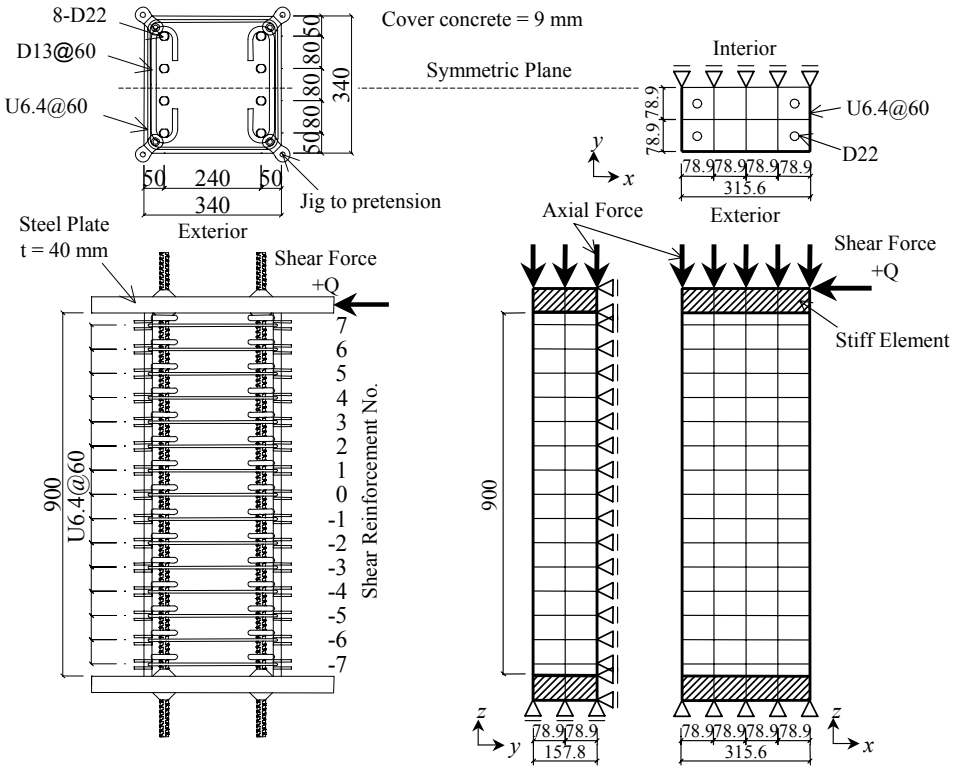

Figure 1. Details of test specimen and finite element model

σ_y=1196 N/mm^2) was used for the longitudinal reinforcements. Moreover, an additional reinforcement (D13 in Fig. 1) was arranged to prevent columns from splitting by bond failure. The lateral prestress was introduced into concrete as follows: (1) the high strength transverse hoops (U6.4 in Fig. 1) were pretensioned to approximately 40% of the yield stress using the rigid steel molds and special jigs shown in Fig. 1, (2) concrete was placed vertically into the molds and cured until the strength of the concrete increased sufficiently, (3) the core concrete was laterally prestressed by removing the steel molds. The product of the ratio (p_w) and the stress (σ_{wp}) of the pretensioned transverse reinforcements is defined as the average lateral prestress σ_L (=$p_w\sigma_{wp}$) to indicate the intensity of lateral prestress. The mix proportion of concrete used in the test specimens is given in Table 2. The coarse aggregate used in the mix is natural round sea gravel with a maximum aggregate size of 25 mm. The mechanical properties of the concrete and reinforcements are shown in Figs 2 and 3, together with their idealizations in FEM analysis.

the test. The horizontal force was supplied by two hydraulic jacks having a capacity of 500 kN and was controlled in displacement. The cyclic horizontal load was applied so as to produce an antisymmetric moment in a column. The horizontal load was reduced when the rotation angle of a column, R, reached ±1/400, ±1/200, ±1/100, ±1/67, and ±1/50, until reaching the peak load. The width of each shear crack near the shear reinforcement was measured using two digital microscopes with a resolution of 0.01 mm three times for each loading cycle and twice for each unloading cycle. The crack width used in the present study is defined as the distance normal to the direction of the crack, as illustrated in Fig. 5. Three strain gauges, the locations and designations of which are also shown in Fig. 5, were attached to each leg of all transverse hoops.

3 RESULTS AND DISCUSSIONS

3.1 Shear Load-Rotation Angle Curves and Shear Strength

The shear load Q-rotation angle R curves obtained from the tests are shown in Fig. 6, compared with the results of FEM analysis. For the typical crack behavior observed during tests, flexural cracks first appeared and then extended to flexural shear cracks near both ends of the specimen. Finally, shear cracks occurred with increasing shear load. The maximum shear loads for RC and LPRC columns are 617 kN when R = 1/100 and 762 kN when R = 1/67, respectively. The shear loads for both RC and LPRC were gradually reduced without any reinforcement yielding due to concrete being crushed in the compressive zone at the top and bottom ends. The shear crack strength and ultimate shear strength obtained from experiments and FEM analyses are presented in Table 3 together with the calculation results reported by Watanabe [2004] that take into account the lateral prestress. The shear crack strength of analysis is defined as the shear load, which causes the strain in the shear reinforcements to increase rapidly. As shown in Table 3, both FEM analysis and the calculation can predict with a fair degree of precision the difference between the shear strengths of the RC and LPRC columns.

The relationships between shear crack stress ${}_{exp}\tau_{sc}(={}_{exp}Q_{sc}/bD)$ and lateral prestress, and between ultimate shear stress ${}_{exp}\tau_{su}(={}_{exp}Q_{su}/bD)$ and lateral prestress are plotted in Fig. 7 together with

Watanabe's data [2004] marked in solid white (σ_B = 35 N/mm^2). The difference in strength of concrete was adjusted by dividing them by the characteristic strength to determine their failure modes. Figure 7 shows that the shear crack strength and ultimate shear strength have increased in proportion to the increasing lateral prestress. Furthermore, Fig. 8 shows a comparison of the shear strengths obtained experimentally and analytically. The predictions of FEM analysis are consistent with all existing experimental data for the shear crack strength and the ultimate shear strength.

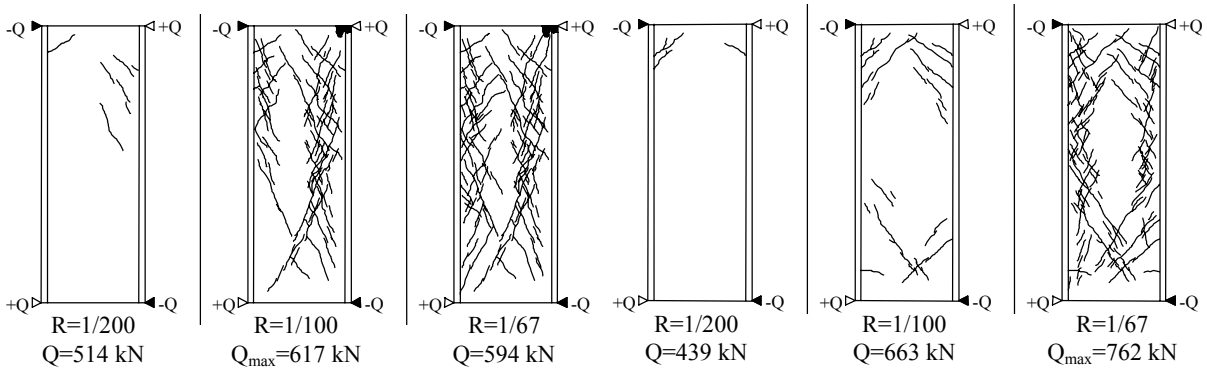
3.2 Comparison of Shear Crack Patterns, Strains in Shear Reinforcement, and FEM analysis

Figure 9 shows a comparison of the propagations of shear cracks in the front of RC and LPRC specimens when the rotation angle is 1/200, 1/100, and 1/67. The crack patterns in the front and back of specimens were essentially similar. The contours of the crack strain obtained by analyses and the diagrams of shear cracks observed experimentally are shown in Fig. 10. The lateral confinement in the LPRC specimen greatly restrained the shear cracks from propagating at a shear load similar to the peak load of the RC specimen, and the final crack pattern of the LPRC differed drastically from that of the RC. Shear cracks developed scatteringly in the upper and lower sides of the LPRC specimen, whereas they developed intensively in the center of the RC specimen. The spacing and width of the scattered cracks in the LPRC specimen are smaller than those of the localized cracks in the RC specimen. Since the ability to transmit shear force across a rough crack is exponentially reduced with increasing crack width [Shinohara *et al*. 1999], a scattered crack with a smaller width can reduce to some extent the decrease in shear stiffness of a column. This small crack spacing that developed in the LPRC specimen is probably due to an increase in bond strength [Braam 1990] and to the tensile stress generated by introducing lateral prestress. FEM analysis using the smeared crack model cannot evaluate an individual crack but can assess the difference in crack patterns between the RC and LPRC specimens. Figure 11 shows the distribution of strains in the shear reinforcement at the maximum shear loads obtained from experiments and analyses to discuss the relationship between the shear crack patterns and the strains in transverse hoops. As shown by Figs 10 and 11, the strain increment in



(1) RC specimen (2) LPRC specimen

Figure 9. Comparison of shear crack propagations in front of RC and LPRC specimens

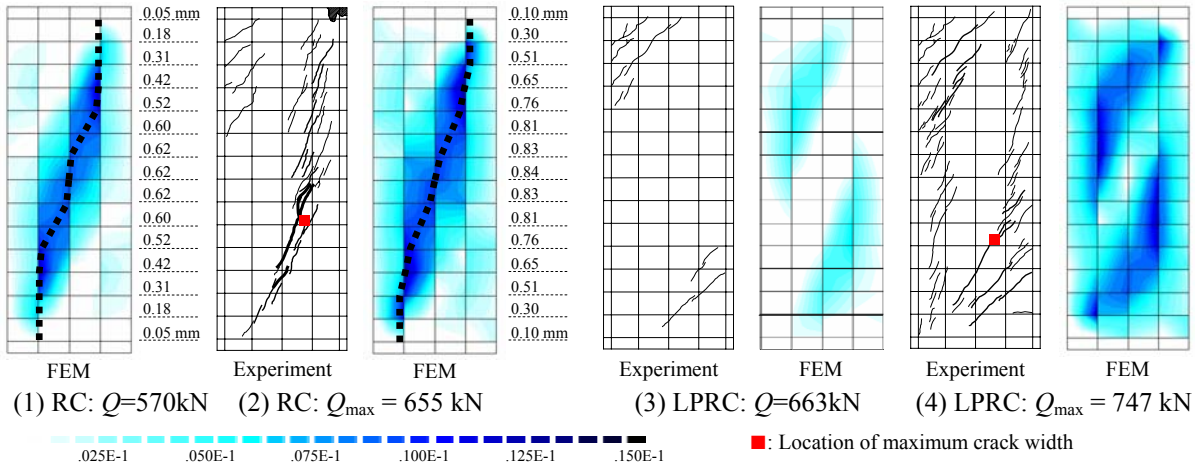


Figure 10. Comparisons between crack pattern from experiment and crack strain from FEM analysis

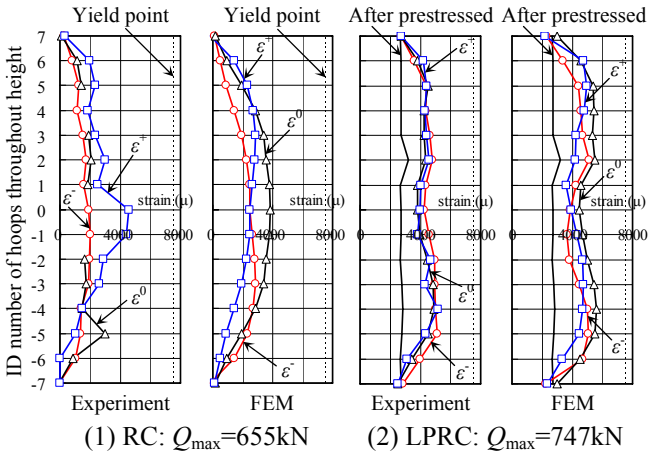

Figure 11. Comparisons between strain distribution of shear reinforcement by experiment and analysis

the shear reinforcement is roughly consistent with the width of shear cracks. In the case of the RC experiment, since the shear cracks localized and deviated to the right around mid-height, the corresponding strain ε^+ was highest, and the three strains of gauges attached at each reinforcement differed from ε^- by a maximum of 2,700 μ. In the case of the LPRC experiment, on the other hand, since the shear cracks did not localize and were scattered over the depth of the column, the differences among three strains on each reinforcement were within 800 μ. The strain distributions obtained by analysis for the RC specimen are anti-symmetric with respect to half height and do not fully correspond with those obtained experimentally because of localized shear cracks, whereas the analytical result for the LPRC shows good agreement with the experimental result, including the shape of the vertical distribution showing higher strains in the upper and lower sides due to the existence of numerous distributed shear cracks.

The relationship between the width of shear cracks and the elongation of shear reinforcements is shown in Fig. 12, where the total crack widths over a reinforcement observed by microscope, $\Sigma_{exp}w$' (see Fig. 5), are plotted as the abscissa and the elongations of the corresponding reinforcement calculated using the strains, $\Sigma_{cal}w$, are plotted as the ordinate. The elongation, $\Sigma_{cal}w$ in Fig. 12(1) is calculated using only one strain at the center, and $\Sigma_{cal}w$ in Fig. 12(2) is calculated using all three strains. If shear cracks are scattered over shear reinforcements, as in the LPRC specimen, the total crack widths, $\Sigma_{exp}w$', can be estimated fairly accurately by one strain of the reinforcement. In the case of localized shear cracks, as in the RC specimen, a better estimate of $\Sigma_{exp}w$' can be obtained by integrating the strain distribution of the three gauges. In addition, the estimated crack width, $\Sigma_{cal}w$, is

over 20% larger than the observed crack width, $\Sigma_{exp}w$', because the tensile strain of concrete between cracks was neglected and micro cracks might have been overlooked.

In order to investigate how accurately the FEM analysis with a smeared crack model can evaluate the extent of actual shear crack damage, the total crack width by FEM analysis, $\Sigma_{FEM}w$, which is estimated from the nodal displacements at both ends of a shear reinforcement by neglecting the strains of concrete, is shown in Fig. 13 together with $\Sigma_{exp}w$' observed by microscope and $\Sigma_{cal}w$ obtained by the strains in hoops. Although $\Sigma_{exp}w$' is observed on the surface of concrete, while $\Sigma_{cal}w$ and $\Sigma_{FEM}w$ are estimated by a reinforcement, these three crack widths exhibit broadly similar behavior due to the small concrete covering of 9 mm (see Fig. 1). The difference between the crack width behaviors of the RC and LPRC specimen is basically consistent with that of shear crack behaviors shown in Fig. 10 and strain behaviors of shear reinforcement shown in Fig. 11 because the total crack width faithfully reflects their behaviors. In particular, the experimental and analytical crack widths, $\Sigma_{cal}w$ and $\Sigma_{FEM}w$, behave in a similar manner. Comparison among the three crack widths indicates that most of the apparent Poisson's ratio is due to the shear cracks. Moreover, FEM analyses using the smeared crack model cannot accurately evaluate a localized crack but can provide valuable information about the total damage in the overall depth of a specimen.

(2) Evaluation of crack width from three gauges

Figure 12. Relations between shear crack width and strain of shear reinforcement

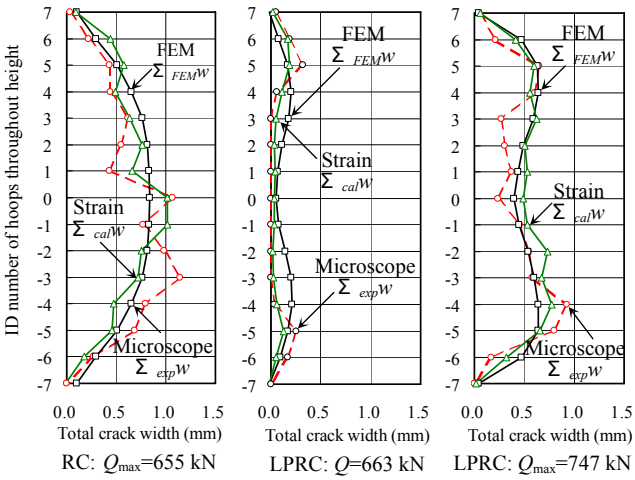

Figure 13. Total crack width obtained by microscope, strain of hoop, and FEM analysis

3.3 Shear Crack Width at Peak Load and Unloading, and Hysteresis

Figure 14 shows the relationship between the width of a shear crack at peak load ($_{exp}w_p$) and that at unloading ($_{exp}w_r$) in front of and behind specimens when the rotation angle is 1/100 cycle for the RC specimen, and 1/100 cycle and 1/67 cycle for the LPRC specimen. The individual crack width of the LPRC specimen is less than that of the RC specimen because numerous scattering cracks developed over the depth of the column, as shown in Figs 9 and 10. In addition, the average ratio of $_{exp}w_r$ to $_{exp}w_p$ in the LPRC specimen is smaller than that in the RC specimen. Specifically, the residual width of a shear crack in the LPRC specimen is reduced considerably compared to that in the RC specimen. The relationship between the shear load and the maximum crack width marked by ■ in Fig. 10 is plotted in Fig. 15 for both surfaces. As for the RC specimen, the crack width increases rapidly immediately after cracking and exceeds 1 mm at the maximum load. The increase in shear load is only 100 kN after cracking. As for the LPRC specimen, the shear load increases by 150 kN after cracking, and the crack width is less than 0.5 mm at peak load and 0.2 mm when unloaded. The transverse prestressing reduces the width values of shear cracks, especially their residual opening, and increases shear

stiffness after shear cracking. Consequently, this prestressing improves durability as well as earthquake resistance for RC structures.

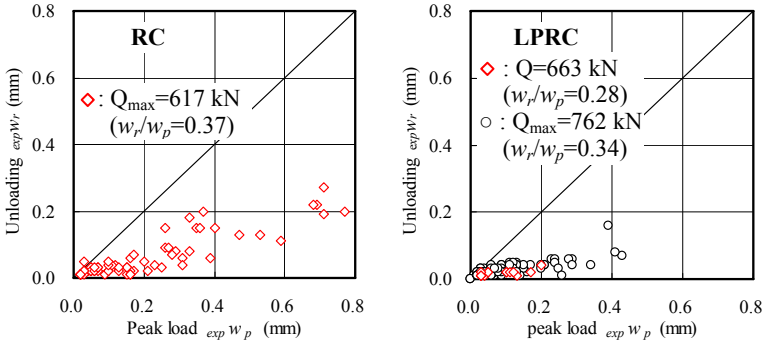

Figure 14. Relationships between crack width at peak load and crack width at unloading

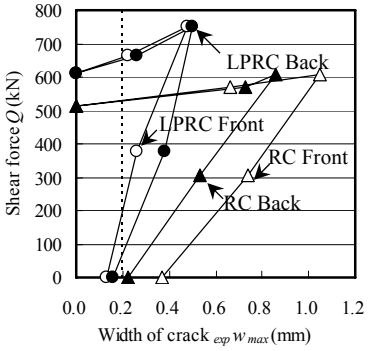

Figure 15. Relationships between shear force and naximum crack

3.4 Compression Strut based on Minor Principal Stress Distribution

Figure 16 shows the distributions of the minor principal stress in the center of the RC and LPRC specimens obtained by FEM analysis [Shinohara *et al*. 2005]. For the RC specimen, the compressive strut formed by a large compressive stress is clearly revealed at a shear load of 550 kN. The width of the strut then reduces slightly and localizes in a diagonal direction at the maximum load. For the LPRC specimen, on the other hand, the compressive strut appears at a shear load similar to the maximum load of the RC, and the width of the strut increases gradually up to the maximum load. As a result, the ultimate shear strength becomes higher. This difference is probably due to the crack patterns of the RC and LPRC specimens described previously.

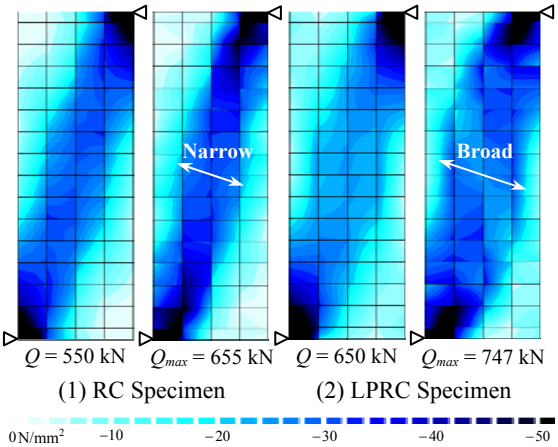

Figure 16. Compression strut based on minor principal stress distribution

4 CONCLUSIONS

The following conclusions are obtained from experiments and 3-D FEM analyses performed on reinforced concrete columns prestressed laterally to investigate the effect of the active confinement on the shear strength and crack behaviors.

1) The shear crack strength and ultimate shear strength have increased proportionally with increasing lateral pressure.
2) The shear crack patterns have changed appreciably, and the spacing and width of cracks have decreased drastically by introducing lateral prestress into a RC column.

3) The close relationship between the width of shear cracks and the distributed strain in reinforcements has been proven both experimentally and by FEM analyses.
4) The transverse prestressing reduces the width values of shear cracks, especially their residual opening after shear cracking, improving durability as well as earthquake resistance.

ABSTRACT

Environmental concerns related to the production of cement in terms of energy consumption and emission of CO_2 are driving the search for more sustainable alternatives. One possible alternative is to use industrial by-products as the binder. At present both fly ash and slag are frequently used as cement replacement materials. Both of these materials provide a more sustainable alternative to concrete and have been shown to increase durability in aggressive environments. Recent research has shown that it is possible to use fly ash or slag as a sole binder by activating them with an alkali component. The development of these materials is still at the early stages, with little knowledge about the long term performance of the materials.

This paper reports the early age durability characteristics of three geoplymer mortars. It reports the compressive strength, resistivity and ultrasonic pulse velocity data at 28, 90 and 150 days, together with the results of sulphate exposure test.

1 INTRODUCTION

Environmental concerns related to the production of cement in terms of energy consumption and emission of CO_2 has led to the search for more environmentally viable alternatives. One of these alternative materials is the use of alkali-activated binder using industrial by-products containing silicate materials. The most common industrial by-products used as binder materials are fly ash (FA) and blast furnace slag. Slag has been used as cement replacement material due to the latent hydraulic properties, while fly ash has been used as pozzolanic material to enhance physical, chemical and mechanical properties of cements and concretes. However, research has indicated that a limit of 70% for slag and 40% for fly ash can be used to replace Portland cement while maintaining acceptable strength and durability (Neville 1996). The utilisation of large proportion of by-products would contribute to the elimination of an environmental problem and to the development of potentially new high-performance material (Puertas 2000).

Recent research has shown that it is possible to use fly ash or slag as a sole binder in mortar by activating them with an alkali component (Adam et al. 2007a; Adam et al. 2007b). There are two models of alkali activation of fly ash/slag, Activation by low to mild alkali of a material containing essentially silicate and calcium will produce calcium silicate hydrate (C-S-H) with low C/S ratio (Bakharev and Patnaikuni 1997). On the other hand, the activation of material containing mostly silicate and aluminates by a highly alkaline solution will form an inorganic binder through a polymerization process (Palomo et al. 1999). In 1979 Davidovits defined this second model as geopolymer (Davidovits 1991).

2 FLY ASH BASED GEOPOLYMER

The reaction mechanism of geopolymer can be described in two steps (Buchwald and Schulz 2005):

1. *Activation*. The alkaline pore solution disintegrates the solid network to produce reactive silicate and aluminate species with low molecular weights. The activation of the solid is achieved with alkaline solutions containing alkali hydroxides, alkali silicates and/or alkali carbonates.
2. *The setting reaction*. Pure alumino-silicate materials, e.g., metakaolin and some types of fly ash, set by a condensation reaction which leads to the formation of alumino-silicate polymers.

The later reaction differentiates geopolymer from other types of alkali activated materials (such as: alkali activated slag) since the product is a polymer rather than C-S-H.

The best known material for producing geopolymer is metakaolin, however due to the limitation on the quantity available it is not suitable as a concrete binder, this has resulted in the substitution of metakaolin with other aluminosilicate materials such as, fly ash and rice husk ash.

To study the strength and durability of fly ash based geopolymer mortars, three different mixes were prepared with fly ash activated by a different weight ratio of sodium oxide in activator to fly ash (Na_2O to FA ratio). The compressive strength, ultrasonic pulse velocity, and resistivity were examined together with the sulphate resistance of the specimens

3 MATERIALS

3.1 Cementitious material

Fly ash, from Gladstone quarry, was provided by Cement Australia Ltd. Chemical analysis of the material is given in Table 1.

Table 1. Oxide composition of the fly ash (mass %)

Oxide	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	K_2O	Na_2O	TiO_2	P_2O_5	Mn_2O_3	SO_3	S^{2-}	Cl
Mass %	49.45	29.61	10.72	3.47	1.3	0.54	0.31	1.76	0.53	0.17	0.27	0.21	0.001

3.2. Activator

The activator used in this study was a sodium silicate based solution which means that the activator contained sodium silicate and sodium hydroxide. Grade D sodium silicate solution (Na_2O = 14.7% and SiO_2 = 29.4%) was supplied by PQ Australia. Sodium hydroxide solution (NaOH) was prepared by dissolving sodium hydroxide pellets with deionised water at least 1 day prior to mixing.

4 MIX PROPORTIONS AND TESTING SPECIMENS

Three different mass ratio of Na_2O in activator to fly ash (Na_2O to FA ratio) were used (i.e. 7.5%, 10%, and 15%). Alkali modulus in activator, which is defined as AM = $[(SiO_2)/(Na_2O)]$ was fixed to 1.25.

Water to solid ratio of 0.37 was used to prepare all the fly ash based geopolymer mortars. The amount of water in the mix was the sum of the water contained in the sodium silicate, sodium hydroxide and the added water, while the amount of solid was the sum of the weight of fly ash, and the solid contained in the activator solution. The sand-cementitious binder ratio was 2.75:1. Table 2 summarizes the composition of the mortar specimens.

Table 2. Details of the mixes (1 liter)

Mortar		*Fly ash (gram)*	*Activator*		*Sand (gram)*	*Added water (gram)*
ID	*Na_2O to FA ratio*		*NaOH 15M (gram)*	*Na_2SiO_3 (gram)*		
Mix1	7.5%	523	46	167	1438	108
Mix2	10%	514	60	218	1412	78
Mix3	15%	496	87	316	136	20

The mixing was performed using a 5-liter Hobart mixer, the mix was then poured into the moulds and vibrated for 1 minute. The structural integrity of the geopolymer specimens left at room temperature was not sufficient to allow the specimens to be demoulded until three days had elapsed, therefore a heat curing regime was applied. After leaving for 24 hours at room temperature, the specimens were wrapped with cling-film and left in the oven for 24 hours at 80ºC. The specimens were then allowed to cool in the mould at room temperature before they were demoulded. Following demoulding, the specimens were left at room temperature until testing.

Compressive strength measurements of 50 mm cube mortars were performed on an MTS machine under a load control regime with a loading rate of 20 MPa/min. Three to five cubes were tested for each data point.

The ultrasonic measurement is conducted on 170x50x50 mm specimens using a portable ultrasonic non-destructive digital indicating tester (Pundit Plus) with a 54 kHz transducer. The resistivity was measured using Wenner probe by the four-point method at 50 mm spacing. All tests were conducted at 28, 90, and 150 days after casting. While the sulphate exposure was conducted by immersing Φ50mm x100 mm cylinders in 4.4% Na_2SO_4 solution, the mass change was measured every 2 weeks up to 12 weeks.

5 RESULTS AND DISCUSSIONS

5.1 Effect of Na_2O to FA ratio on strength

Figure 1 indicates that an increase in the Na_2O to FA ratio resulted in a significant increase in the compressive strength. Increasing the Na_2O to FA ratio means an increase in both alkali content and soluble silicates and consequently an increase in the reaction rate (a higher concentration of reactants induces a higher reaction rate). In geopolymer mortar, alkali hydroxide is needed to dissolve silicate and aluminate monomer from the fly ash grain. A small increase in strength, with age, was observed at the lowest Na_2O to FA ratio (7.5%). At higher concentrations, the strength remained constant with time.

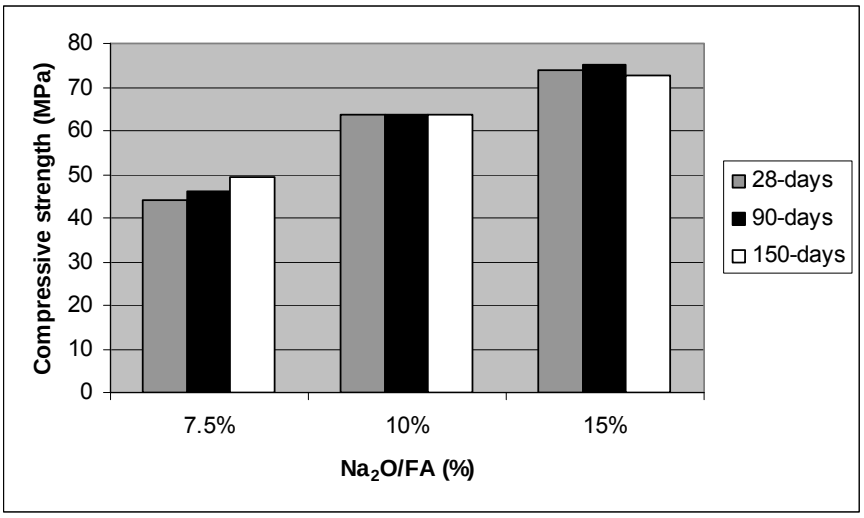

Figure 1. Strength of geopolymer mortars with different Na_2O to FA ratio

5.2. Effect of Na_2O to FA ratio on ultrasonic pulse velocity

The effect of the Na_2O to FA ratio on the ultrasonic pulse velocities is shown in Fig. 2. It was found that mixtures with a higher percentage of Na_2O in the activator had higher values of the UPV. Since the ultrasonic pulse will propagate more easily through the solid phase than that of empty space, the higher UPV would indicate a higher solid volume fraction/density and a lower porosity of the specimens.

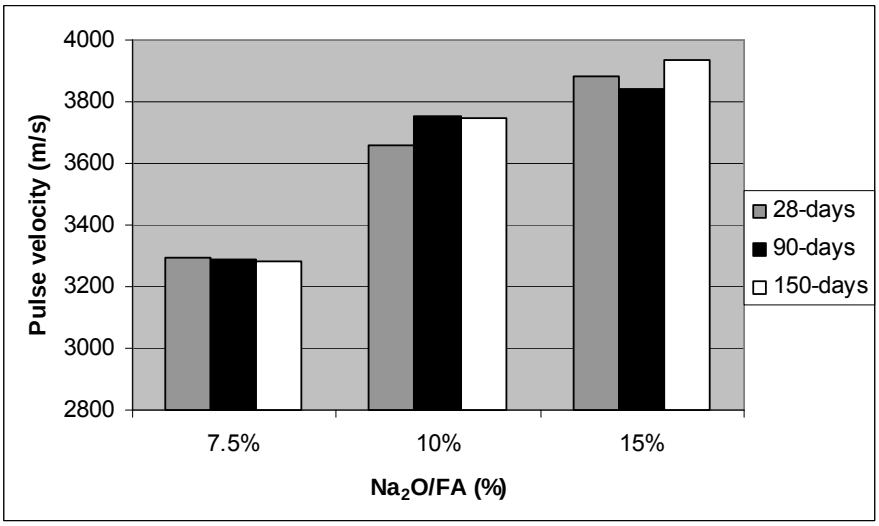

Figure 2. UPV of fly ash based geopolymer mortars with different Na_2O to FA ratio

There was a strong relationship between strength and UPV of geopolymer mortars, as can be seen from Fig. 3. By regression analysis using Microsoft excel the relationship may be described as :

$$\mathbf{f_c} = 3.9556e^{0.0007V} \quad (1)$$

Where f_c = compressive strength of the mortar (MPa)
V = pulse velocity (m/s)

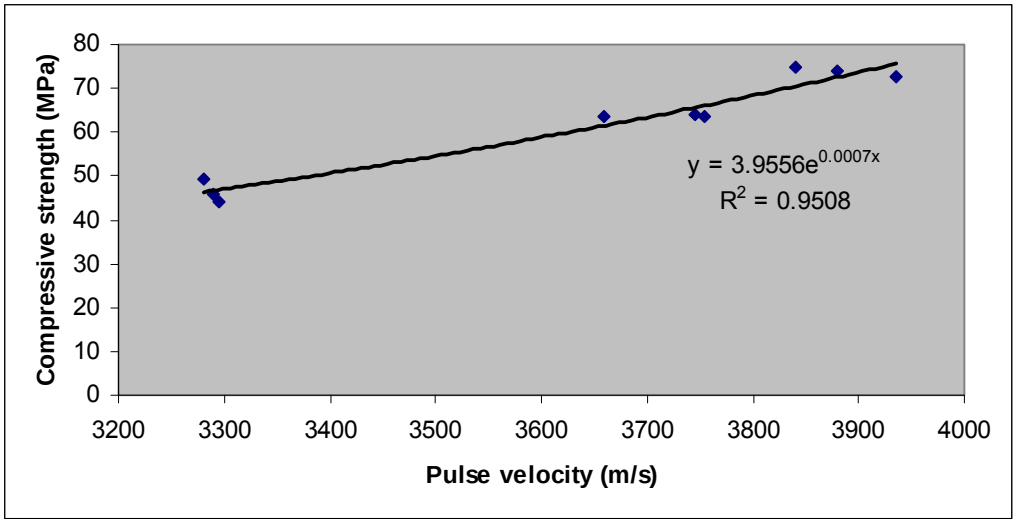

Figure 3. Relationship between UPV and Strength of geopolymer mortars

5.3. Effect of Na_2O to FA ratio on sulphate resistance

The deterioration of concrete from sulphate attack is due to the formation of ettringite and gypsum, caused by the sulphate reacting with the C_3A and lime in the cement (Neville, 1996). Both the gypsum and ettringite form expansive products which are less structurally stable than the cement matrix. Both the fly ash and slag have reduced C_3A content compared to OP cement and as such would be expected to be more resistant to sulphate attack. The density of the material will also influence the sulphate resistance, with the higher density giving a greater resistance.

The change in mass for the geopolymer specimens are given in Fig. 4. The data shows that the 7.5% and 10% Na_2O follow a similar trend, with an initial fall in mass followed by a slight rise. The 15% Na_2O shows an initial rise, followed by a fall and then a further rise. All variations are within 1.5% of the initial mass and may be a function of the handling a weighing procedure.

None of the specimens displayed any visual sign of deterioration, Fig. 5, although a slight discolouration due to crystallisation on the surface of the mortars was observed. There was no cracking of the specimens or an indication of ettringite or gypsum products.

Overall there is no indication, to date, of any variations in the performance of the specimens. All are displaying a good level of resistance to sulphate attack.

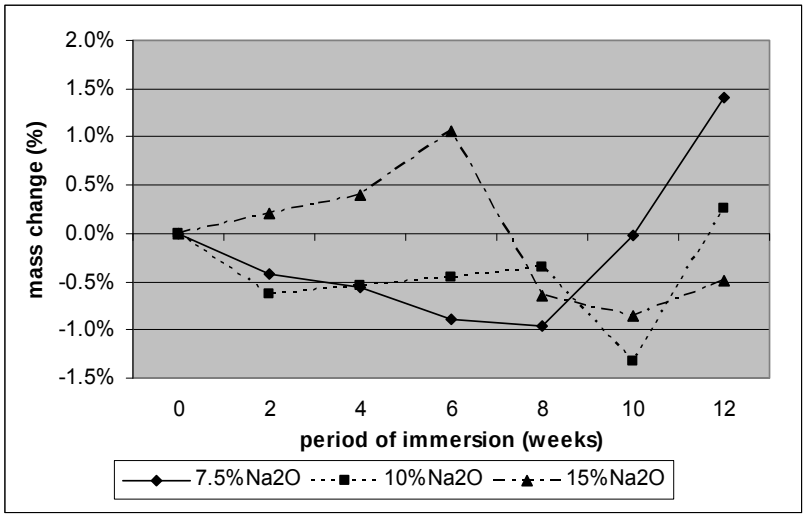

Figure 4. Mass change of fly ash based geopolymer mortars with different Na_2O to FA ratio after several periods of immersion

Figure 5. Geopolymer mortars with different Na_2O to FA ratio after 12 weeks of immersion

5.4 Effect of Na_2O to FA ratio on resistivity

The resistivity of concrete is one of the parameters used to assess the likelihood of corrosion of steel in concrete, Table 3, although the value can only be used if half-cell potential measurement shows that corrosion is probable (Bungey et al. 2006).

As can be seen from Table 4, the resistivity of geopolymer mortar exposed to laboratory environment was very high (more than 100 kΩ cm) at 90 & 150-days for all mixes. However, the value was very low when the specimens were saturated. This condition is attributed to the high amount of hydroxyl ion in the pore solution of geopolymer mortar, which in the presence of moisture leads to a high conductivity, and hence a low resistivity. When the specimens are dry, the hydroxyl ions are not able to move in the pore solution and hence a low conductivity and high resistivity is observed.

This finding is similar to that of Portland cement mortar, Fig. 5, since the average relative humidity in the lab was 40%. Contrary to the resistivity measurements of saturated specimens at 180-days, the 28-

day tests showed that the resistivity decreased as the ratio of Na_2O to FA increased. The higher ratio of Na_2O to FA increased the density of geopolymer mortar, thus slowed the rate of drying.

Table 3. Interpretation of resistivity measurement (Bungey et al. 2006)

Resistivity (kΩ.cm)	*Likelihood of significant corrosion when steel activated (for non-saturated concrete)*
< 5	Very high
5 – 10	High
10 – 20	Low/moderate
> 20	Low

Table 4. Resistivity of geopolymer mortars with different Na_2O to FA ratio and ages

Mix	*Resistivity (kΩ cm)*			
	Laboratory environment (air dry)			*180-days saturated*
	28-days	*90-days*	*150-days*	
7.5%Na_2O	>100*	>100*	>100*	8
10%Na_2O	71	>100*	>100*	8.9
15%Na_2O	43	>100*	>100*	15

*the equipment can only measure up to 99 kΩ cm

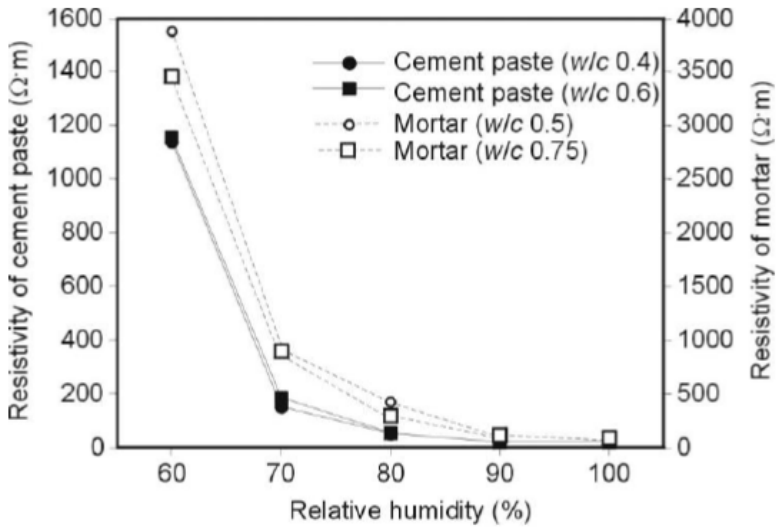

Figure 5. Dependence of resistivity of cement paste and mortar on water/cement ratio and relative humidity of the environment (Bertolini et al. 2004)

CONCLUSIONS

- The Na_2O to FA ratio has significant influence on the strength of fly ash based geopolymer mortars.
- Strength development with age was only observed on lower concentration of activator, while at higher concentration, no further strength development was observed after 28 days

- The ultrasonic pulse velocity was influenced by Na_2O to FA ratio, the mixtures with a higher Na_2O to FA ratio had higher values of the UPV which is related to the density of the mortar
- There is a strong relationships between strength and UPV for geopolymer mortar
- The Na_2O to FA ratio exhibits no observable effect on the sulphate resistance to date, with all specimens showing good resistance to sulphate attack.
- The resistivity of geopolymer mortar depends on the density and the pore-water composition which is related to the Na_2O to FA ratio
- The moisture content of mortar and the humidity of the environment also affected the resistivity of the geoplymer mortar

ABSTRACT

Durability is the ability of concrete to withstand any deterioration process during its service life. Different concretes require different degrees of durability depending on the exposure environment and properties desired. The long-time behavior of concrete structures has shown that their main cause of distress is reinforcement corrosion. This type of damage is responsible for the huge financial cost spent each year on the repair of deteriorated structures.

The electrical resistivity of concrete is one of the main parameters controlling the initiation and propagation of reinforcement corrosion specially in railway ties or in structures in which concrete is used for protection from stray currents. Electrical resistivity is well correlated with durability parameters such as diffusion coefficient, capillary absorption and porosity.

The main aim of this study is achiving to ultra high electrical resistivity in concrete; in this paper, bulk electrical resistivity of concrete is measured using a new instrument in which bulk electrical resistivity is calculated in different frquency ranges. The effect of silica fume and metakaolin as pozzolanic admixtures has been investigated. Also the effect of aggregate content types is studied in this research.

1 INTRODUCTION

Corrosion of steel reinforcment is responsible for premature deterioration of concrete structures worldwide, particularly in marine environment of hot regions such as Persian Gulf. It is well known that the durability of materials and structures depends both on the environmental conditions at the exposed surfaces of the structures and on the material resistance to the action of aggressive substances [Antonio Costa and Julio Appelton 2002].

Electrical resistivity is an important durability characteristic of concrete to resist the passage of electrical current and it may directly affect the rate of steel corrosion. This would be of more importance in electrically powered rapid transit lines, where high resistivities are required.

Electrical resistivity is fundamentally related to the permeability of fluids and diffusivity of ions through porous materials such as concrete. Therefore, electrical resistivity also can be used as an indirect measure of the ability of concrete to prevent penetration of chloride salt solutions that may cause corrosion of the reinforcing steel [David A. Whiting and Mohamad A. Nagi 2003].

In other words, electrical resistivity may be considered as a function of concrete quality and pore structure. Consequently parameters such as water to cement ratio, cement content, cement type, pozzolanic materials, compaction, curing period, age of concrete may affect electrical resistivty.

In the case of metals embedded in concrete, the electrolyte for the corrosion cell is the concrete itself. A resistivity of less than 5 K.Ohm.cm can support very rapid corrosion of steel [Brown, 1980]. If the electrolyte has high resistance to the passage of current, or if the electrolyte is dry and unable to support ionic flow, then corrosion will occur only at a very low rate, if at all. Various researchers [Tremper, 1958; Vassie, 1980; Alonso et al., 1988] have determined that corrosion can be limited by increasing resistivity. A table of suggested values [Langford and Broomfield, 1987] is shown in Table 1.

When resistivities exceed a value of 20 K.Ohm.cm the risk of corrosion is low. Where steel is actively corroding, however, Broomfield et al. [1993] state that resistivity must exceed 50 K.Ohm.cm to reduce corrosion to an acceptable rate, and that resistivity must exceed 100 K.Ohm.cm to stop corrosion entirely.

Table 1. Relationship between resistivity and corrosion rate of steel in concrete

Electrical resistivity (KΩ.cm)	Corrosion rate
<5	Very High
5-10	High
10-20	Moderate
>20	Low

Purpose of this study is to increase the bulk electrical resistivity of concrete in laboratory condition. The effect of cementitous materials, aggregate content, and different pozzolans on electrical resistivity are investigated using a new commercial electrical resistivity-meter.

2 EXPERIMENTAL INVESTIGATION

2.1 Materials

The cementitious materials used in this study were Portland cement (PC) equivalent to ASTM Type II, silica fume (SF) obtained from Azna ferro-silicon alloy manufacture. Metakolin used in this research

was provided from ASAN SERAM Company, Iran. The chemical composition of the Cement, Silica fume and Metakaolin are given in Table 2.

Table 2. Chemical composition of Metakaolin, cement and silica fume.

Components	SiO_2	Al_2O_3	Fe_2O_3	CaO	Na_2O	K_2O	MgO	TiO_2	P_2O_5	L.O.I
Metakaolin	51.85	43.87	0.99	0.20	0.01	0.12	0.18	1.74	0.03	-
Cement	22.42	4.68	3.68	63.2	0.25	0.75	3.63	-	-	0.45
Silica Fume	93.16	1.13	0.72	-	-	-	1.6	-	-	1.58

Silica aggregates were provided from Techno-Silica plant, Iran. Polycarboxylate ether polymer superplasticizer and lignosulphonate plasticizer were used for the mixes in order to improve the workability of fresh concrete.

Aggregates with maximum size between 12-19 mm must be used for preparing ordinary concrete. Therefore, S-curve graph has been served for optimized grading, also the cost of raw aggregates and the quality of aggregate packing is to be optimized [Genadij Shakhmenko and Juris Birsh 1998] (shows in 'Fig. 1').

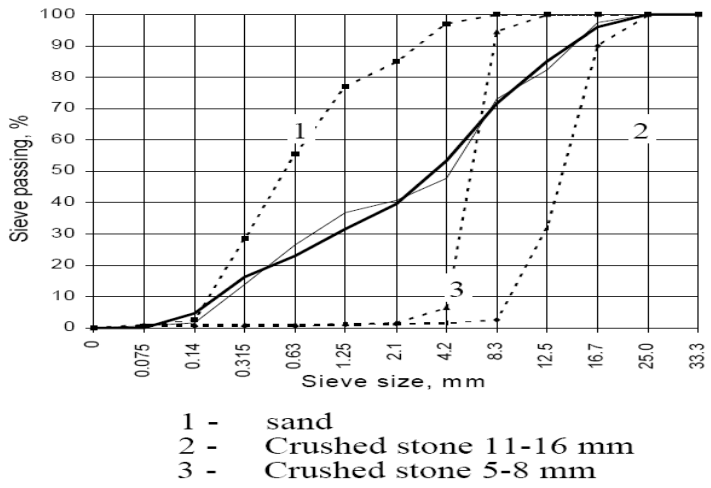

Figure 1. S-Curve for grading aggregates.

2.2 Mix proportions

Concrete of 6 different mix designs were selected among many mix designs studied during the research program. The mixes are presented in Table 3. Fine and coarse aggregates were used in 30% and 70% proportions, respectively.

2.3. Sample Preperation, Casting and Curing

Three specimens were made for each mix proportion. Concrete of each mix was casted into 10 cm cubic molds. In order to reduce void space, compaction was done using a steel tamper in 4 layers, each layer compacted by 30 impacts. The molds were covered with the burlap kept wet for 24 hours after casting. The specimens were removed from the molds and were allowed to cure in water saturated with calcium hydroxide at 80 °C for 28 days. Specimens were tested for the electrical resistivity at the ages of 7, 14, 21 and 28 days.

Table 3. Details of concrete mixtures

Materials	Mix					
	1	2	3	4	5	6
Cement (kg/m^3)	600	550	550	400	650	650
Water (kg/m^3)	300	250	250	200	350	350
W/C ratio	0.5	0.45	0.45	0.5	0.5	0.5
Silica-fume (kg/m^3)	400	320	350	320	-	350
Metakaolin (kg/m^3)	250	230	180	135	350	-
Cementitous Materials (kg/m^3)	1250	1100	1080	855	1000	1000
Aggregates (kg/m^3)	900	1100	1100	1350	1100	1100
SP (% by weight of cement)	1	1	1	1	1	1

It has been found that hot water curing will accelerate electrical resistivity growth [David A. Whiting and Mohamad A. Nagi 2003]. It seems specimens with smaller amount of cementitiuos materials have higher growth in resistivity at the end of the curing period.

2.4 Test Procedure and Measurement

Sudden temperature variations may lead to microcracks in concrete. To prevent initiation of microcracks, temperature of specimens should be slightly declined a few hours before testing. Specimens were tested at saturated surface dry condition.

It's important to dry the surface before testing as the moist surfaces may cause resistivity declining and inaccurate measurement. After drying the surfaces, electrical resistivity of concrete has been determined by two cuprous plates. Sufficient fresh cement paste has been injected between cuprous plate and specimen surfaces for complete connection (as shown in 'Fig. 2').

The new instrument innovated in Construction Materials Institute has been applied. It should be noted that the alternative current has been used in testing procedure and the resistivity hase been determined by measuring the respective voltage. The device which is shown in the follwing picture Measures the bulk electrical resistivity of concrete by providing measurement in different frequency ranges.

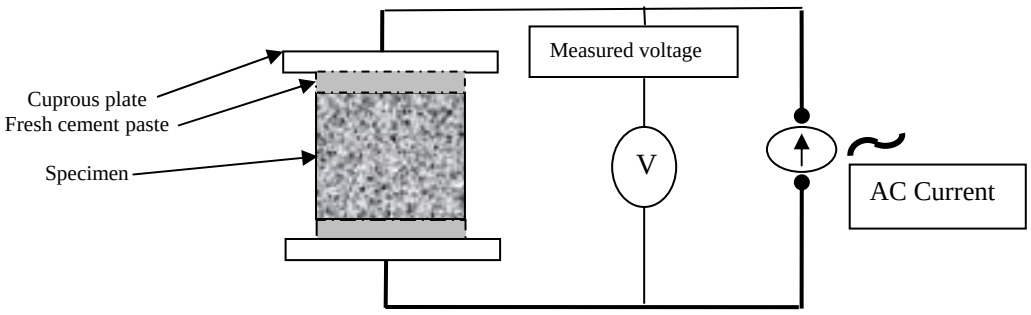

Figure 2. schematic diagram of testing procedure

3 RESULTS AND DISCUSSIONS

3.1 Results

The Results of the electrical resistivity of are illustraed in Table 4. Values are avarage of the three specimens of each mix design.

Table 4. Electrical Resistivity of specimens at the ages of 7,14,21 and 28 days

Age (days)	Electrical Resistivity (K.Ohm.cm)						
	Mix	1	2	3	4	5	6
7		1930	1970	5880	8340	17	600
14		3040	4940	8160	16590	46	1350
21		6460	8510	10130	18090	163	3340
28		7000	11090	17610	18500	217	3730

The above results in Table 4 compared with Table 1, show that concrete with ultra-high electrical resistivity has been gained.

3.2 Disscussions

3.2.1 Effect of Aggregates Content

According to the Figure 3, increasing the aggregate contents can accelerate the electrical resistivity. The electrical resistivity of aggregate is much higher than that of cement paste. While there is no specific study on the effect of aggregate type on electrical resistivity of concrete, one would expect that resistivity of concrete made with limestone aggregate would be less than that of concrete made with silica aggregate [David A. Whiting and Mohamad A. Nagi 2003].

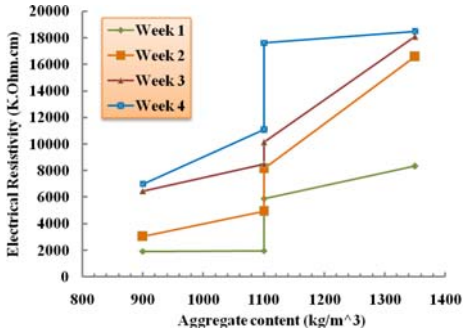

Figure 3. Relation between aggregate content and electrical resistivity

3.2.2 Effect of Cementitious Materials

Supplementary cementing materials such as silica fume and metakaolin have been used in concrete production of this research in relatively large amounts to improve durability charactersitics of concrete. Because of their pozzolanic effect and their physical properties, these materials improve microstructure of the cement matrix, and reduce concentrations and mobilities of the ions in the pore solution. Therefore they exert an influence on the electrical resistivity of concrete. In most cases, these materials create a finer pore size distribution and lower ionic concentration, which leads to higher electrical resistivity than in normal Portland cement concrete [Whiting et al., 1993].

The relation between cementitious materials and electrical resistivity has been shown in 'Fig. 4' obtained from samples NO. 1,2,3 and 4.

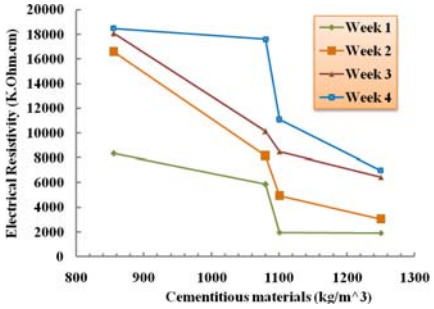

Figure 4. Relation between cementitious materials and electrical resistivity

Concerning the increase of cement content, it seems that decreasing the aggregate content decreases the electrical resistivity in concrete.

3.2.3 Effect of Different types of Pozzolanic Materials

According to relatively high w/c=0.5 in this study, there are some cappilary pores in cement paste. Because of a low cement content, even by a complete hydration process, there would not be sufficient CH for applying the whole pozzolns, considering the high content of pozzolanic materials. Therefore a considerable amount of pozzolanic materials remains non-reactive in the paste and it must be expected a physical effect not chemical; the pores have been filled by non-reactive pozzolans, so grading of non-reactive pozzolans becomes more important.

Comparison between resistivity of silica-fume, metakaolin and combination of them has been shown in 'Fig. 5' obtained from samples NO. 1 (Silica Fume+Metakaolin), 5 (Metakaolin), and 6 (Silica Fume).

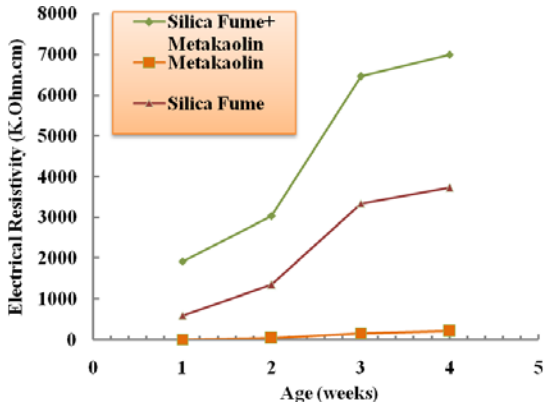

Figure 5. Comparison between resistivity of silica-fume, metakaolin and combination of them

In this research, optimum amounts of pozzolanic materials were found in each sample (about 37% and 16% by weight of cementitous materials for silica-fume and metakaolin respectively). Silica-fume and metakaolin separately has lower enhancement in electrical resistivity rather than their combination, however silica-fume is more efficient than metakaolin. This is shown in Fig 5.
Silica fume has a better effect on improving electrical resistivity than metakaolin for its finer particles and when using a combination from both pozzolans, there would be another grading beside the aggregate grading merely, so blank spaces like capillary pores will be filled more because of better physical role of non-reactive pozzolans.

4 CONCLUSION

In this study, the fundamentals of electrical resistivity have been reviewed and a concrete mix proportion with ultra-high electrical resistivity has been found. The electrical resistivity of concrete is a measure of its ability to resist passage of electric current and ionic migritaion within the concrete.

In general, following factors seem to be effective for increasing the electrical resistivity of concrete:

- Since cement paste has higher conductivity, limiting the amount of cementitous materials would be effective
- Optimum combination of silica-fume and metakaolin has been deduced from presented review instead of applying them seperately.
- Hot water curing may be useful to achieve higher values of electrical resistivities.
- For achiving higher electrical resistivity, effect of physical parameters are significant like the chemical parameters, too.

ACKNOWLEDGMENTS

ABSTRACT

There is often a need to evaluate the in place strength of concrete in existing structure for an accurate assessment of structural capacity. In place test methods can be used for a quantitative assessment of the strength, for this goal it is necessary to establish a strength relationship for the concrete in the structure. The relationship can be developed only by performing in –place tests at selected locations and taking companion cores for strength testing. The use of in place testing do not eliminate the need for coring, but it can reduce the amount of coring required.

A statistical study was carried out on a building (Punta Perotti) in Bari before its demolition. Punta Perotti, a building exposed for more than 10 years to particular aggressive environmental conditions (near the sea and in a windy area), of which are well known the technical schedules of original materials, was selected in order to study the life cycle of the materials and structures, until the demolition process. About 180 cores (10 cm diameter) and 290 microcores (2 cm diameter) were taken from the pillars of the structure made in concrete at different planes (-1, 0,1,2,3,6) after the non destructive testing (ultrasonic tests and rebound hammer tests) made on the same pillars. The Italian (OPCM 3274), European (PrEN 13791) and USA (ACI 228) guide lines were followed both in the in situ measurements and in the data analysis. The statistical data analysis was carried out by means of one – way ANOVA method. Some of the possible correlations between non destructive testing and mechanical testing, and between compressive strength of cores and microcores will be analyzed in this work.

1 INTRODUCTION

In Italy, for the seismic reliability, the Decree 3274 of 2003 and its successive modification (OPCM 3431/2005), predicts a founded quantitative process on following phases: structural knowledge, definition of the required performances, evaluation of the existing structure in accord to actualised performing level, plan of adaptation and at last, evaluation of the adequate structure.

The interventions of seismic reliability imply the necessity to elaborate in opportune way the data concerned the material properties.

In the verification of structural reliability , methods of analyses compatible with the acquaintance of the building must be chosen. It is necessary to redefine a complete and reliable model of the structure. It must be reduced the total outlay for the intervention of the structural reliability.

About the structure to analyse, it must be necessary to know the technical norms utilized in phase of planning. It is necessary to know the constructive practice at the age of the building and the original function. The characteristic strength of the concrete in the existing buildings is obtained from the results of tests in situ divided the "Factor of confidence". This last one depends on the level of the knowledge of the all structure. To obtain the appropriate type of analyses and the relative levels of "confidence", three different types of knowledge must be defined:

- LC1: Limited knowledge
- LC2: Adequate knowledge;
- LC3: Accurate knowledge.

The aspects that define the levels of knowledge are: geometry (the geometric characteristics of the structural elements), structural details (the numbers and disposition of the armours, the consistency of the not structural elements), materials (the mechanical properties of the materials). The acquired level of knowledge determines the method of analysis, and the values of the factors of confidence to apply to the property of the materials.

For the knowledge of the characteristic compression strength of the concrete, the mentioned Norm makes possible to substitute (not more than 50%), with a large number of non destructive tests (at least the triple one).

The same Norm indicates in the surface of plan of 300 m^2 the minimal cores number to extract, variable from three to nine in accord to the plan of investigation (limited, extensive or exhaustive). Apart from these general indications for the evaluation of the strength of the concrete in situ, do not exist consolidates procedures of combined investigations (destructive tests and non-destructive tests).

As shown in literature [OPCM 3274 2003] the relationship between concrete compression strength measured by means of mechanical testing and the measurements obtained by means of in situ non destructing testing results to be disperse and does not easily correlated.

The main object of this work is to try to validate the use of non destructive testing (ultrasonic measurements, rebound number and so on) through the identification of reliable correlation curves reducing the cores number to extract from the studied structure.

It is necessary to identify a good practice to select the eligible test stations of the same structural element on which to do the cores to minimize the errors in the technical evaluation.

To reach this goal a consistent number of experimental data (mainly ultrasonic measurements, rebound number and mechanical compressive test) was raised in order to lead statistical studies. ENEA has identified the Punta Perotti structure in Bari (Fig. 1) as a good case of study. Punta Perotti

was a building (14 levels high, about 1560 m^2 for level) exposed for more than 10 years to particular aggressive environmental conditions (near the sea and in a windy area), of which are well known the technical schedules of original materials and was selected in order to study the life cycle of the materials and structures, until the demolition process.

2 EXPERIMENTAL

On the complex of Punta Perotti it has been carried out a wide campaign of destructive and non destructive tests (Fig. 2-3-4). In particular the tests used for the data analysis reported in the present article are:

- ultrasound and rebound Hammer tests were carried out in situ on 90 pillars at three different heights (test stations) on six different floors of the building (-1, 0, 1, 2, 3, 6) and were extracted cores and microcores from the same places of the test stations.
- ultrasound velocity measurements obtained in laboratory on 180 cores and 290 microcores and on which have been executed relative strength measurements.

The used instrumentations for the tests in situ are:

- Schmidt Concrete Test Hammer for normal concrete structures. Impact energy 2,207 N/m.
- Digital CM42 CoverMaster Concrete Pachometers (microprocessor COVERMASTER CM9) equipped with an standard probe from 7 to 90 mm
- Low frequency Ultrasonic Instrument RP5000 SIRIO equipped with a microcomputer and two probes of 50Hz frequency and crystal of 1’’
- Professional hydraulic core drill for manual use with endowed column of sliding of diamond crowns of diameter 3,5 cm and 10 cm, for perforation to water on all the superficial ones of armed concrete

The used instrumentations for the laboratory tests are:

- Low Frequency RP5000 SIRIO Ultrasound instrument endowed of microcomputer and two probes of 50 KHz frequency, crystal from 1"½
- Low Frequency KrautKramer 23 LF Ultrasound instrument, computer laptop inside acquisition board A/D converter and two probes of 50 KHz frequency, crystal from 1"
- Low Frequency Boviar Ultrasound instrument endowed of palm computer and two probes of 50 KHz frequency, crystal from 1"½
- Low Frequency Numeric Ultrasound instrument and two probes of 50 KHz frequency, crystal from 1"
- 250 KN CONTROLS Press for automatic compression tests equipped with computer for data acquisition

3 DATA ANALYSIS

All the acquired data were used to try to establish a quantitative assessment of the strength for the concrete in the existing structures of Punta Perotti. In order to develop the strength relationship, it is generally necessary to correlate the in place tests parameter with the compressive strength of cores obtained from the structure. Furthermore by combining results from more than one in place test (for example ultrasonic test and rebound hammer), a multivariable correlation can be established to estimate strength. Combined methods are reported to increase the reliability of estimated strength. For example an increase in moisture content increases pulse velocity but decrease the rebound number, so their combined use results in a cancelling effect that improves the accuracy of the estimated strength [ACI 228 1R -03].

For this reason it was decided to evaluate the in situ experimental results both with the strength versus the alone ultrasonic velocity variable ($R\_ac = a \times V^{c}$) and versus the ultrasonic velocity and rebound variables ($R\_abc = a \times IR^{b} \times V^{c}$).

The result of the comparison between the multivariable and single variable correlation, Fig. 5, shows that the calculated values are quite similar. For this reason it was decided to work on the curve correlation obtained only versus the ultrasonic velocity.

A further interpretation of the data is carried out in order to try to define the homogenous groups of data with the aim to define a wide statistical sample to obtain the best correlation curves.

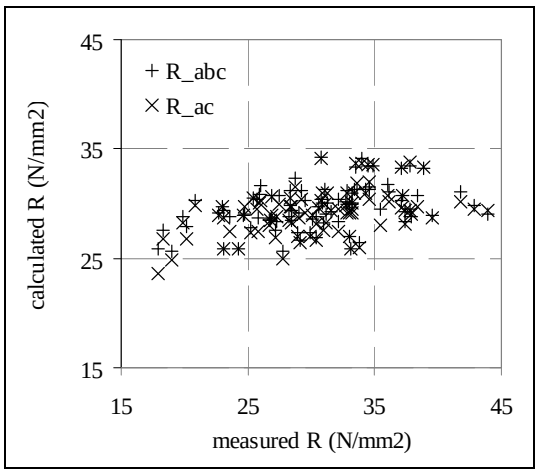

Figure 5. Comparison between multivariable (R_abc) and single (R_ac) correlation.

For this purpose it was used the software Analyse-it in order to use methodology ANOVA (ANalysis Of VAriance). ANOVA is one instrument of statistics, developed in order to verify the significance of the differences between the arithmetic means of two or more similar statistics populations.

ANOVA allows to decompose and to measure the incidence of the various variation sources on the values observed of two or more groups of data [Analyse-it for Microsoft Excel].
The concrete for its nature it is a material that has strongly variable physical characteristics if measured in punctual way.

ANOVA is, in your opinion, a good statistical instrument to deal the data obtained from this type of experimental campaigns. ANOVA is more suitable of the t of Student, commonly used for this type of analysis.

The base hypotheses of this methodology are that the data must be between independent each other, normally distributed and that the variances of several the groups must be homogenous. These hypotheses turn out satisfied on the measures that we carried out on the structure of Punta Perotti.
The totality of the data has been decomposed in various groups in which a single parameter varied (i.e.: the floor, the test stand, the instrument of measure etc.).

Through the elaboration of the data, they were defined the groups of different specimens for physical causes, and those with similar behaviour have joined, to the aim to carry out one statistical study on the maximum number of data between homogenous samples.

The obtained results can be therefore synthesized:

- ANOVA has confirmed that there is a variation of the compression strength and of the ultrasound velocity in the concrete of Punta Perotti versus the analyzed floors (Figure 6).
- From the statistical analysis carried out on the same pillar of the same floor at different height, it turns out that there are not meaningful differences between the values of velocity (Figure 7) and strength (Figure 8); therefore in the subsequent analyses we have considered indifferently all the measurements obtained from the pillars of the same floor.
- Always with ANOVA it was verified that there is not a meaningful difference between the measurements of ultrasound velocity carried out in situ on the pillars and the ultrasound measurements carried out in laboratory on the cores with same ultrasound instrument (Figure 9). Therefore for the statistical analysis the ultrasonic velocity values measured on the cores were used in order to have approximately the double quantity of the data.

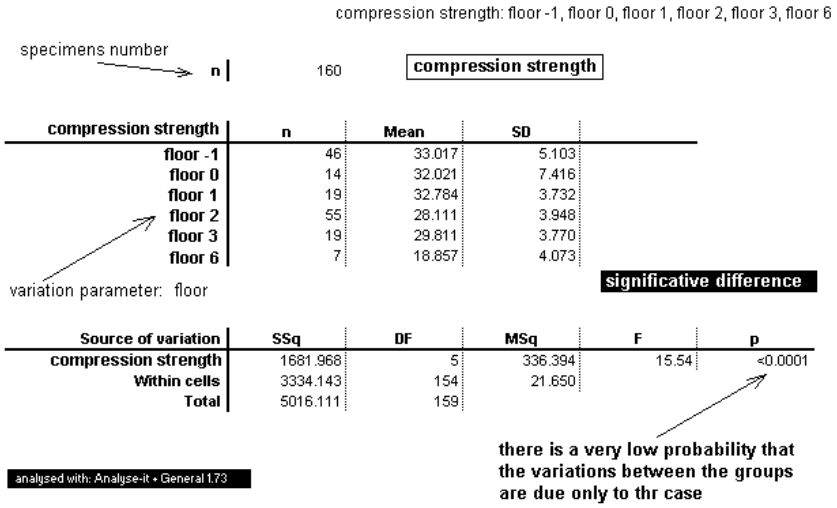

Figure 6. ANOVA results: comparison between compression strength obtained on different floors

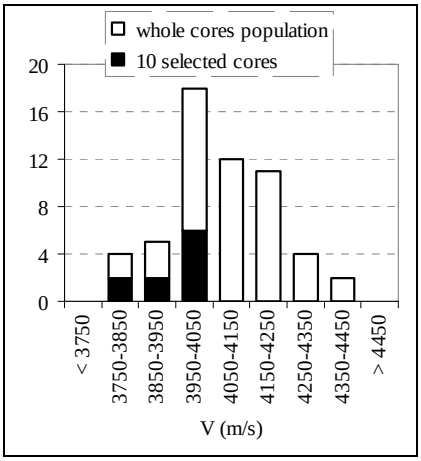
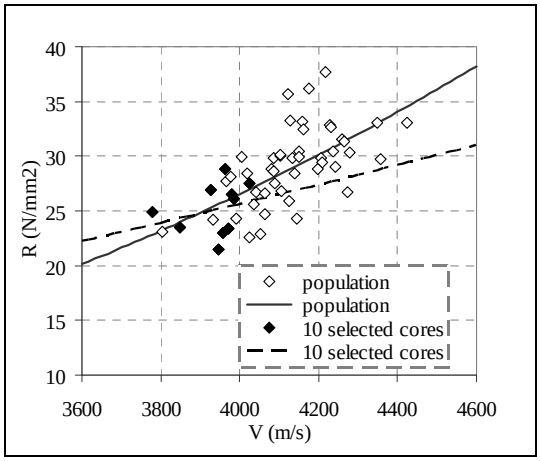
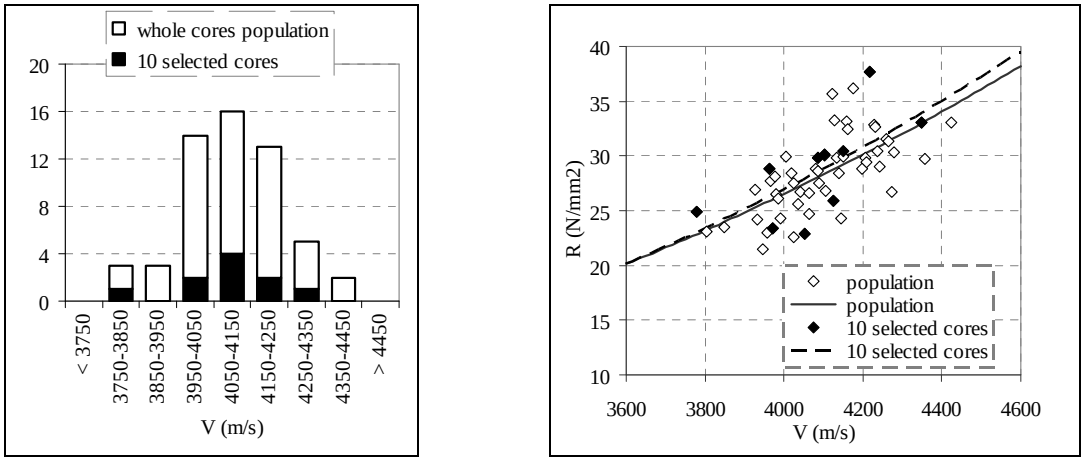
4 CORRELATION CURVES ANALYSIS

The main goal of this study is to try to minimise the number of cores on the structure and obtain a representative correlation curve. To reach this goal, first of all ad hoc correlation curves between ultrasonic velocity and strength measurements for every floor using all cores available were calculated. The second step was to calculate the correlation curve using only 10 ultrasonic and strength measurements, that is the number of the cores indicated by the Italian Guide Lines [OPCM 3431 2005] for a structure as Punta Perotti. At the beginning it was calculated the correlation curve with 10 measurements choosing the ultrasonic velocity measurements in the range of the minimum, medium and maximum values.
To evaluate the goodness of the correlation curve obtained with 10 measurements with respect that one obtained with the measurements available on the same floor, it was considered as parameter the ***S***um of ***S***quared ***E***rrors (*SSE*) that is minimised with the regression calculation. It was then defined the $SSE_{population}/SSE_{10selected}$ ratio. If this ratio is near 1 then the two regressions result to be quite similar. In this way it was possible to establish that there is a very good correspondence between the correlation curve obtained in all floors with both the 10 medium and maximum values of the ultrasonic velocity, with except the floor 2 (Figures 10-11).





Figures 10-11. Distribution of the ultrasonic velocity measurements and regression curves of the 10 selected data considering the minimum values of ultrasonic velocity.



Figures 12-13. Distribution of the ultrasonic velocity measurements and regression curves of the 10 selected data considering similar mean value and standard deviation.

Due to this singularity, it was decided to identify another methodology and it was chosen 10 measurements with mean value and standard deviation of the ultrasonic velocity similar to the values obtained from all the measurements of the same floor.

This kind of analysis was applied to the 2nd floor obtaining a good correlation between the two curves (Figures 12-13).

It can be concluded that in the selection of the core locations, it is appropriate to include the widest range of concrete strength in the structure as it is possible.

In order to verify the hypotheses of pre-selected zones on which carrying out the cores, an exhaustive analysis of all the possible decuples of cores is in progress. For giving to an order of magnitude of the problem, the exhaustive analysis of the possible decuple for floor -1 in the structure of Punta Perotti is estimated in about 400.000.000 possible cases, while for floor 2 is estimated in more than 3.300.000.000 possible cases.

5 CONCLUSIONS

A wide campaign of non destructive and destructive tests on the same structure (Punta Perotti) was carried out in order to study a methodology to built up the best correlation curve to define the mechanical strength of the concrete.

The main goal of this research work is to support the designer to assess the reliability of an existing structure, without having a complete knowledge of its present condition, in the choise of the best position in which to do the cores. To reach this goal it was used an statistical approach. Preliminary results seems to demonstrate that a previous campaign of non destructive testing and an accurate statistical analysis of the results can help to identify the most appropriate zone in which doing the cores. Further studies are underway to improve this method.

ABSTRACT

Nowadays, in the purpose of energy saving and eco-friendly technologies and materials, increasing interest is accorded to natural vegetable fibers. Many studies have shown that vegetable fibers are an alternative to asbestos in fiber reinforced cement products manufacturated by the Hatscheck process. Few works have demonstrated the low thermal conductivity of such composite materials resulting from effect of the mixture fiber/matrix.

The aim of this study is to produce low–cost building materials in the purpose of saving energy using heat-treated and chemically treated sugar cane bagasse and fique fibers as reinforcement in cement (OPC) based materials. Consequently, the influence of the type and weight of additives on the insulating thermal properties (conductivity) and on the mechanical properties (flexural strength) are prospected.

This study evidences that composites composed with pyrolyzed bagasse fibers have better thermal properties than others composites. The higher mechanical properties are noted for composites manufactured with alkali treated fibers.

1 INTRODUCTION

Composite materials incorporating vegetable natural fibers have known an increasingly interest during the past few decades [Toledo Filho et al. 2003, Savastano et al. 2000, Savastano et al. 2003, Bilba et al. 2003, Arsène et al. 2007, Coutts 1988]. These environmentally friendly materials are low-cost [Coutts 1988] and offer advantages such as reduction of electrical consumption by air conditioning. Moreover, the use of vegetable fibers in replacement of synthetic fibers is interesting in developing countries where the availability of tropical plants and agricultural wastes is important. Due to health reasons, since 1973, various regulations are applied to restrict and ban the use of asbestos in France [Bilba et al. 2004] and other countries. Many studies have shown that, regarding the mechanical behaviour, vegetable fibers are an interesting alternative to asbestos in fiber reinforced cement products manufactured by the Hatscheck process [Savastano et al. 2000, Savastano et al. 2003, Savastano et al. 2001] although few works have demonstrated the low thermal conductivity of such vegetable fiber-Portland cement based composite materials [Toledo Filho et al. 2003, Savastano et al. 2001] resulting from effect of the mixture fiber/matrix.

The aim of this study is to produce low–cost insulating materials for building construction in order to obtain habitability and to save energy. Although thermal properties are really involved in applications of such materials, it is essential to evaluate if their mechanical properties are in good agreement with the civil engineering codes [Blankenhorn et al. 2001]. Consequently, the influence of the type of treatment and amount of fibers on the mechanical and thermal properties are prospected.

2 MATERIALS AND METHODS

Samples were elaborated at Universidad del Valle (Cali, Colombia) using a process followed by Delvasto [2006] and de Gutiérrez and al. [2005] while the thermal and mechanical studies were developed at Université des Antilles et de la Guyane (Guadeloupe, France).
Two types of vegetable fibers were used: bagasse, solid residue of sugar cane after juice extraction (provided by Sugar Cane Factory in Guadeloupe) and Colombian plant fique (provided by a Colombian Fique sacks factory). They will be noted respectively “BAG” and “FIQ”.

Two types of treatments were applied:

- Heat–treatment : pyrolysis under controlled atmosphere (N_2 flow, 2L/h) during 2 hours and at 200°C which is the optimal temperature to obtain retified fiber without formation of char [Bilba & Ouensanga 1996]. The pyrolyzed fibers will be named “BAGP”.
- Chemical treatment: attack by a 5% by mass alkaline solution of $Ca(OH)_2$ for bagasse and fique fibers. The alkali treated fibers will be named “BAGB” and “FIQB”.

A Portland cement marketed as ASTM type I usually used in Colombia, a graded natural river sand, a limestone filler and water were used as the matrix. 93.5 % by weight of the limestone filler is Calcium carbonate ($CaCO_3$). The size distribution, determined by using a Malvern laser diffraction analyzer, of Portland cement gives an average granulometry of 15µm and the limestone filler has an average particle size about 1 µm.

According to these results, the Portland cement has a factory addition what is a calcareous material. The sand is appropriated for use in cement based mortars, its apparent density is about 2605 kg/m^3 and its average particle size is approximately 0.6 mm.

2.1 Composites Preparation

The content of sand and calcium carbonate were kept constant at 50% and 30% by weight of cement respectively. The composites studied were elaborated with a matrix based on Portland cement. The

proportions of the matrix compounds were in weight percent with respect to Portland cement (wrtc): sand 50 %, limestone powder 30 %, bentonite 1.5 and 3 %, cellulose pulp 4 %, silica fume 5 %, an aqueous copolymer dispersion of butyl acrylate and styrene from BASF (Acronal® 296 D) 7.5 %. The amount of fibers was changed from 0 % to 3 % wrtc. Slurry of each mix contains a water/cement ratio of 0.9 (weight by weight) being prepared before its pouring on a casting bed that was subjected to vacuum to obtain a flat sheet. After the slurry dewatering process, pads (160 x 50 x 8 mm^3) cut from the fresh laminate were cured for 21 days at 100% of relative humidity and left to air dry in the laboratory for 7 days at room temperature.

About 19 mixes were elaborated: 3 samples for the 3 types of fibers for 2 fiber contents and 1 as control (without any fiber). The detail of the mixes is shown in [Table 1]. The mixes reinforced with fique alkali treated (FIQB) correspond to codes: M86, M90; The mixes reinforced with bagasse alkali treated (BAGB) correspond to codes: M71, M74. The mixes reinforced with pyrolyzed bagasse (BAGP) correspond to codes: M80, M83. The composites will be noted “CBAGP”, “CBAGB” and “CFIQB”.

Table 1: Proportions of the mixes elaborated.

Composites	**Fibres and treatment**	**Bentonite (% wrtc)**	**Fibres (% wrtc)**	**Acrylic Polymer (% wrtc)**	**Silica Fume (% wrtc)**	**Pulp (% wrtc)**
Control (M 75)		3	0	7,5	5	4
CFIQB (M90)	FIQB	3	1,5	7,5	5	4
CBAGB (M74)	BAGB	3	1,5	7,5	5	4
CBAGP (M83)	BAGP	3	1,5	7,5	5	4
CFIQB (M86)	FIQB	3	3	7,5	5	4
CBAGB (M71)	BAGB	3	3	7,5	5	4
CBAGP (M80)	BAGP	3	3	7,5	5	4

2.2 Thermal conductivity testing

Thermal tests were conducted under controlled laboratory conditions (temperature ~ 20°C and relative humidity of 70–80%) on 112 days old specimen. The apparatus used was a thermal conductivimeter “CT–mètre” with a thermal probe commercialized by Controlab (Saint–Ouen, France). Six measurements were conducted for each composite with one hour interval between each measurement in order to evaluate the standard deviation of the results.

2.3 Flexural strength testing

Composites flexural strength was measured under three-point bend loading with a span of 50mm. The tests were conducted 112 days after specimen fabrication. The specimens were loaded continuously to failure at a speed rate of 0.5 mm/minute. The tests were carried out in an Instron (model 3367 - Guyancourt, France) testing machine equipped with a 500N load cell.

3 RESULTS AND DISCUSSION

In this paper, results of the tests on 112 days old specimen are presented. At this age, the principal hydration processes of cement have almost completely been done and the formulations of the composites are very stable [Bilba et al. 2004, Taylor 1997]. The evolution of thermal conductivity according to the amount of fibers is reported in [Figure 1]. Dash lines correspond to control specimen. The thermal conductivity values are of same order of magnitude whatever the type of fibers. Evolution of mechanical properties determined by three-point bending test is presented in [Figure 2].

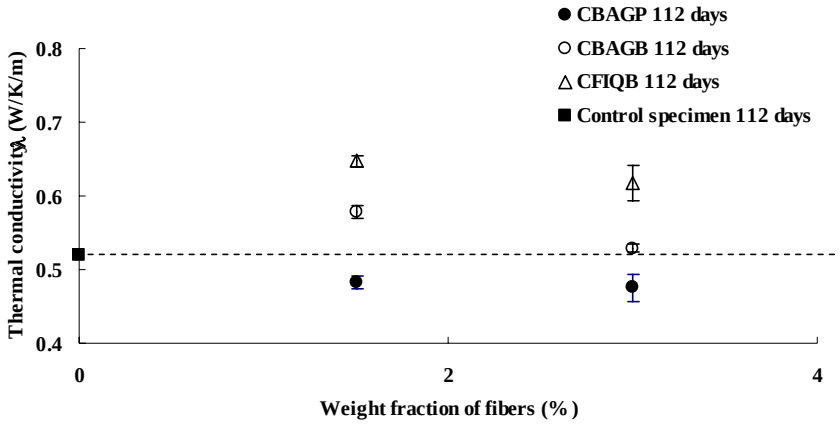

Figure 1. Evolution of thermal conductivity of 112 days old vegetable fibers/cement composites according to weight fraction of fibers.

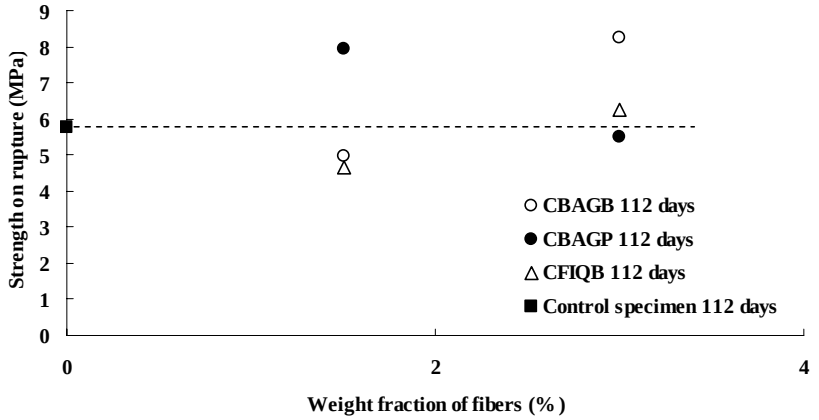

Figure 2. Evolution of flexural strengths of 112 days old vegetable fibers/cement composites according to weight fraction of fibers.

3.1 Influence of weight fraction of fibers

By increasing the weight fraction of fibers, there is a progressive decrease of the thermal conductivity. This result is in good agreement with Asasutjarit et al. [2007] results: when cement/fiber is higher, the thermal conductivity of a cement board increases. The weaker heat conductor materials are CBAGP because the more pronounced addition of fibers effect is for those composites; indeed all the thermal conductivity values of CBAGP are lower than the control specimen one.
The effect of fiber content has been correlated with the treatment. At low fiber content (1.5% wrtc), strengthening effect is observed only for composites with pyrolyzed bagasse fibers. On the contrary, at 3% (wrtc) of fibers, the better mechanical properties are measured for composites elaborated with bagasse and fique fibers using alkaline treatment.
In case of thermally treated fibers, the flexural strength decreases with increasing fiber content. A strengthening effect of mechanical properties, with increasing fiber content, is noted for composites containing chemically treated fibers. However, at low content of chemically treated fiber (1.5 %), the composites flexural strength is lower than for the control specimen. This behaviour with 1.5% weight fraction of fibers points out the importance of fiber adhesion and porosity.
Between 1.5% and 3% (wrtc) of fiber content, mechanical properties are supposed to follow a linear variation. By extrapolation, a fiber content of 2% is found. In these conditions, flexural strengths are closer for the two composites made of bagasse fibers and remain higher than the control specimen one.

These results are confirmed by former results **[5]** that evidence an optimal pyrolyzed bagasse fiber content of 2% (wrtc) for improved mechanical properties and an increase of mechanical strength thanks to the addition of pyrolyzed bagasse fibers or alkali treated fique fibers.

3.2 Effects of fiber treatment

As shown in [Figure 3], pyrolysis at 200°C significantly improves thermal properties of these composites because thermal conductivity values of CBAGP are lower than the control specimen one. The value of thermal conductivity is more than 20 % lesser for the CBAGP than for the commercial cellulose boards which report 0.68 W/K/m [Asasutjarit et al. 2007].
The most important decrease of thermal conductivity values is noted for alkali treated fibers/cement composites. Nevertheless, up to 3% of alkali treated fibers, the values keep higher than for the control specimen. This means that the inclusion of pyrolyzed fibers limits the heat transfer.
With 3% of pyrolyzed bagasse fibers, the composites do not offer greater mechanical properties because the strength of CBAGP is lower than the control specimen, whereas strengths of alkali treated fibers/cement composites are higher than the control specimen one. At 3% weight fraction of fibers, CBAGB and CFIQB behave better and seem to be well designed for improved mechanical properties of building materials.

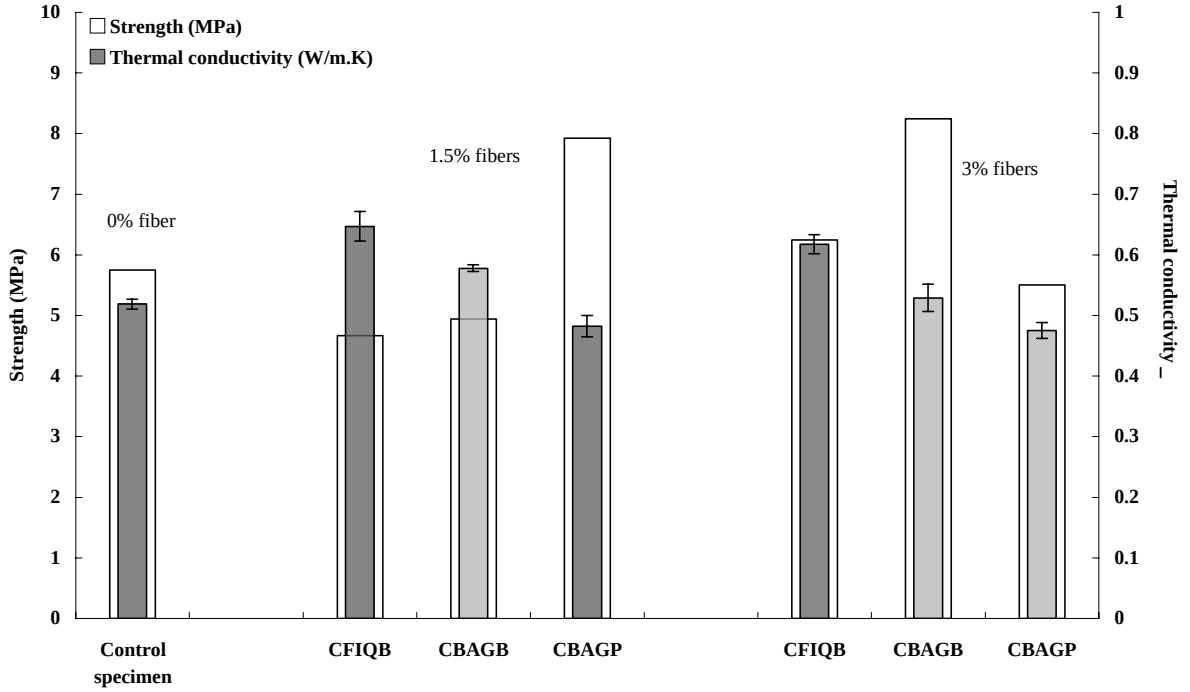

Figure 3. Comparison of thermal conductivity and flexural strengths of 112 days old vegetable fibers/cement composites according to weight fraction of fibers.

3.3 Influence of nature of fibers

A comparison of mechanical and thermal properties of CFIQB and CBAGB allows an assessment of effect of botanical origin of fibers.
According to Fig. 3, the less insulating materials are elaborated with alkali treated fique fibers as all thermal conductivity values for CFIQB are higher than the others.
Regarding the strength values (Fig. 2 and 3), its trend according to the weight fraction of fibers is similar for CBAGB and CFIQB but we note that CBAGB present higher flexural strength than CFIQB.

Alkali treatment dissolves the hemicellulose matrix of vegetable fibers and thus, increases surface roughness. However, it improves little or degrades slightly the vegetable fibers properties. While heat treatment (pyrolysis), which increases significantly fibers mechanical strength, increases in a less way the vegetable fibers roughness in comparison with alkali treatment [Arsène et al. 2007]. Thus, these two factors allow the interpretation of the flexural strength according to fiber weight fraction and nature of fibers.

4 CONCLUSIONS

Thermal conductivity of vegetable fibers/cement composites is an important parameter in the use of such materials in construction for saving energy. In this study, particular attention is given to the influence of weight fraction of fibers, fibers treatment and nature of fibers on thermal properties. Composites elaborated with bagasse fibers are weaker heat conductor materials than those elaborated with fique fibers. Although for thermal insulating applications, one should prefer the weaker heat conductor that is to say CBAGP. But if requirements on mechanical strength are more severe, composites with alkali treated fibers have to be preferred.
Treatment effectiveness can be limited by roughness or fiber/matrix adhesion problems.
In order to evaluate the interest of a treatment or the nature of reinforcement, we have to compare the composites characteristics to control specimen (without any fiber) characteristics. In this study, the reference specimen contains aggregates and plasticizers and fiber content is limited to 3% (wt). In such conditions, improving effect of alkali treatment is not noted, at the contrary of results reported by Arsène et al. [2007] in the case of an ordinary Portland cement paste.
This study allows the determination of an “optimal” weight fraction of fibers. Indeed, if one wants to find a good deal between great thermal and mechanical properties, a formulation within 2.25% of bagasse fibers appears to be optimal.
Composites with fique fibers present weaker mechanical properties than composites with bagasse fibers.
This study has to be supplemented by additional experiments on specimen containing higher fiber content. Indeed, it will be useful in order to determine the potentialities of use of these composites as insulating materials.

Sung Tae, Chae [4]

T11

ABSTRACT

Various problem such as durability degradation may happen when extra water is added to concrete. Because of these reasons, the change of water content is managed by using rapid evaluation method of unit water content such as electric capacity method, heat drying method making use of micro wave, unit capacity mass method among various methods. Especially, in Japan, guidance for the change of water content(±10, 15, 20kg/m^3 etc.) were regulated and used. However, it is the real situation that the guidance which was regulated in Japan evaluate suitability only considering production and measurement error under the circumstances which are not considering the degree of durability degradation.

Therefore, this study tries to investigate the influence of addition of extra water in the concrete on the durability degradation of concrete when it was added by artificial manipulation or by management error. From the test results, a guideline of the contents of extra water for the quality control is suggested with the consideration of the degree of durability degradation and the probable error resulted from the addition of extra water.

The contents of extra water for tests are set as 0, 15, 25, 35kg/m^3. To examine the durability degradation of concrete, freezing and thawing, carbonation, chloride penetration and compressive strength are tested.

1 INTRODUCTION

Water is indispensable in order to cause hydration reaction and secure a certain level of liquidity when fabricating concrete. Generally, as shown in Figure 1, when the unit water content within concrete increases, such materials as coarse aggregate or mortar are segregated, and the increase in bleeding or the shrinkage crack due to an increase in drying shrinkage might also generate porosity on the lower part of aggregate or reinforcing bar, which deteriorates adhesiveness between reinforcing bar and the concrete. Besides, other deterioration might be lead such as settlement cracking, a surface deterioration through water transfer or the drop in penetrating resistance for salt, water and gas with internal porosity increases. Accordingly, such methods as electric capacity method, heat drying method are being suggested to improve the durability of concrete structure and the credibility of quality control and to quantitatively manage the quality of concrete at the construction site.

Especially in Japan, guidance for the change of water content (±10, 15, 20kg/m^3 etc.) were regulated by relevant institutions such as Ministry of land, infrastructure and transport, as shown in Figure 2. However, it is the real situation that the guidance which were regulated in Japan evaluate suitability only considering production and measurement error under the circumstances which are not considering the degree of durability degradation, which means that the Ministry of land, infrastructure and transport of Korea set $\sqrt{10^2+10^2} \fallingdotseq \pm 15\,\mathrm{kg/m^3}$ as a standard for an evaluating, considering such probable errors as fabrication error of ±10kg/m^3 and measurement error of 10kg/m^3.

Therefore, this study tries to investigate the influence of addition of extra water in the concrete on the durability degradation of concrete when it was added by artificial manipulation or by management error. From the test results, a guideline of the contents of extra water for the quality control is suggested with the consideration of the degree of durability degradation and the probable error resulted from the addition of extra water.

2 TEST PLAN AND PROCEDURE

2.1 Test Plan

As shown in Table 1, we set five-step test variables of 155, 165, 175, 185 and 195kg/m^3 as standard test variables, based on the unit water content, considering most frequently used concrete mixture among three major ready-mixed concrete companies. In order to examine the possible problems by the change in unit water content at the plant for ready-mixed concrete, we also established four-step increase in water content (0, +15, +25, +35kg/m^3) at each unit water content as test factors. As for the accelerated concrete, the evaluation on compressive strength for each age, freeze-thaw resistance, penetration resistance of chlorine ion and carbonation had been implemented in accordance with the test methods specified in the Korean Standards (KS).

Table 1. Test Plan and A Mix of Concrete

Water-Cement Ratio (%)	Fine Aggregate Ratio (%)	Unit Weight (kg/m^3)				
		Water		Cement	Fine Aggregate	Coarse Aggregate
48	45.7	155	0 +15 +25 +35	320	885	1050
52		165	0 +15 +25 +35	320	872	1036
55		175	0 +15 +25 +35	320	860	1021
58		185	0 +15 +25 +35	320	848	1007
61		195	0 +15 +25 +35	320	836	993

2.2 Materials

Physical properties of materials used in this concrete experiment are shown in Table 2.

Table 2. Physical properties of materials used

Cement	Type : Normal Portland Cement (Type I), Density : 3.15g/cm^3, Fineness : 3,200cm^2/g	
Aggregate	Fine Aggregate	Type : Sea Sand, Density : 2.61g/cm^3, FM : 2.57
	Coarse Aggregate	Type : Ground gravel, Maximum size : 25mm, Density : 2.64g/cm^3, FM : 6.96

2.3 Test Items and Evaluation

The evaluation on the test items and the durability of concrete had been implemented in accordance with the KS, as shown in Table 3.

Table 3. Items of Measurement

Items of Measurement	Instantaneous compliance
Compressive Strength	3, 7, 28day
Freezing-Thawing Resistance	0,50,100,150Cycle
Penetration Resistance of Chlorine Ion	28day
Accelerated Carbonation	7, 14, 21, 28day

The test for the penetration resistance of chlorine ion was implemented in accordance with RCPT (Rapid Chloride penetration test) and ASTM.

Freeze-thaw resistance test was conducted by 10 × 10 × 40cm of specimen, a test of KS F 2456's (resistance test of rapid freeze-thaw of concrete) B type was freezing in air and thawing in water. It makes 1 cycle of -18℃ ~ +4℃ feeze-thaw for 4 hours. The test for rapid carbonation resistance conditions on temperature(20±2)℃, relative humidity(60±5)% by KS F 2584(rapid carbonation test of concrete). The measurement for carbonation depth was sprayed a reagent by KS M 8238, it measured depths of discoloration to madder from concrete surface. The measurement ages are 7, 14, 21, 28 days

3 TEST RESULTS AND CONSIDERATION

3.1 Test result of Compressive Strength

Test result of compressive strength by the change in water content within concrete in Figure 3 shows that compressive strength increases as it ages 3, 7, to 28 days and it increases as Water-Cement Ratio and Unit water content are low. In other words, when the water content within concrete increases, compressive strength decreases overall.

At each water-cement ratio vs. unit water content, when we say that W0's compressive strength rate in the 28th day without summand is 100, and if a summand of + 15 occurs as shown in Figure 4 (a figure describing a relative compressive strength rate according to summand in percentage, a relative compressive strength rate is 84~87%. If a summand of +25 occurs, a relative compressive strength rate is 67~76% and +35 summand results in relative compressive strength rate of 61~62%.

This result is calculated adding safety rate to design standard strength. But, it is evaluated to take into consideration of possible compressive strength result below the design standard strength if +25 of summand occurs. In case of B Class with 59%-185, 61%-195, material segregation occurs from +15 summand. Therefore, it was intended to exclude from the test analysis.

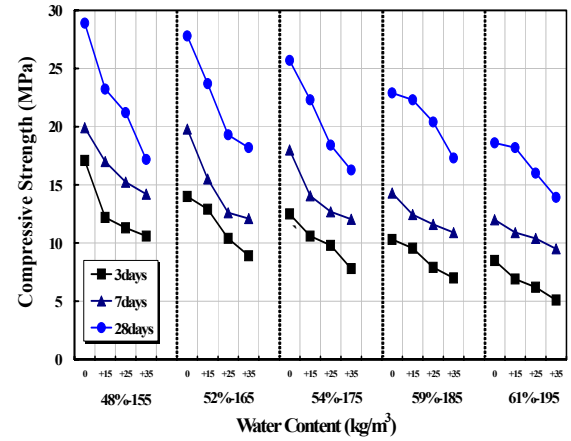

Figure 3. Compressive strength of concrete according to unit water content

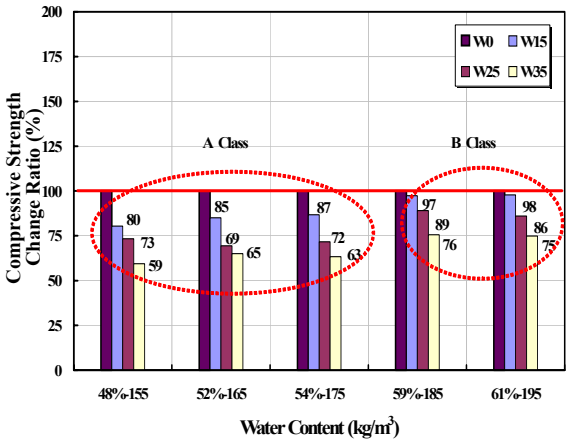

Figure 4. Decrement of compressive strength according to unit water content

3.2 Resistance to Freezing and Thawing

Figure 5 illustrates that the relative dynamic modulus of elasticity for 48%-155 decreases to 73~75% and the relative dynamic modulus of elasticity for 52%-165 decreases to 61~71% at the cycle 150 with an increase in water content. However, at 54%-175 and 59%-185, there is no such difference caused by adding water, showing great similarity in the results either adding water or not. When adding +25, +35 kg/m^3 of water to the specimen, it might cause the problem of fracturing during the freezing and thawing test, making it impossible to measure. Especially at 61%-195, all specimens were fractured at the cycle 150. From the results above, it might be inferred that freezing-thawing resistance caused by an increase of the unit water content shows relatively slight degradation when the water-cement ratio have higher compressive strength.

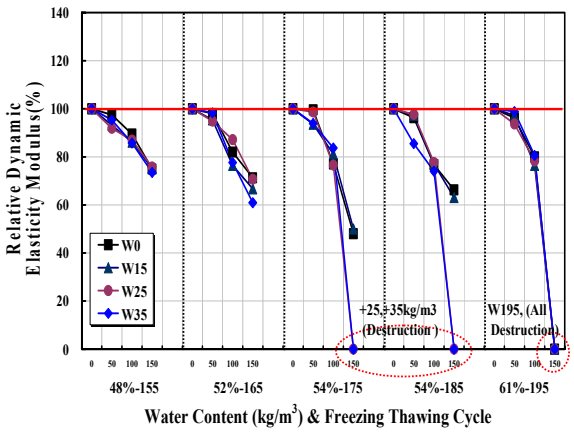

Figure 5. Relative Dynamic Elasticity coefficient

3.3 Penetration Resistance of Chlorine ion

As shown in Table 4 and Figure 6, which indicates a test result of penetration resistance of chlorine ion by adding extra water, Class B with relatively lower strength undergoes greater influence by the

change of unit water content and has thicker chloride ion penetration, compared to Class A. When adding +15 or +25kg/m^3 of water , in all cases compared to W0, the result shows a thicker penetration of chlorine ion with approximate thickness of 0.08~0.61mm for Class A and 1.29~2.55mm for Class B. However, when adding +35kg/m^3 of water, chloride ion penetration grows greater with approximate thickness of 3.23~7.97mm. Therefore, it is suggested that the addition of water would not exceed +25kg/m^3 considering penetration resistance of chlorine ion at normal strength even when the water content within concrete increases due to the artificial addition and the addition caused by management or fabrication error.

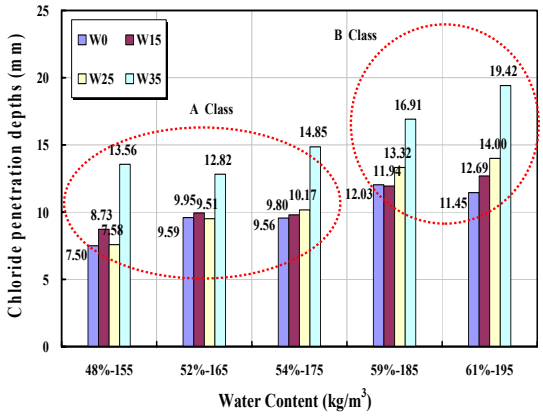

Figure 6. Depth of penetration of chlorine ion according to unit water content

Table 4. Depth of penetration of chlorine ion according to unit water content

Unit water content	W0(mm)	W15(mm)	W25(mm)	W35(mm)
155	7.50	8.73	7.58	13.56
165	9.59	9.95	9.51	12.82
175	9.56	9.80	10.17	14.85
185	12.03	11.94	13.32	16.91
195	11.45	12.69	14.00	19.42

Table 5. Photograph of penetration of chlorine ion according to unit water content

Unit water content	W0	+15	+25	+35
155				
165				
175				
185				
195				

3.4 Resistance to Carbonation

1) Thickness of Carbonated Penetration

While the increase rate of carbonated thickness ranges from 4 to 17% when adding +15 kg/m^3 of water, the addition of +25 or +35kg/m^3 of water lead an increase 24~77% and 35~130%, respectively, suggesting a consideration for the resistance to carbonation. (See Table 6.)

Table 6. Depth of penetration of Carbonation according to unit water content

Unit water content		W0(mm)	W15(mm)	W25(mm)	W35(mm)
155	28days	7.50	8.73	7.58	13.56
165	28 days	9.59	9.95	9.51	12.82
175	28 days	9.56	9.80	10.17	14.85
185	28 days	12.03	11.94	13.32	16.91
195	28 days	11.45	12.69	14.00	19.42

2) Durability Estimation by using Coefficient of Carbonation Speed

As shown in Figure 7 and Table 7, a coefficient at the same condition of CO_2 concentration of 5±0.2% could be calculated in accordance with the formula (1). The coefficient, ranged from 2.0 to 4.0mm/day$^{0.5}$, increases as the water content within concrete increases.

$$C = A \cdot \sqrt{t} \quad (1)$$

Where, C is carbonated thickness, t is the time passed, A is a Coefficient of Carbonation Speed

As given in Figure 8 through Figure 12 and Table 8, the estimation of durability using the coefficient of carbonation speed showed that it would take approximately 100 years to reach 30mm in its cover at the ratio of 48% - 155% while it would take 55 to 60 years with a higher ratio ranged from 52%-165 to 61%-195. When adding +15kg/m^3 of water, it showed comparatively gentle decline its durability with an average decreasing rate of 14% while its decreasing was considerably rapid with the average of 36% and 52%, respectively, when adding +25, +35kg/m^3 of water The water gain from the manufacturing or management error had a great influence on the process of long-term carbonation of concrete, which led an increase in internal porosity and a decrease in the resistance to carbonation which had been resulted from the penetration of carbon dioxide or water. Therefore, the water-cement ratio should not exceed 48% and the unit water content should be less than 155kg/m^3 to secure the durability of 100 years for the carbonation of concrete. Especially, in order to secure the durability on the carbonation of concrete structure even when the unit water content within concrete increases due to its manufacturing error caused by adding water, the water added to the concrete might not +25kg/m^3.

4 CONCLUSION

Based on the test results above, we might draw a conclusion that when the unit water content within concrete increases due to the errors caused during the quality control or the manufacturing, compressive strength decreases, not to mention of durability of concrete such as Freezing-Thawing Resistance, Penetration Resistance of Chlorine ion, Carbonation Resistance. The results of this research might be summarized as follows:

1) From the result of compressive strength test, it could be inferred that when adding +15, +25 and +35 kg/m^3 of water, relative compressive strength would decrease to the level of 84 ~ 87%, 67 ~ 76% and 61 ~ 62%, respectively. Therefore, it is recommended to take into consideration for not adding more than +25kg/m^3 of water in order to maintain a certain level of designed compressive strength.

2) From the result of the test for freeze-thaw resistance, it could be inferred that an increase in compressive strength would lead a decrease in freeze-thaw resistance with the change in the unit water content, especially with lower than 52%-165.

3) From the result of the test for penetration resistance of chloride ion, it could be inferred that when adding +15 or +25kg/m^3 of water , in all cases compared to W0, the result shows a thicker penetration of chlorine ion with approximate thickness of 0.08~0.61mm for Class A and 1.29~2.55mm for Class B. However, when adding +35kg/m^3 of water, chloride ion penetration grows greater with approximate thickness of 3.23~7.97mm. Therefore, it is suggested that the addition of water would not exceed +25kg/m^3 considering penetration resistance of chlorine ion at normal strength even when the water content within concrete increases due to the artificial addition and the addition caused by management or fabrication error.

4) From the result of carbonation test, it could be inferred that the water gain from the manufacturing or management error had a great influence on the process of long-term carbonation of concrete, which led an increase in internal porosity and a decrease in the resistance to carbonation which had been resulted from the penetration of carbon dioxide or water. Therefore, the water-cement ratio should not exceed 48% and the unit water content should be less than 155kg/m^3 to secure the durability of 100 years for the carbonation of concrete. Especially, in order to secure the durability on the carbonation of concrete structure even when the unit water content within concrete increases due to its manufacturing error caused by adding water, the water added to the concrete might not +25kg/m^3.

5) From the test results above, it could be inferred that the quality control on the mix designed unit water content should be noted in order to maintain a certain level of durability performance when there is an increase more than +25kg/m^3, which might lead considerable deterioration of concrete.

ABSTRACT

The main objective of repair mortars, usually applied in patching is to restore the geometry and integrity of the material and the repassivate the reinforcing steel. Repair materials can be of two different natures: cement based or polymer based. In the case of cementitious repair materials, a polymer may be added that will dissolve or disperse during mixing. With any of these alternatives the steel should exhibit after repair a very low corrosion rate which is described as "be repassivated". An additional property appreciated in repair mortars is their resistance to the penetration of the aggressive substances: carbonation and chloride ions.

In present paper, four different repair materials are tested in an accelerated manner in order to rank them for application in a particular structure. The tests performed have been water absorption, mercury porosimetry, corrosion potential and corrosion rate after carbonation and after chloride penetration. The accelerated carbonation was made in a chamber at 100% CO_2 and the accelerated chloride ingress by applying an electrical field. The results indicate very different performance regarding corrosion of the steel: While one of the mortars exhibited immediate corrosion depassivation when tested, there is another not depassivated after one year in the same conditions. These different behaviours claim for the need to test these materials. In the paper attempts are made to justify the very different performance from the results obtained on the microstructure.

1 INTRODUCTION

Steel embedded in concrete is protected against corrosion due to its alkaline nature as a result of $Ca(OH)_2$ evolution during hydration of cement. However, concrete structures are subjected to aggressive environments which may cause degradation depending on their performance, throughout their service life. In alkaline concrete with a pH value greater than 12, a passive layer of ferro-oxides is formed over the reinforcing steel. This passivity may break down mainly in two ways; ingress of chloride ions and carbonation of concrete cover which lead into reinforcement corrosion.

Many repair operations involve only patches where the repair material to be used is in the form of (polymeric/cementitious) mortar. Cementitious mortars are recently preferred because of the repassivation effect of cement hydration but polymer latex utilization is also common in order to improve permeability and bonding properties.

Although cementitious repair mortars reproduce passive layer over the steel, primers applied on rebar surfaces are also used to overcome the risks resulting from poor compaction of these rapid hardening repair mortars. On the other hand, they are used in order to achieve a complete bond between mortar and steel.

In this study, four different commercially available rapid hardening cementitious repair mortars and steel primers are tested against carbonation and chloride induced corrosion by Polarization Resistance electrochemical technique. To characterize the repair materials regarding the corrosion resistance and able to make a comparison, accelerated chloride migration tests, accelerated carbonation tests, capillarity and mercury intrusion porosimetry (MIP) tests are applied.

2 EXPERIMENTAL

The four commercial pre-mixed repair mortars used are of cementitious nature and the contents are unknown . Water-to-cement ratios of mortar were adjusted according to the specifications of set of fats. For the accelerated chloride migration tests 7x7x7 cm cubic specimens and for accelerated carbonation tests, 2x5.5x8 cm prisms containing two identical steel bars were cast. In both of the tests, half of the steel bars embedded in mortars were coated with the primer of each brand. Before embedding the steel bars into the mortars, they were cleaned in an HCl solution, washed with water, immersed in acetone and dried with hot air. Prisms, having the same dimensions, without steel bars were also produced to perform capillarity test. After being demoulded, carbonation and chloride migration specimens were put in a chamber having a 95% RH and 20±2^{o}C for 7 and 28 days, respectively.

2.1 Carbonation experiments

Specimens for accelerated carbonation were stored in laboratory conditions for drying during 28 days and then are subjected to accelerated carbonation under 100% CO_2, 50% RH and 20±2^{o}C. Prior to location of the samples in the carbonation chamber and in the following days, weights and corrosion rates were measured every day. On account of CO_2 binding of hydration product (calcium hydroxide) of cementitious mortars, weight propagations were observed. When the rate of increase became negligible, it is assumed that carbonation process had finished and specimens were immersed in water. Daily corrosion measurements were continuously taken after immersion.

2.2 Migration experiments

A container, filled with a 1 M of NaCl solution, was sealed on a face parallel to the rebar axis [Castellote *et. al.* 2002]. Migration of the chloride ions is accelerated by 12V potential difference between the solution container and opposite side of the specimen as shown in Figure 1. Some days

after initiation of the test, catholyte solution was neutralized with 0.05 M of HCl solution, in order to maintain a pH value of around 6 – 8.

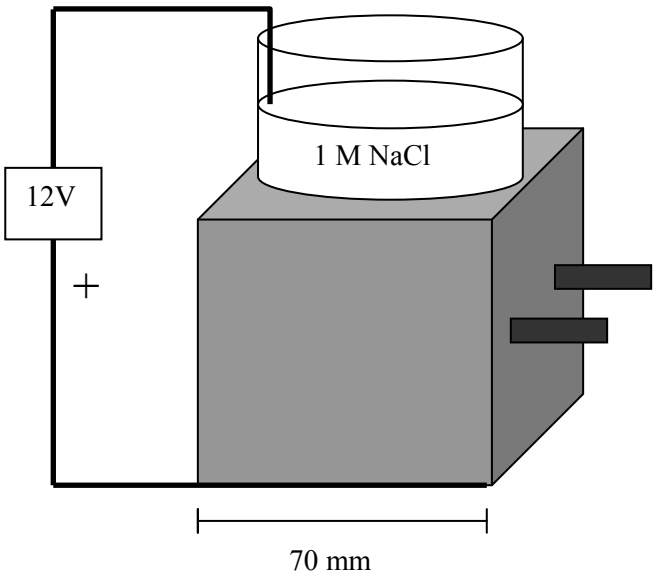

Figure 1. Accelerated chloride migration test setup

Prismatic specimens without rebar and for capillary water absorption tests were cured in a chamber having a 95% RH and 20±2°C for 28 days. Afterwards, they were left for drying in laboratory conditions for 60 days. The capillary water absorption by means of increase of weight per unit area is illustrated in Figure 3. The test and the calculation of coefficients m and k, resistance to water penetration and coefficient of capillary absorption, respectively, are performed according to Fagerlund [1982].

3. TEST RESULTS

Figure 2 illustrates the increase in weights of specimens during carbonation. In the figure, first letter denotes the coded mortar brand and the second one shows the situation of the embedded steel. Here, C is the abbreviation of 'coated'with primer and B is 'bare'.

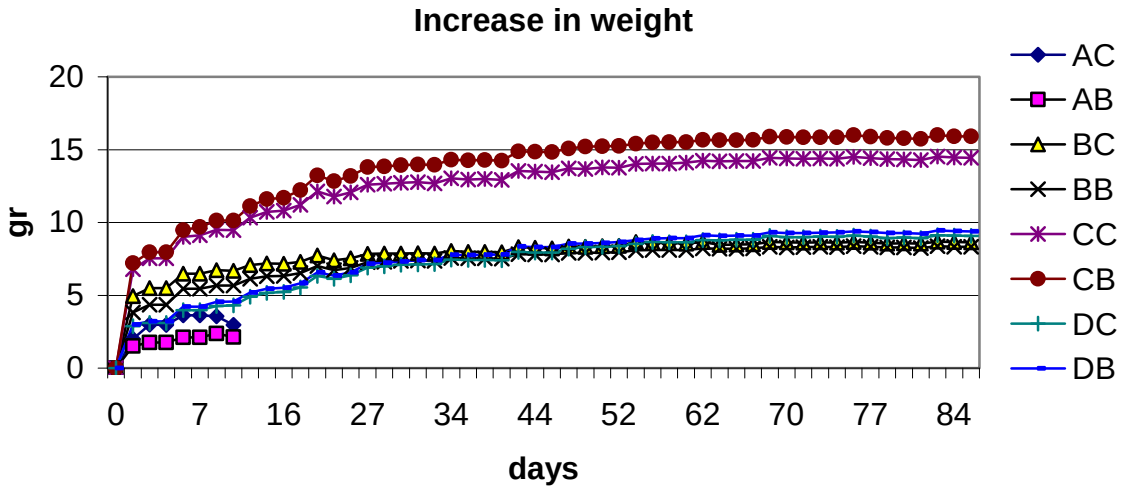

Figure 2. Weight rise of specimens subjected to accelerated corrosion tests

In order to investigate the pore structure of the hardened mortars, mercury intrusion porosimetry test was also applied.

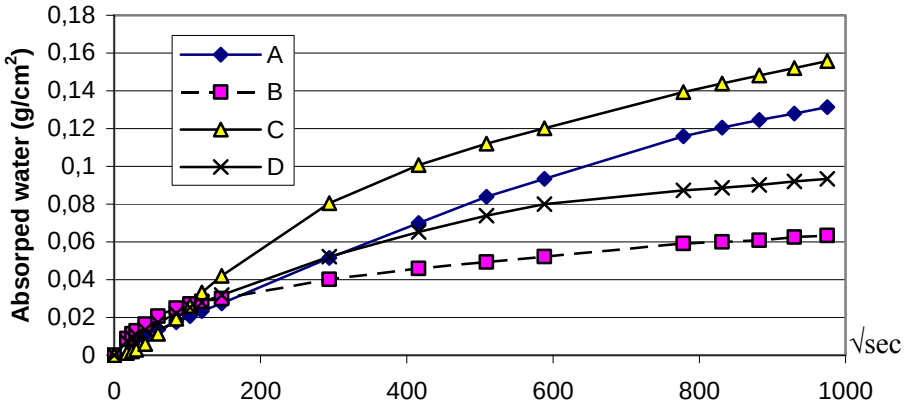

Figure 3. Capillary water absorption of the four repair mortars

Figure 2 and 3 show the increase in weight due to capillary suction and during carbonation, respectively. Except mortar A, rate of carbonation and water absorption by capillarity of mortars are in the same order.

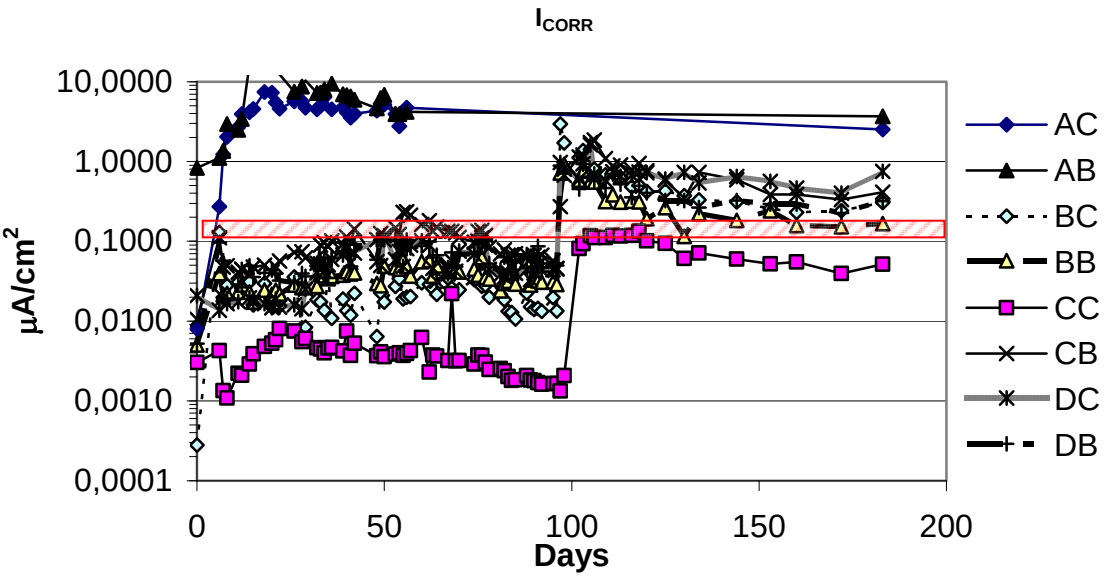

Figure 4. Corrosion rate evolution of accelerated carbonation specimens

Corrosion rate and corrosion potential evolution of the rebars embedded in repair mortars, during the accelerated carbonation tests is demonstrated in Figures 4,5 and 6. Other than the rebars in mortar A, none of the embedded steels seemed to corrode during the carbonation period until they contact to water. At the time all mortars are completely carbonated, they were immersed in water so corrosion rates were drastically increased and corrosion potentials decreased. These results prove again that steel does not depassivate in a dry concrete even if in low pH value-environments. Following the immersion in water, primer of mortar C showed the best performance followed by mortar B.

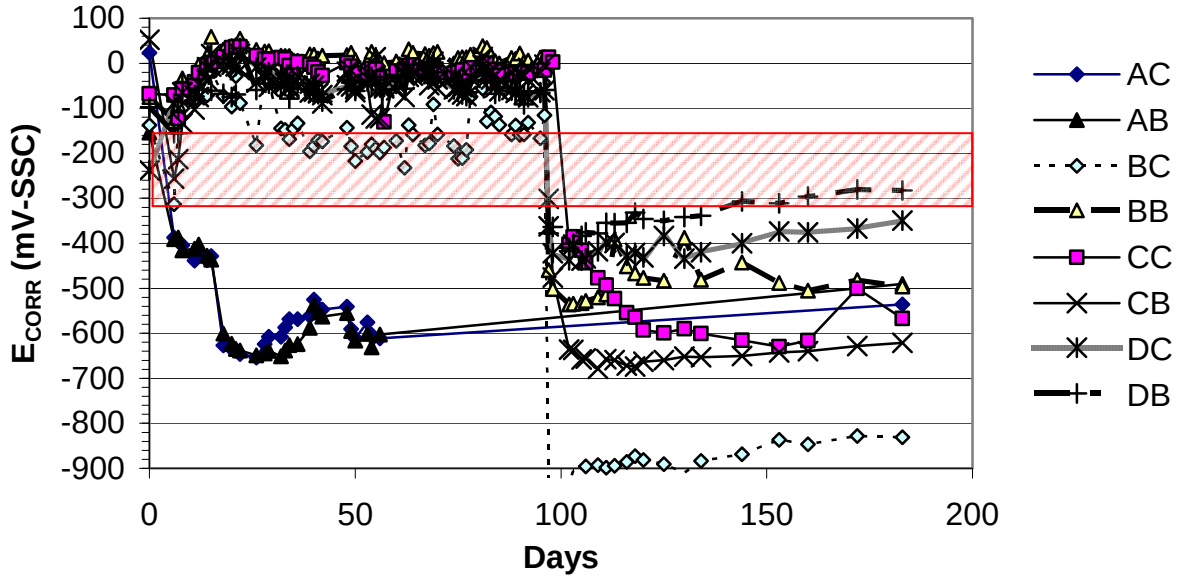

Figure 5. Corrosion potential evolution of accelerated carbonation specimens

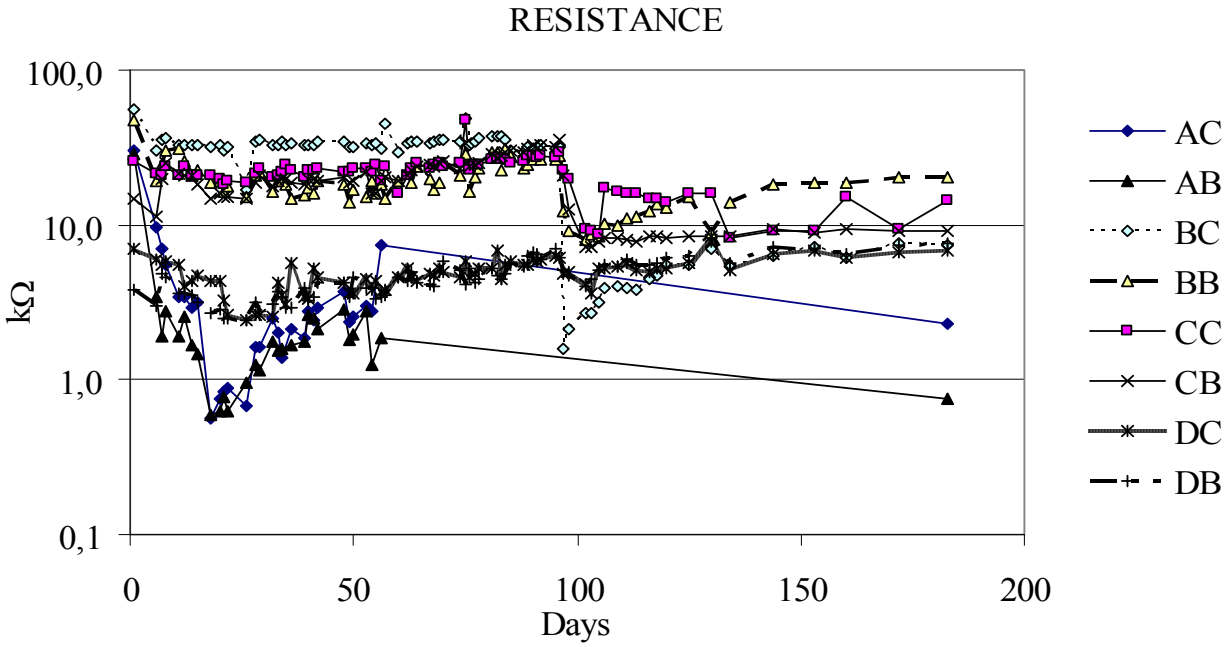

Figure 6. Electrical resistance evolution of accelerated carbonation specimens.

Results of the accelerated chloride migration test on the same mortars can be seen in Figures 7-9. Corrosion initiation of the steels in mortars by means of corrosion rate (Fig. 7) and corrosion potential (Fig. 8) was in correspondence. Also, for all mortars, bare steels started to corrode earlier than coated ones as expected. Surprisingly, onset of corrosion in mortar A was immediate as the carbonation specimens and mortar B remained passive after almost one year of 'accelerated' migration test while the latest initiation of all mortars was at about two months (mortar C). Time to corrosion initiation was similar for mortars C and D.

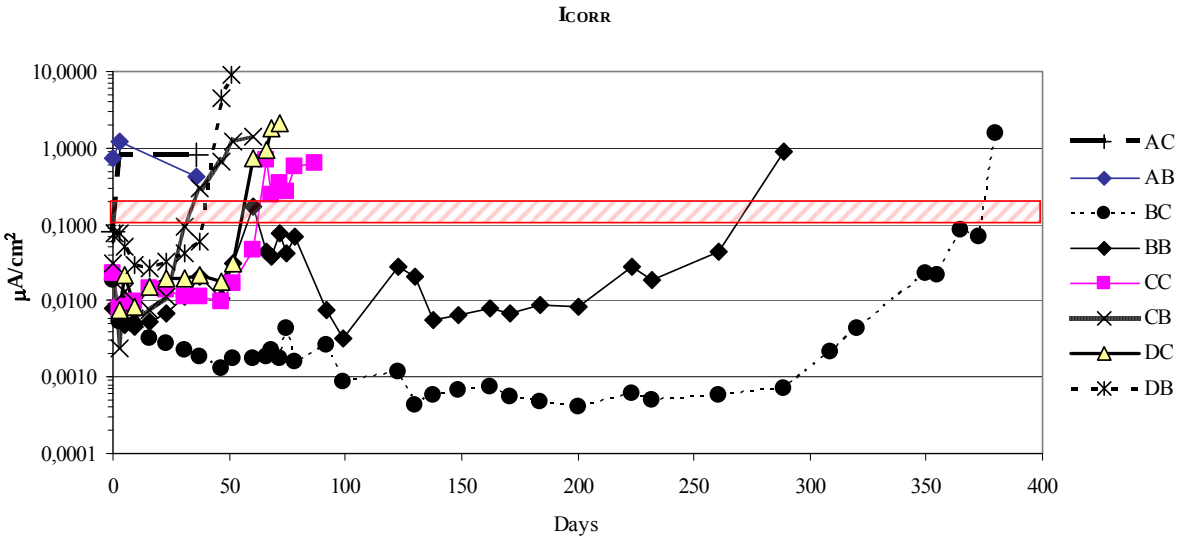

Figure 7. Corrosion rate evolution of accelerated chloride migration specimens

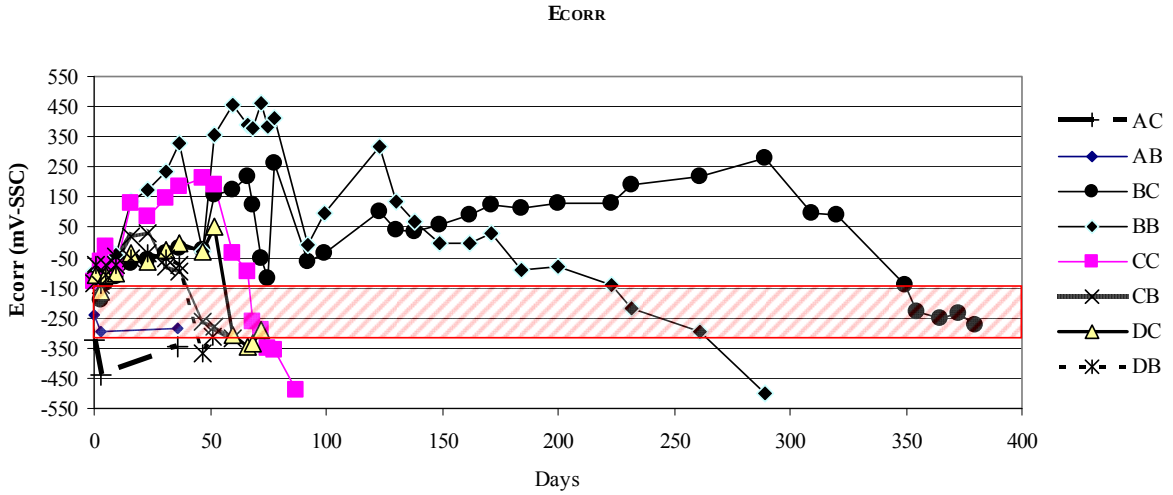

Figure 8. Corrosion potential evolution of accelerated chloride migration specimens

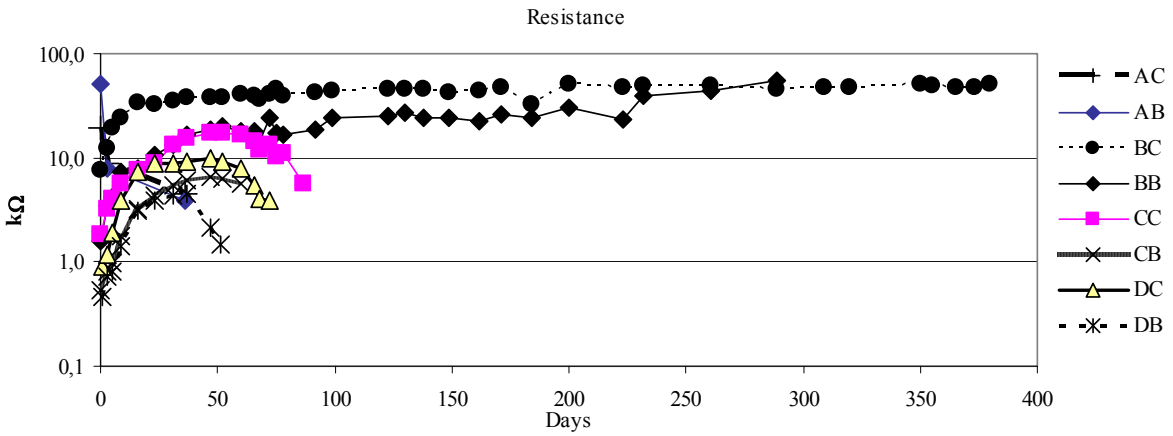

Figure 9. Electrical resistance evolution of accelerated chloride migration specimens

The pore size distribution and pore volume characterization of repair mortars is defined in Figures 10 and 11. Cumulative and incremental relative volumes by means of pore size are plotted versus pore

diameter. In Figure 11, it can easily seen that the peaks, called threshold diameter and defined as 'The highest amount of porosity per change in equivalent diameter in MIP method' [Cook & Hover 1999] are located between 1 nm and 0.01 nm. Provided these results are compared with the chloride-induced corrosion test results, it can be deducted that the smaller threshold diameters, the later corrosion initiation on account of chloride attack.

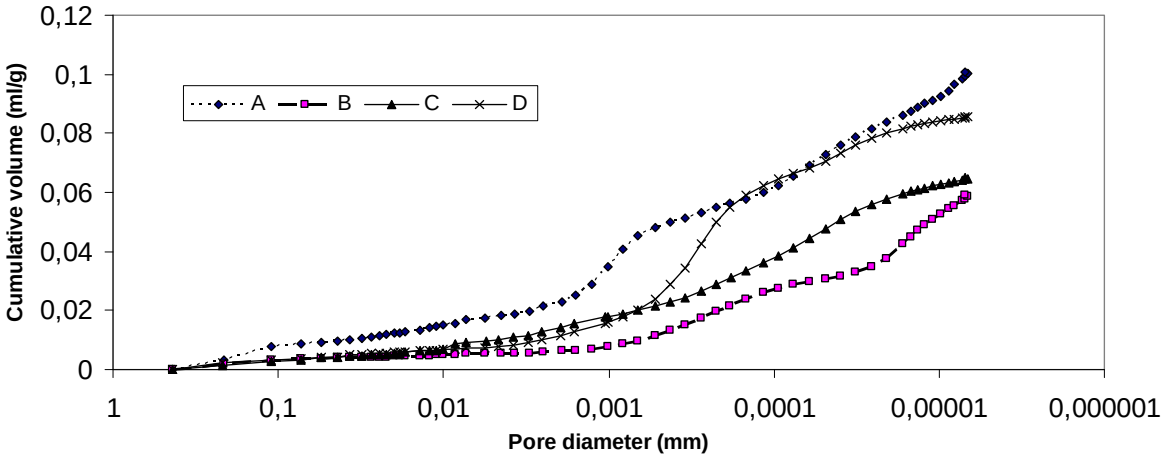

Figure 10. Cumulative pore size distribution of hardened repair mortars

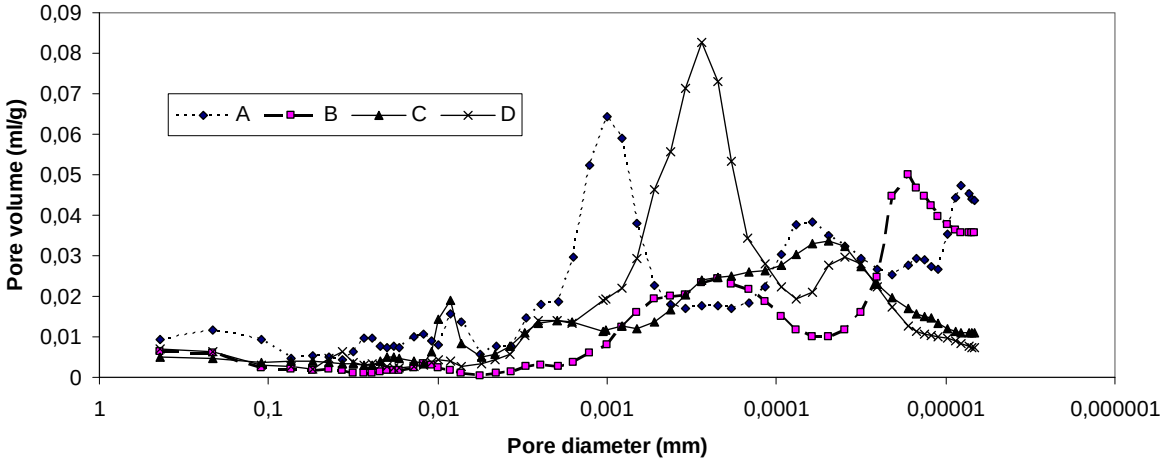

Figure 11. Incremental pore volume distribution of hardened repair mortars

4 DISCUSSION

The four different repair mortars perform very differently regarding protection against corrosion in spite the four are for the same use and purpose. In all cases the presence of a primer has been beneficial.

Regarding carbonation, primer of mortar C seemed somewhat more protective than the rest of the primers. Although mortar C had the highest amount of continuous capillary pores, coated rebars in this mortar didn't corrode after total carbonation. When an electrical field of 12V is applied to the mortars to accelerate chloride diffusion into concrete, mortar B showed an excellent performance through one year. Time to corrosion initiation was earlier but similar for mortars C and D.

Regarding the techniques to monitor the corrosionperformance, the most illustrative is the measurement of the polarization resistance because the electrical resistance or corrosion potential alone may be misleading as can be deduced from Figure 12.

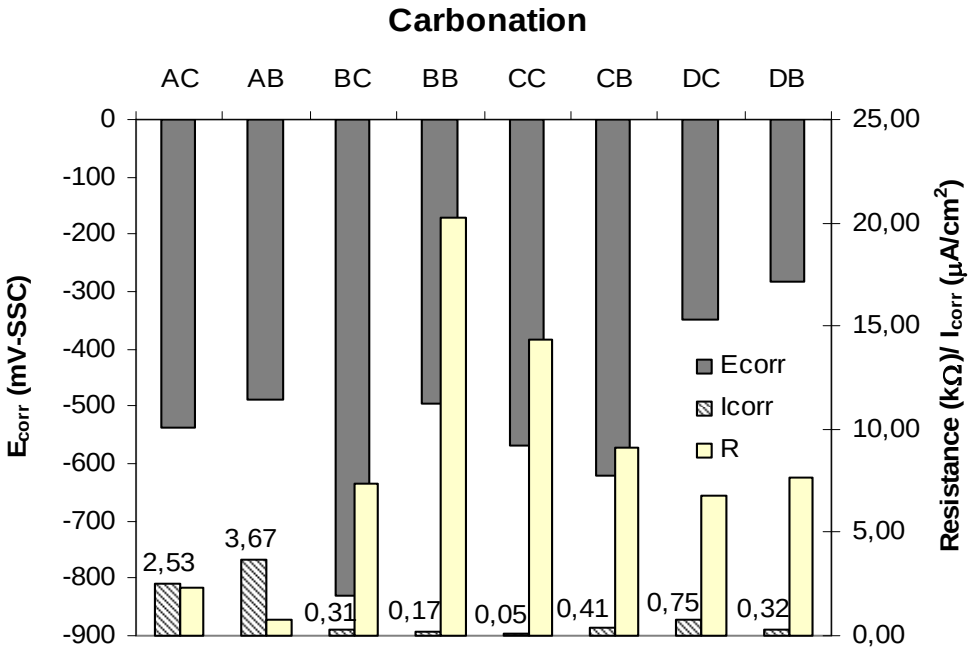

Figure 12. Ultimate values of carbonation specimens regarding with I_{corr}, E_{corr} and R_{ohm}.

CONCLUSION

Although more work is necessary to link composition of the repair mortars with corrosion performance, in present results evidences have been shown on the relation between low porosity or averaged pore radius and resistance to carbonation and chloride penetration.

The other main deduction made is that the presence of a primer has always delayed the corrosion onset and has contributed to lower further corrosion rates.

Coarse aggregate mineralogy, size and water content influence on concrete permeability

T 11

ABSTRACT

The main objective of the experimetal work carried out was the evaluation of the influence of coarse aggregates geological source, dimension and water content in the concrete permeability. Four different aggretates, obtained from different geological environments, were selected, like granite, basalt, calcareous and marble coarse aggregates. After their mechanical and physical characterization, three concrete mixtures were produced with constant volume proportions, workability, mixing and curing conditions using different sizes of each aggregate type. Concrete durability parameters, such as capillary water absorption and oxygen permeability, measured at 28 days, were found to be affected by coarse aggregate size and its water content rather than aggregate mineralogy, as presented and discussed.

1 INTRODUCTION

The most common natural coarse aggregates used for concrete production are crushed rock extracted from pits and quarries of different geological sources. In what concerns the european aggregates industry, more than 28000 extraction sites across Europe produce around 3 billion tons of aggregates per year [UPEG 2006] and a quarter of this value is used in new residential building. Regarding the production of aggregates per EU citizen per year, the average annual production represents 7 tons per citizen [BGS 2006]. Nevertheless, the economic relevance of aggregates differs significantly among the member states. While some countries are interested in recycling others have a significant internal market, being Portugal one of the countries where the aggregates industry reveals economic relevance. More than 82 millions tons of aggregates were produced in Portugal, during the year of 2004, representing about 8.4 tons per citizen [Bleishwitz & Banhn-Walkowiak 2006].

Igneous, sedimentary and metamorphic rocks represent 30, 20 and 40% of national land, respectively [IGM 2000]. Igneous rocks are mainly granites and basalts and are predominant at North and Centre of Portugal, respectively. Sedimentary rocks are of calcareous nature and metamorphic are schist, quartzite and marble, and can be extracted at Centre and South of Portugal.. "Lisboa" and "Vale do Tejo" regions are responsable for 80% of total sand produced in Portugal [Gonilho Pereira 2005].

Large urban centres, like Lisboa and Setúbal (Centre of Portugal), Braga and Porto (North of Portugal), represents the higher production and consumption of aggregates. Therefore, calcareous and granite aggregates represent more than 70% of total of aggregates produced and consumed in Portugal.Thus, in the portuguese scenario, the selection of the coarse aggregate type for concrete production is determined by its demand and production in a specific region. However the choice of aggregate type should be decided based on concrete requirements [Ribeiro *et al* 2002]. Mechanical and physical characteristics of concrete, such as density, compressive strength or abrasion, are mainly determined by the mechanical and physical properties of aggregates [Aitcin & Perraton 2001]. This experimental work presents and discusses the relevance of coarse aggregate type, dimension and water content in concrete permeability and durability.

2 EXPERIMENTAL PROGRAMME

2.1 Aggregates selection and properties evaluation

The most common and relevant aggregates from Portuguese quarrying industry, were selected for this experimental work: granite (G), basalt (B), calcareous (C) and marble (M).

Aggregates mechanical and physical properties were evaluated according to European and Portuguese standards and laboratory tests were carried out in core specimens extracted from rock as well as in coarse aggregates obtained from quarries. Compressive strength and properties related to durability were determined in rock core specimens and coarse aggregates. Core specimens were evaluated in what concerns their compressive strength [ISRM 1981], capillary water absorption [LNEC-E392 1993], absorption and capillary coefficient [NF B 10-502] [DIN-52617], and oxygen and water permeability [Pacheco Torgal *et* al 2006]. Sieve analysis, particle volume index [LNEC-E223 1968], crushing values [BS-812 1990], bulk and particle density, particle water absorption and Los Angeles abrasion were evaluated in coarse aggregates [LNEC-E227 1970]. Experimental details of equipment used and procedures for each of these tests are described elsewhere [Pacheco Torgal *et* al 2006].

2.2 Concrete mixing conditions

A total of 12 different concrete mixes were produced with the four aggregate types. For each aggregate type, three different concrete compositions were produced, and designated as mix (A1A2), mix (A1), and mix (A1SAT) [Table 1]. Coarse aggregates of different particles size, were mixed in concrete in

both dry (mix A1A2 and mix A1) and water saturated states (mix A1SAT). Faury composition method was used for each mix formulation. Parameters like cement content, aggregate size distribution, water/cement ratio and voids volume were kept constant. To maintain the aggregate particle size distribution, standard sieve analysis curves were produced in laboratory for each type of aggregates, thus obtaining a constant modulus of fineness (aggregate size A1=6,4 and aggregate size A2=7,0).

Concretes were produced with constant workability, mixing and curing conditions and were cured for 28 days, at 90% of relative humidity and approximately 20ºC constant temperature.

Table 1. Concrete mix proportions

	Aggregate type			
	Basalt	*Granite*	*Calcareous*	*Marble*
Cement CEM II/B-L 35.2 (kg/m^3)	450.0			
Water (l/m^3)	198.0			
Mix (A1A2) Sand (kg/m^3)	697.5	697.5	697.5	697.5
Aggregate A1 (kg/m^3)	511.9	475.7	459.4	502.8
Aggregate A2 (kg/m^3)	471.4	345.2	418.7	448.4
Added water during mixing (%)*	-	1.5	35	1.5
Final slump (cm)	13	11	11	13
Mix (A1) Sand (kg/m^3)	813.8	813.8	813.8	813.8
Aggregate A1 (kg/m^3)	839.9	780.5	753.8	825.1
Additional water during mixing (%)*	4	13	16	5
Final slump (cm)	10	11	10	11
Mix (A1SAT) Sand (kg/m^3)	813.8	813.8	813.8	813.8
Aggregate A1 (kg/m^3)	839.9	780.5	753.8	825.1
Water adjustment (%)**	-	-	-	20
Final slump (cm)	10	10	10	10

* Added water includes water aggregates absorption and water adjustment to obtain approximately constant workability measured by slump test (12 ±2cm).
** Water adjustment to obtain constant slump.

Mixes (A1A2) and (A1) were produced using coarse aggregates in a relatively dry state. Therefore additional water was used to compensate aggregates initial absorption, considering that aggregates can absorb 70% of total water corresponding to its saturation [Ribeiro *et al* 2002]. A second water adjustment was preformed, during mixing, to obtain maintain concrete workability. Mix (A1SAT) was produced with water saturated with dry surface coarse aggregates particles that were saturated by water immersion during 24 hours and dry surface was obtained by leaving water to evaporate, in laboratory environment.

3 RESULTS AND DISCUSSION

3.1 Aggregates properties

Mechanical and physical properties of aggregates, obtained in core rock specimens and in fine and coarse aggregates, are presented in table 2.

Basalt presents the highest compressive strength, of about 140MPa followed by granite with 100MPa. Compressive strength mean results of calcareous and marble rocks are between 60 to 70MPa. The

compressive strength results of calcareous and marble are within the minimum value (60MPa) recommended for aggregates to be used in concrete production [Coutinho 1997].

Table 2. Mechanical and physical properties of fine and coarse aggregates.

	Aggregate type				
	Sand	*Basalt*	*Granite*	*Calcareous*	*Marble*

** obtained in core rock specimens

Aggregates are considered regular, suitable for the production of ordinary concrete, whenever their bulk density is between 1200 and 1700 kg/m^3, and particle densities are between 2300 and 3000 kg/m3 [Coutinho 1997]. All coarse aggregates presented Los Angeles abrasion lower than 50%, maximum mass loss recommended for aggregate to be used for concrete production. Aggregates are considered acceptable for concrete production when present aggregate crushing value, equal or lower than 45% [Coutinho 1997], which was verified for the four different aggregates.

Calcareous presented the highest oxygen permeability while basalt and marble did not allow the oxygen penetration, in the performed test conditions. In what concerns water penetration, basalt and marble are impermeable, granite has a very low permeability and calcareous presents the highest water penetration. However, both oxygen and water permeability results were very low in all cases. Calcareous presented the highest water absorption, in opposition to the marble that presented almost none absorption.

Granite, basalt and marble are almost impermeable, presenting very low capillarity, and that calcareous is water inhibitor, presenting weak capillarity [Tables 3-4].

Table 3. Aggregates class according to its absorption coefficient [NF B 10-502].

DIN 52617 absorption class	Absorption coefficient ($kg/m^2/h^{0,5}$)	Category of the aggregate
Rapid suction	> 2	
Water inhibitor	$0,5 < A \leq 2$	Calcareous
Almost impermeable	$0,001 < A \leq 2$	Granite, basalt and marble
Impermeable	$\leq 0,001$	

Mechanical and physical properties of the four types of aggregates [Table 2, Table 3], are characteristic of regular aggregates of good quality.

Table 4. Aggregates class according to its capillarity coefficient [DIN-52617].

NF B 10502 capillarity class	Capillarity coefficient ($kg/m^2/h^{0,5}$)	Category of the aggregate
Strong capillarity	> 4	
Weak capillarity	$1,5 \leq C \leq 4$	Calcareous
Very low capillarity	C < 1,5	Granite, basalt and marble

3.2 Concretes produced

Compressive strength, determination of absorption and capillary coefficients, vacuum water absorption and oxygen permeability were carried out to characterize concrete and mortars produced, at 28 days of age.

Compressive strength test was performed in 15cm high and 7,5cm diameter size cylinders.The absorption and capillary coefficients were obtained as performed in rock cores. Permeability to oxygen and water was also carried out in cylindrical specimens of 5cm high and 4cm diameter extracted from concrete cubes. Experimental details of equipment used and procedures for each of these tests are described elsewhere [Pacheco Torgal *et* al 2006], [Pacheco Torgal & Castro-Gomes 2006].

The influence of coarse aggregate type, size, as well dry or water saturated conditions, on the concrete durability parameters were determined. The average results of the tests carried out in the different types concrete mixtures, (A1A2), (A1) and (A1SAT), are presented in tables 5, 6 and 7, respectively.

Table 5. Average test results obtained in concrete mixtures A1A2.

	Aggregate type			
	Basalt	*Granite*	*Calcareous*	*Marble*
Compressive strength (MPa)	33	35	33	33
Absorption coefficient ($kg/m^2/h^{0,5}$)	2,09	1,78	2,32	2,01
Capillarity coefficient ($g/cm^2/min^{0,5}$)	2,72	2,30	3,00	2,58
Vacuum water absorption (%)	15	15	18	15

All concrete mixes have quite similar compressive strength values, of the same level of magnitude. In concrete mix (A1A2) the compressive strength obtained is slightly higher than in other mixes, which is caused by the use of aggregates of larger particle size A2. Regarding capillary coefficients, all concrete mixes have showed weak capillarity. Some mixtures can be classified as having fast suction behaviour and others can be classified as water inhibitors in what concerns absorption coefficient results.

The highest values of vacuum water absorption results are presented by mixtures produced using calcareous aggregates. Regardless the aggregate type, (A1A2) mixtures presented higher vacuum water absorption, followed by (A1) mixtures and (A1SAT) mixtures, which have presented the lowest of all results. Following this trend,oxygen permeability is higher for (A1A2) mixtures than those obtained for (A1) mixtures, which in turn is higher than the results obtained for mixtures (A1SAT).

Considering all concrete results of absorption and capillarity coefficients, vacuum water absorption and oxygen permeability, a decreasing tendency is observed from mixes (A1A2) to mixes (A1) and (A1SAT). Thus, the production of concrete using smaller size aggregates reduces capillary and vacuum absorption, as well as permeability. This phenomenon can be explained once the existence of larger coarse aggregates contributes to the increase of path length of capillary pores and its interconnectivity and the increase of porous cement-aggregate interface zone, where absorption of water by capillary phenomenon occurs [Metha 1986]. The trend found of decreasing absorption, capillary coefficient or even oxygen permeability, is clear in all cases except in concrete produced with granite aggregates. Nevertheless, tendency of diminishing results of these tests is quite evident, particularly vacuum water absorption, which decreases in all cases of different aggregates when aggregate size is reduced and water saturated. It is possible that vacuum water absorption, that measures total open porosity, is less affected by sample drying than pores interconnectivity which may strongly affect capillary absorption or oxygen permeability.

When comparing the performance of concrete mixes (A1) and (A1SAT), it is evident that mixes with saturated aggregates present lower results than with dried ones. Since aggregate sizes did not change from mixes (A1) to (A1SAT), there is not any modification of capillary pores pathways, but rather a change of cement aggregate interface porosity might have occurred [Aitcin & Perraton 2001]. It is believed that since the aggregate is water saturated before mixing it does not absorbs water from the cement mortar fraction, during hydration. Consequently the cement aggregate interface will have lower porosity when aggregate is water saturated.

Finally the results of different properties presented in tables 5, 6 and 7, obtained in concretes produced with different aggregates are of same level of magnitude, thus indicating that aggregates mineralogy and geological source appears to not influence it significantly.

4 CONCLUSIONS

Concretes using coarse aggregates of different geological sources, granite, basalt, calcareous and marble, were produced in specific mix proportions and laboratory controlled conditions. The influence of coarse aggregate type, particle size, as well as dry or water saturated conditions, on the concrete mechanical and durability parameters were determined. It was found that aggregates type, particle size or water content during mixing does not influence significantly concrete mechanical behaviour. Regardless of aggregate geological type, concrete durability properties are significantly influenced by aggregates particles size and water content. Concrete mixtures produced using larger size aggregates presented higher vacuum water absorption and oxygen permeability, than mixtures using smaller size aggregates. Concrete mixtures using saturated aggregates presented lower vacuum water absorption and oxygen permeability than mixtures were aggregates were introduced in a relatively dry state.

T 11

ABSTRACT

This paper examines the possibility of using finely ground waste glass as partial natural sand replacement in concrete. The reduction of waste glass particle size was accomplished in the laboratory by crushing and grinding the waste glass in a jar mill. The compressive strength at 7, 28 and 90 days, was determined for different ground waste glass sand percentage replacement in concrete.

Absorption and permeability tests were also carried out. A test method was followed to verify the potential concrete expansion caused by the alkali silica reaction.

The results showed a very significant compressive strength improvement with the increasing of percentage replacement of natural sand by ground waste glass. A higher compressive strength was obtained with a lower expansion verified by the bar tests. The same trend for durability properties were also observed in this study.

The results obtained attested the high possibility of recycling and using of the ground waste glass collected in central region of Portugal as natural sand replacement in concrete mixtures.

1 INTRODUCTION

Nonrecyclabe waste glass constitutes a problem for solid waste disposal in many municipalities in Portugal. Traditionally, most nonrecyclabe mixed-colour broken glass results of the bottling industry. The current practice is still to landfill most of the nonrecyclabe glass. Since the glass is not biodegradable, landfills do not provide an environment-friendly solution. Nowadays, the civil construction industry search the alternatives for satisfy the increasing needs for the concrete production. The attractive use of the waste glass in the construction materials is caused by the fact that not all waste glass can be recycled into new glass. For the glass industry, the impurities, transports costs and mixed colour waste streams difficult the useful raw glass stocks. United Nations estimates the volume of yearly disposed solid waste to be 200 million tons, 7% of which is made up of glass the world over [Topçu & Canbaz 2004]. In Portugal, 7.5% of 4 712 458 tons of solid waste produced during 1999 and 2005 was glass. In fact, only 30% of the total used bottles are actually reuse and recycled, it means 70% is disposed as landfill. The efforts to reduce the landfilling of waste glass, because they are not biodegradable, has been done over past few decades by several others researches by studies using the waste glass as an aggregate, including Schmidt & Saia [1963], Johnston [1974], Figg [1981], Polley at al [1998] and Shayan & Xu [2004]. Our earlier results [Oliveira at al 2007] also showed that glass particles 75µm-150µm size range did not cause expansion in the accelerated mortar bar test, which agree with the observations of Shayan & Xu [2006], but according to Bazant at al [1998] the glass particle around 1.5 mm caused excessive expansions.
Using waste glass, as coarse aggregate in concrete, did not have a marked effect on the workability of concrete, but the compressive strength decrease in proportion to an increase in waste glass [Topçu & Canbaz 2004]. According to Park at al [2004], the increase in the content of waste glass fine aggregate on concrete showed a slump decrease tendency influenced by the grain shape and the fineness modulus of the waste glass aggregates. These authors observed a decreasing compressive strength along with an increase in the mixing ratio of the waste glass aggregate. They found the highest compressive strength in concrete containing 30% of waste glass aggregates.
Thus, taking in account the influence of the waste glass as fine aggregate on the concrete workability an additive was used to maintain the same slump for all mixtures tested in this work. A basic experimental study on the mechanical and durability properties of concrete containing waste glass collected in the central region of Portugal was carried out.

2 METHODS

2.1 Materials

A commercial Portland cement type CEM I 42.5R conforming to European Standards EN–197-1 with Blaine fineness of 384.8 m^2/kg and with a particle density of 3140 kg/m^3 was used for all mixes. A fly ash with Blaine fineness of 400.9 m^2/kg and with a particle density of 2380 kg/m^3 was used for all mixes As the aggregate for producing concretes, natural sand was used with maximum particle size 4.76 mm, a particle density of 2520 kg/m^3 and Modulus of Fineness of 3.47. The coarse aggregate was a 12.7 mm crushed granitic stone with a particle density of 2698 kg/m^3 .The amber waste glass was ground in a jaw crusher to produce a fine glass sand with maximum particle size 4.76 mm, a particle density of 2509 kg/m^3 and Modulus of Fineness of 2.40. Fig. 1 show the grading distribution of fines aggregates determined in according of the ASTM C136.

2.2 Concrete mixtures

A reference mix 1:0.29:1.87:3.14 (cement : fly ash : fine aggregate : coarse aggregate) with a water/cement ratio of 0.60 was used. Other mix proportions were formulated based on this mix to include the fine glass sand mentioned above. The purpose of the trial was to determine the effect of glass sand as natural sand replacement, at 25, 50 and 100% dosage rates. Table 1 gives details of the 4 mixes used in field trial.

100% CGS	350	101.5	1099	0	654.5	210

[a] GCS = crushed glass sand

2.3 Workability

The tests conducted on the fresh concrete included the slump test and flow table test, in according to EN 12350-2 and EN 12350-5, respectively. The workability was evaluated by conducting slump test in accordance with EN 12350-2. The slump for control mix was was 100 mm ± 10 mm. As the sand content increases, the slump decreases due to the reduction of equivalent fineness modulus. For concretes with sand glass content, high-range water reducer admixture was used to obtain the same workability as indicated for control mix. The dosage of admixture is about 0.2% by weigth of cement for 25% sand glass content and 0.3% for 50% and 100% of sand glass content.

2.4 Compressive strength test

The compressive strength tests were conducted, in according with EN 12390-3, at 7 and 28 days for 150 mm concrete cubes maintained in fog room (21 ± 2ºC, 100% RH).

2.5 Expansion test

The alkali silica reaction (ASR) test was was applied to check the influence of sand glass percentage replacement in concrete expansion. Three concrete bar specimens, with the dimensions 40 x 40 x 160 mm, were made for each mixing containing glass sand. Normal procedure was to cure them for 24 h, immerse them in water for 24 h, and then store them in 1 N NaOH solution at 80ºC in a closed container. Changes in the length of the concrete bars were checked for the following 14 days after their surface was dried by using a comparator, a length comparison measuring device with an accuracy less than 0.002 mm.

2.6 Capillary sorptivity test

The sorptivity tests were carried out on samples, with 7.5 x 7.5 x 15cm, after drying in oven, at a temperature of 60ºC ± 5ºC. The samples were stored until the weight loss was negligible. The preparation of samples also included water impermeability of their lateral faces, reducing the effect of water evaporation. The test started with the registration of samples weight and, afterwards, they were placed in a recipient in contact with a level of water capable to submerge them about 5 mm. After a predefined period of time, the samples were removed from the recipient to proceed to weight registration. Before weighing, the samples superficial water was removed with a wet cloth. Immediately after the weight, the samples were replaced in the recipient till reach the following measuring time. The procedure was repeated, consecutively, at various times such as 10, 20, 30, 40, 50, 60, 70, 90, 130 and 150 min (min = minutes) until the last reading. Because of small initial surface tension and buoyancy effects, the relationship between cumulative water absorption (kg/m2) and square root of exposure time ($t^{0.5}$) shows deviation from linearity during first few minutes [3]. Thus, for the calculation of sorptivity coefficient, only the section of the curves for exposure period from 10 min to 90 min, where the curves were consistently linear, was used. The sorptivity coefficient (k), was obtained by using the following expression:

$$\frac{W}{A} = k\sqrt{t} \tag{1}$$

where W= the amount of water adsorbed in (kg); A= the cross section of specimen that was in contact with water (m^2); t = time (min); k = the sorptivity coefficient of the specimen ($kg/m^2/min^{0,5}$).

2.7 Water and oxygen permeability test

For determination of concrete oxygen and water permeability it is used a permeability cell and the tests were conducted by the procedures described by Gomes at al [2002]. For these tests, cylindrical test specimens are prepared with 5cm of diameter and about 4 cm of height. This permeability cell allows submitting samples, with the referred dimensions, to a certain pressure, guaranteeing that the flow of oxygen through the sample is uniaxial. So much plus, that in the adopted methodology, specimens are first dried in oven at 60ºC, for 48 hours. The water permeability test can take place after the oxygen permeability test, in a similar way and with in the same specimen.

3 RESULTS AND DISCUSSION

3.1 Compressive strength

The compressive test results for concretes containing amber waste glass fine aggregates are shown in the Fig. 2. It was observed that with increase of amber waste glass content, the strength of concrete increase. For each mixing rate of the amber waste glass (25%, 50% and 100%), the compressive strength increased by 26%, 26% and 34%, respectively, at 7 days. For 28 days the increase was 24%, 25% and 29%. It was observed a strength development coefficient from 7 to 28 days of 1.30 for the reference mix, 1.27 for the mix with 25% of waste glass, 1.29 for 50% mixing rate and 1.25 for 100% mixing rate. These results are in opposition of the results obtained by Park at al [2004] and by Topçu & Canbaz [2004]. In general, the strength of concrete containing glass is lower than that with natural aggregate. Strengths are particularly low when high alkali cement is used. This apparent disagreement was probably caused by replacement of cement with around 30% fly-ash that demonstrated effective in controlling the large retrogression of strength. By the other hand, the use of a more fine aggregate as natural sand replacement can improve the aggregates particle packing by the filler effect. When the specific surface of aggregate is increased for a constant mix proportion, the amount of cement relative to the surface of the aggregate decreases. Lallard & Belloc [1997] state that as the maximum paste

thickness between aggregate particles decreases the compressive strength increases. In dry packing of particles, it has been observed that the highest stresses exist at the contact points of aggregate particles. Thus, when paste is introduced into the packing and it is placed between two close aggregates, the paste will be highly stressed, yielding a greater matrix strength.

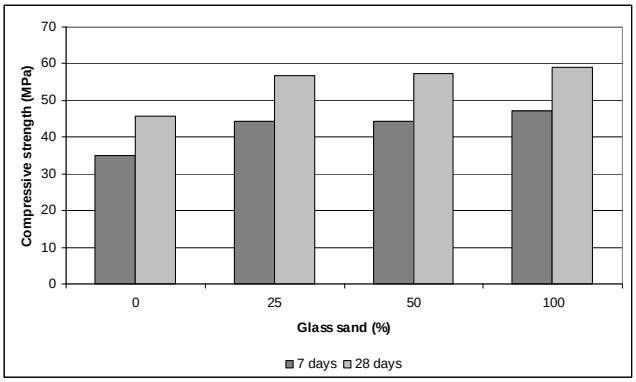

Figure 2. Compressive strength vs sand glass content for 7 and 28 days.

3.2 Influence of glass sand content on the concrete expansion

All the concretes prisms stored at the conditions described in 2.5 showed insignificant expansion (<0.1%) at the age of 14 days (Fig. 3), indicating that no deleterious alkali silica reaction expansion took place by that age. In Fig. 3, curves for mixes with natural sand replaced by 100% and 50% of waste glass sand presents an expansion development with the age inferior or similar to the control mix. Despite the expansion increasing at 14 days, about 60% more than control mix, for the mix with 25% of waste glass sand, it is observed that the fly ash content in the mixes lead for a more stable behaviour. This effect provide ample evidence that both fly ash and waste glass sand can be used together to produce concretes with relative high strength without any adverse reaction.

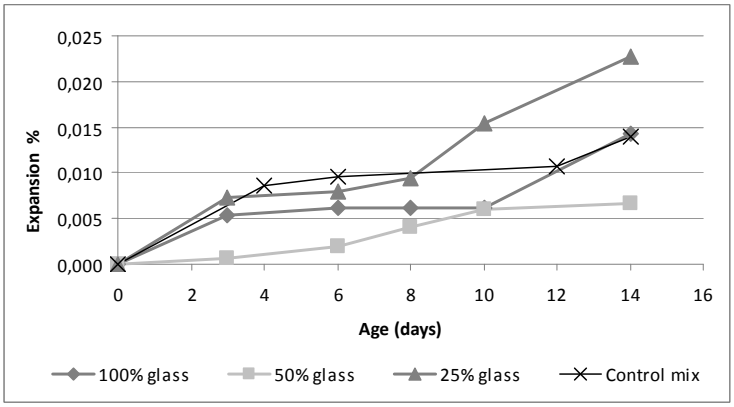

Figure 3. Expansion of concrete bars with various sand glass content imersed in NaOH solution.

3.3 Mix proportions and durability evaluation.

It was observed that the sand replacement by the waste glass sand reduced the concrete sorptivity coefficient. Fig. 4 shows that the reduction attaint a maximum of 39% for 28 days with 100% of natural sand replacement and 29% of reduction at 63 days for the same waste glass rate. This reduction can be influenced by the favorable effect of waste glass sand gradings that improve the particles packing almost certainly reducing the quantity of capillary pores.

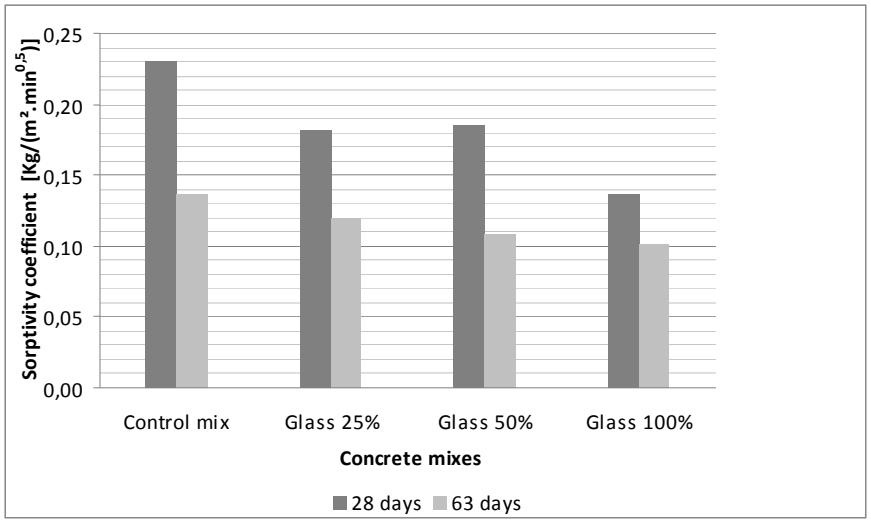

Figure 4. Sorptivity coefficient of different concrete mixes at 28 and 63 days

Figs. 5 and 6 presents the results obtained on concretes produced with different waste glass sand replacement rate. All results presented in both figures are medium values obtained from testing of 4 specimens. Fig.5 shows the influence of natural sand replacement by waste glass sand on the oxygen permeability cofficient at the concrete age 28 and 63 days. At 28 days it was observed an increase, between 20 and 30%, in the oxygen permeability for mixes with 25% and 50% of waste glass sand, but a significantly decreasing when the total natural sand was substituted by waste glass sand. In general, the oxygen permeability is reduced by an half with the concrete age evolution. At the end of 63 days the oxygen permeability of the concrete with waste glass sand is the same order of the concrete with natural sand.

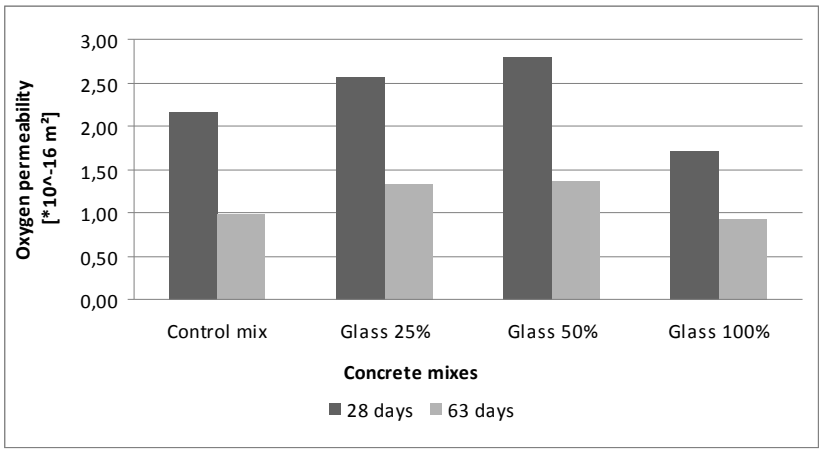

Figure 5. Oxygen permeability coefficient of different concrete mixes at 28 and 63 days.

Fig. 5 shows a similar behaviour for the concrete water permeability, which means a reducing with the time, an increase with combination of natural sand and waste glass sand and the same order values for concrete produced with waste glass sand and for natural sand.

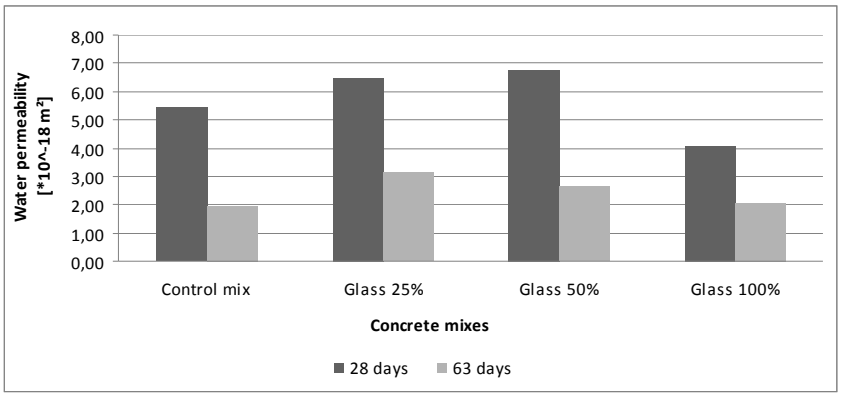

Figure 6. Water permeability coefficient of different concrete mixes at 28 and 63 days.

4 CONCLUSION

The effect of using waste glass sand in concrete mixes has been investigated. Four different mixes having a specified characteristic compressive strength of 40 MPa were prepared. It was necessary to use a high range water reducer with waste glass sand to maintain adequate workability at required constant w/c ratio. The compressive strength was increasead with the waste glass sand rate in concrete, where the alkali silica reaction was largely mitigated by addition of a suitable fly ash. The increase of waste glass sand is also beneficial to reduce the concrete sorptivity coefficient, but give a control mix similar permeability behaviour only for 100% waste sand rate. Finally, the results of this study indicate waste glass sand to be a satisfactory substitute for natural fine aggregate providing considerable economic and environmental benefits to the community.

Dubravka Bjegovic [3]

T 11

ABSTRACT

Development of novel building materials based on a cement binder, and improvement of the properties of existing materials made considerable progress at the end of last century and at the beginning of this century. One of innovative types of concrete that occurred in this period is a high-performance fibre-reinforced concrete (HPFRC). To the present day a small number of structures made of this kind of concrete were constructed. Tunnelling is one of rare fields of civil engineering in which application of HPFRC has not been closely investigated so far.

In this paper is shown an experimental research work carried out on different concrete types: Conventional concrete and high-performance fibre-reinforced concrete. Experimentally obtained values of mechanical properties of the said concrete types were used in modelling the behaviour of secondary tunnel lining. In numerical analyses, the parameters that were varied were the following: the type and cross-section of concrete in secondary tunnel lining and the type of durability loading. The analyses carried out showed that HPFRC used for fabrication of secondary tunnel lining has higher durability and safety than other concrete types.

1 INTRODUCTION

The New Austrian Tunnelling Method (NATM) is a method for excavation of large cross-section underground structures without using temporary supports. This method has been developed as a result of relevant experience, a number of measurements both on structures and models, and theoretical analyses. According to NATM, a tunnel consists of primary and secondary supports. Primary support is used to permanently support the tunnel cross-section and, in interaction with rock mass, to carry the total load. Secondary support, i.e. tunnel lining is installed after settlement and deformation of the primary support system has been completed. [Kovacevic et al. 2004]

All theories to date suggested that secondary lining has not been considered as a static portion of the system, but rather as structural and protective element and thus it is designed as such. Measurements of deformations in the secondary lining of constructed tunnels showed significant growth in stress and deformations during use. [Kovacevic 2003, University of Zagreb 2004] It was found that durability of the primary support elements is being reduced over time and the mechanical properties are being lost. Loss of mechanical properties of the primary support system results in additional load on secondary lining, causes changes in the state of stress and deformations, and consequently affects durability of the secondary tunnel lining. Such loss is caused, in most cases, by (1) creep, swelling or weathering of the rock mass, (2) corrosion of steel anchors and/or loss of shotcrete durability, and (3) creep of shotcrete. The factors influencing durability of primary and secondary support systems can be analyzed through numerical simulations. [Skazlic 2005]

In this paper a description is given of the test results obtained experimentally for main mechanical properties of conventional concrete (C25/30) and of two types of high-performance fibre-reinforced concrete (HPFRC 1 and HPFRC 2). HPFRC 1 and HPFRC 2 differed according to the values obtained for compressive and flexural strengths, and modulus of elasticity. The said materials were selected because conventional concrete is the material that is most used for installing secondary tunnel lining, and HPFRC is a new type of concrete that has not been widely used for this purpose. Compared with other concrete types used for installing secondary tunnel lining, HPFRC has much higher strengths, stiffness, toughness and durability. Such higher tensile strength and toughness of HPFRC, relative to conventional and fibre-reinforced concretes, provide the mobilization of the rock mass and thus preservation of its strength, which is one of the main principles of NATM and modern tunnelling in general. By the use of materials having higher tensile strength and toughness, higher stability and durability of structures are ensured. [Skazlic 2005, Skazlic & Bjegovic 2005]

The values of mechanical properties obtained in experimental investigation for the above three concrete types were used in modelling the behaviour of secondary tunnel lining. In numerical analyses, the parameters varied were: (1) the type and cross-section of the concrete in secondary tunnel lining; and (2) the kind of load. In addition, the durability of the secondary tunnel lining was analysed with respect to the parameters varied. The analyses carried out illustrated that loss of mechanical properties of some elements of the primary tunnel support can have significant effects on durability of secondary tunnel lining. Thus, it was established that secondary tunnel lining has higher bearing capacity and safety when HPFRC is used instead of conventional concrete.

2 EXPERIMENTAL WORK

In experimental work, the values of mechanical properties required to numerically model the state of stress and deformations in secondary tunnel lining were determined. The mechanical properties tested were the following: (1) compressive strength (according to HRN.EN12390-3 and HRN.EN196-1 standards); (2) flexural strength (according to HRN.EN12390-5 and HRN.EN196-1 standards); and (3) static modulus of elasticity (according to HRN.U.M1.025 standard). All the values of the above mechanical properties were used in the case when specimens were cured in water until the date of testing. The results are shown in Table 1. The illustration of mechanical properties tests is given in Figure 1.

Table 1. Mechanical properties of various concrete types necessary for numerical modelling.

Property	Concrete type		
	Conventional concrete (C25/30)	HPFRC 1	HPFRC 2
Compressive strength (MPa)	38.9	141.7	211.3
Flexural strength (MPa)	5.5	13.3	40.1
Static modulus of elasticity (GPa)	29.2	40.8	48.7

Figure 1. Concrete mechanical properties tests required to numerically model compressive strength (left), flexural strength (middle), and modulus of elasticity (right).

3 NUMERICAL MODELLING OF THE BEHAVIOUR OF SECONDARY TUNNEL LINING

The numerical simulation of the behaviour of the secondary tunnel lining was carried out using the final difference method by means of the Fast Lagrangian Analysis of Continua program package (FLAC).

The tunnel was modelled on the basis of the parameters of the Konjsko Tunnel constructed on the Zagreb-Split Motorway. Mechanical properties of rock mass employed in calculations were the following: ρ = 2.3 Mg/m^3, c = 100 kPa, φ = 20°, E = 200 MPa and ν = 0.3. The height of tunnel overburden was 30 metres. Primary support system was installed using shotcrete C25/30 of 25 cm-average thickness and steel IBO anchors of ϕ = 25 mm, L = 8 m, and steel RA 400/500. Non linear models of material behaviour were used in numerical modelling.

The numerical simulation of excavation stabilization with primary support system was run in the following steps (Figure 2):

1. Determination of primary state of stress,
2. Excavation phase 1.and application of shotcrete and ground anchors, and
3. Excavation phase 2 and application of shotcrete and ground anchors.

In the numerical analyses of the state of stress and deformations of the secondary tunnel lining the parameters varied were the following: (1) the type of concrete with which the tunnel lining elements were constructed (C25/30, HPFRC 1, and HPFRC 2); (2) the thickness of secondary lining (10, 20, 30 and 40 cm); and the main load on secondary tunnel lining causing the loss of its durability (failure of ground anchors; failure of shotcrete; loss of rock strength by 50 %; failure of the primary tunnel support; and loss of rock strength by 25 %). For the chosen concrete types and cross-section of the

secondary tunnel lining, and for given combination of permanent load, the maximum stresses in the tunnel cross-section obtained by parameter analysis are shown in Figures 3 and 4.

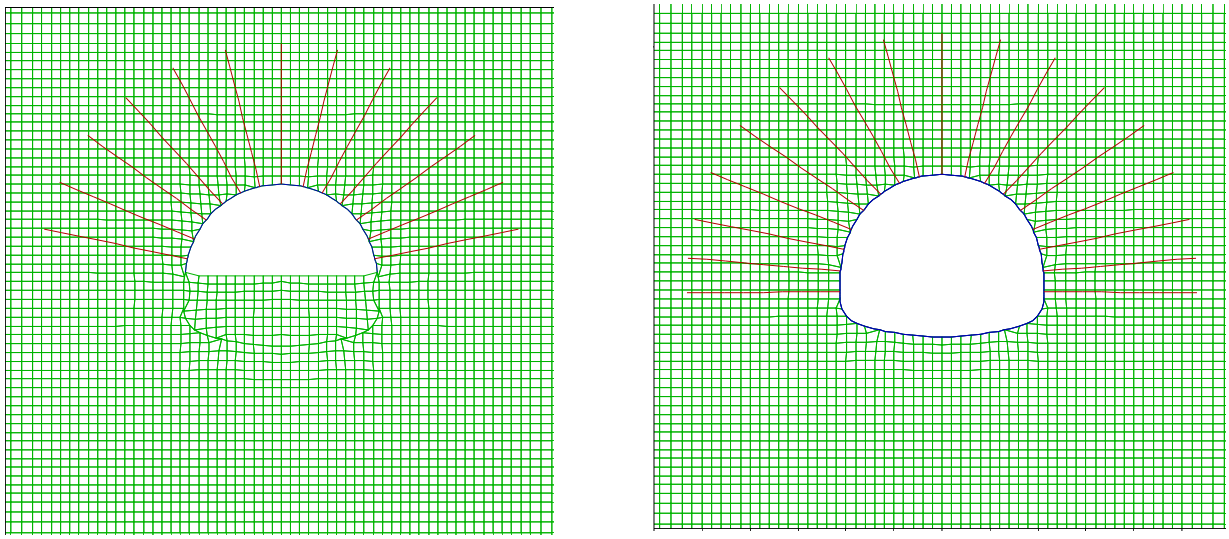

Figure 2. Numerical simulation of excavation phase 1 (left) and excavation phase 2 (right).

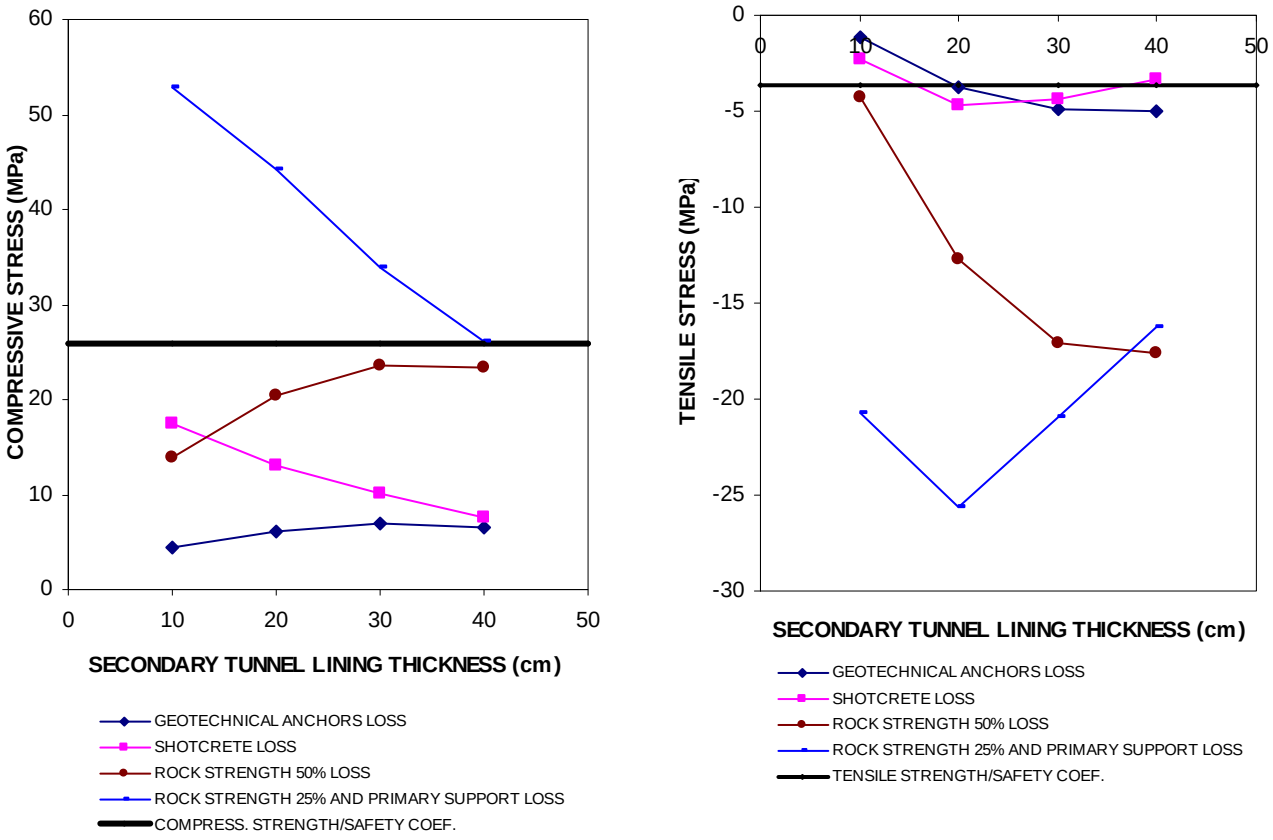

Figure 3. Results of numerical modelling of the behaviour of the secondary tunnel lining installed with concrete C25/30.

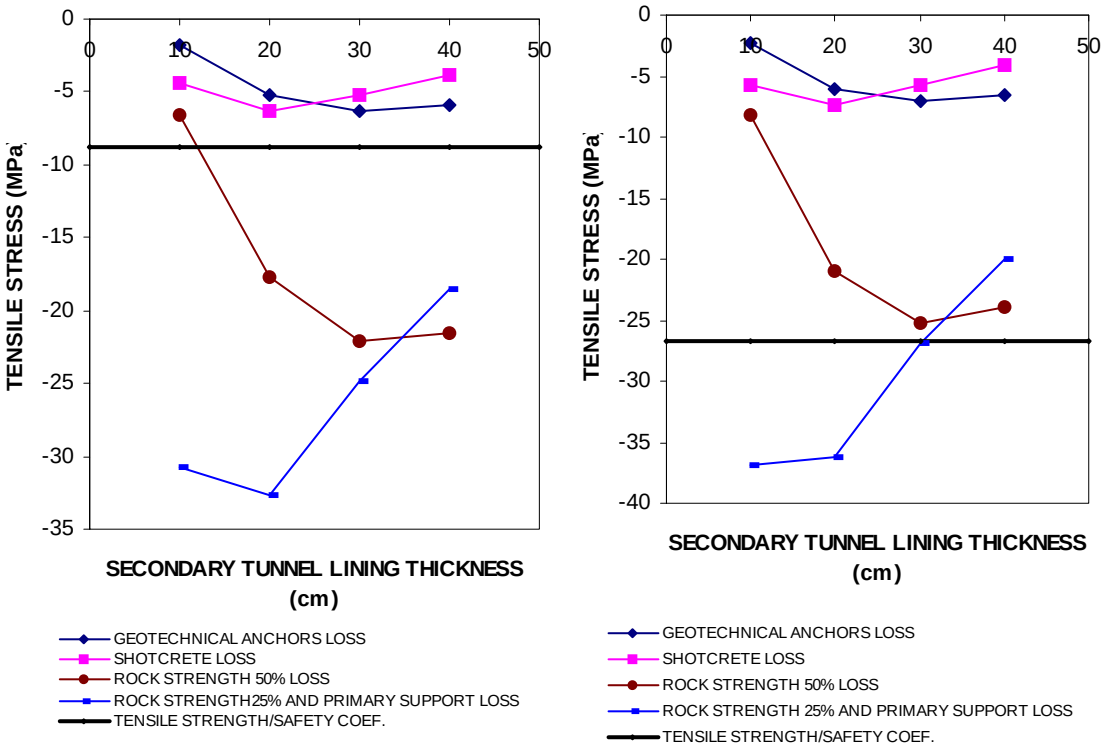

Figure 4. Results of numerical modelling of the behaviour of secondary tunnel lining with HPFRC 1 (left) and HPFRC 2 (right).

4 ANALYSIS OF RESULTS

The analysis of the results obtained for the behaviour of the secondary tunnel lining was made taking into consideration the criterion of allowed stresses (See Figures 5, 6 and 7). Resistance, i.e. computational strength of secondary tunnel lining was obtained by dividing the values of strength shown in Table 1 by factor of safety. The factor of safety used was 1.5, based on French recommendations for HPFRC. [AFGC/SETRA Working Group, 2002]

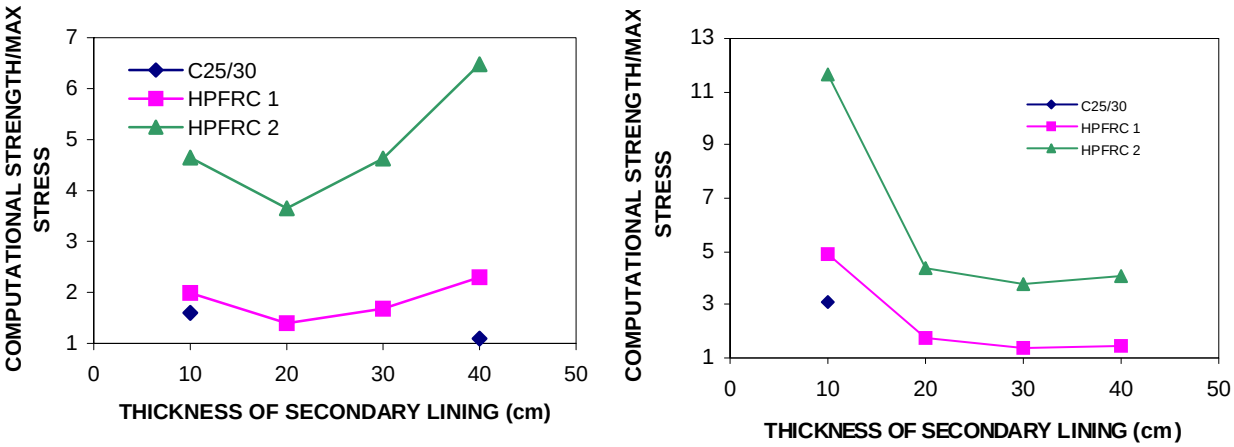

Figure 5. Safety factors in tension obtained for different types of concrete in secondary tunnel lining in the case of shotcrete failure (left) and anchors failure (right).

In Figures 5, 6 and 7, safety factors in compressive and flexural failure of the secondary tunnel lining are shown versus the thickness of secondary lining and load. The safety factor is defined as a ratio between computational strength and maximum compressive strength and/or tensile stress. Only the cases are illustrated for which the safety factor is higher than or equal to 1, i.e. in which secondary tunnel lining has permanent bearing capacity for the load analyzed.

The Table 2 presents the analysis of the results of numerical modelling of the behaviour of the secondary tunnel lining. For particular concrete types and the cross-section of the secondary lining, the cases are illustrated when bearing capacity in compression or in tension under main permanent loads is not allowed.

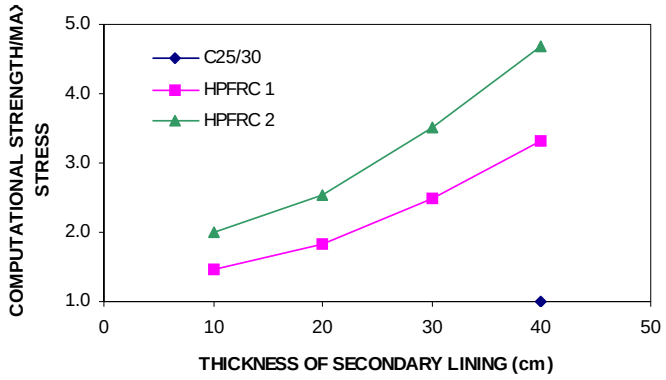

Figure 6. Safety factors in compression obtained for different types of concrete in secondary tunnel lining in the case of rock strength loss of 25 % and primary support failure.

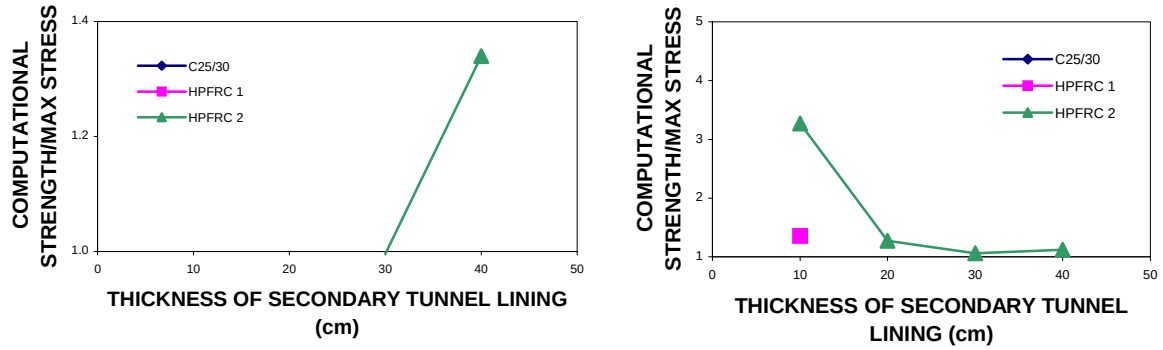

Figure 7. Safety factors in tension obtained for different types of concrete in secondary tunnel lining in the case of loss of rock strength by 25 % and primary support failure (left) and loss of rock strength by 50 % (right).

The analyses described above showed that the mixtures of new concrete types, i.e. HPFRC 1 and HPFRC 2, exhibit significantly higher bearing capacity and safety than the concrete type used so far for installation of secondary tunnel lining. As for durability aspect, it can be said that secondary tunnel lining may, in time, be exposed to high load due to loss of mechanical properties in some primary tunnel lining elements. The calculations described did not take into account extraordinary actions on these structural elements such as possible explosion from terrorist attacks. When this kind of load is considered together with permanent loads, it is safe to conclude that HPFRC is the optimum concrete composition for secondary tunnel lining because it has significantly higher safety and bearing capacity than concrete types used for this purpose up to date. As in this paper two different types of HPFRC were analyzed, when deciding between these two HPFRC types, the site conditions and total costs should be taken into account.

Table 2. Results of numerical modelling in the cases when bearing capacity of the secondary tunnel lining, due to its reduced durability, cannot to carry main loads.

Concrete type	Type of failure	Main load	Thickness of secondary lining (cm)
C25/30	tension	- primary support failure and loss of rock strength by 25 %	10, 20, 30, 40
C25/30	tension	- primary support failure and loss of rock strength by 25 % - loss of rock strength by 50 % - shotcrete failure -anchors failure	10, 20, 30, 40 10, 20, 30, 40 20, 30, 40 20, 30, 40
HPFRC1	tension	- primary support failure and loss of rock strength by 25 % - loss of rock strength by 50 %	10, 20, 30, 40 20, 30, 40
HPFRC2	tension	- primary support failure and loss of rock strength by 25 %	10, 20, 30

5 CONCLUSIONS

In this paper analyses were made of the durability of secondary tunnel lining installed with three different materials (two different types of HPFRC and conventional concrete). The material that has been most commonly used for this purpose so far is conventional concrete, and HPFRC is a new concrete type exhibiting higher tensile strength and toughness the use of which for tunnel lining is yet to be more widely applied. In numerical modelling of the behaviour of the secondary tunnel lining the experimentally obtained values of mechanical properties of these concrete types were used. In numerical analyses the parameters varied were: (1) the type and cross-section of the concrete in secondary tunnel lining, and (2) the type of load (failure of ground anchors; failure of shotcrete; loss of rock strength by 50 %; failure of primary tunnel support; and loss of rock strength by 25 %). In addition, the durability of the secondary tunnel lining with regard to the above parameters was analyzed. The analyses performed illustrate that loss of mechanical properties of some elements of the primary tunnel lining may have significant effect on durability of the secondary tunnel lining. It was also found that secondary tunnel lining has higher bearing capacity and safety when HPFRC is used for its construction instead of conventional concrete.

T 11

ABSTRACT

In last years a lot of effort has been devoted to the determination of chloride threshold values for service life prediction of concrete structures. Both data and determination methods are being collected using many different experimental conditions, either in laboratory or in real structures. Most of the information dealing with critical chlorides relates to conventional reinforcement, but there is a lack of information on chloride threshold for prestressing steel, and even practically inexistent in prestressed concrete elements.

Present paper gives preliminary results of a more ambitious experimental study being carried out in prestressed beams of 1.5m length. Four methods for chloride penetration are being considered, those are: 1) Natural-1: ponding method, using a pool on one surface of the beam, which contains the Chloride dissolution, 2) Natural-2: using wetting/drying cycles, 3) Migration test, using a field of 12V and 4) Potentiostatic test, controlling the surface potential of the wire by polarising at different potentials. The source of chloride used was a 0.5M NaCl dissolution. Besides, several methods to determine the critical time for rebar depassivation are also being used, through the measurement of E_{corr}, i_{corr}, and Potential and Current variations in the wires of the beam.

After depassivation, the profile of chloride penetration along the wires of the beams is determined through the measurement of different parameters: % of free and % of total chloride. Finally the apparent diffusion coefficient, D_{app} has being calculated. In present paper results are given from the beam tested under migration induced method, the only one between the tested methods that, till now, has shown depassivation of the wires. The D_{app} values found for the prestressed concrete beam are in the order of 10^{-10} cm^2/s.

1 INTRODUCTION

Penetration of chloride ions from de-icing salts or marine environments are common causes for degradation of concrete structures and responsible for most of the damages and investment in repair works. By these reasons efforts are being devoted in standards and construction codes in order to give rules and guidelines for designing durable structures. Also efforts are being derived to the developing of models, deterministic or probabilistic, [Andrade *et al*. 2000, Duracrete 2000, Tanner & Andrade 2000], to more accurately approach to the calculation of the service life of concrete structures; however most of them are based on Tuutti´s Model [Tuutti 1982].

Service life models consider that reinforced concrete exposed to chloride polluted environment initiate corrosion when a certain amount of chlorides arrives to the rebar surface [Lambert *et al* 1967, Hope 1987, Glass & Buenfeld 1997, Alonso *et al* 2002]. The so-called chloride threshold level is considered an essential parameter for assessing the probability of reinforcement corrosion, and becomes one of the key parameters needed for service life prediction, being of interest to have tests methods and expressions to introduce in the models.

In spite of the numerous studies performed to establish the critical chloride level for the onset of corrosion, a wide range of chloride threshold values have been suggested even using apparently similar testing conditions and materials, which makes not feasible to define a single value. Thus, a reliable quantification of the critical chloride content is considered a prerequisite for service life calculation. The reason has been attributed to the number of variables that affect the chloride threshold, among them are: the type and content of cement, the exposure conditions, the distance from the sea in marine environments, the time of exposure, the environmental temperature, the oxygen availability at the rebar surface, the type of steel, the electrical potential of the rebar surface, etc.[Rasheduzafar *et a*, 1990, Hansson & Sorensen 1990, Hussain *et al* 1995, Arya & Xu 1995, Sandberg 1995, Mammoliti *et al* 1996, Thomas 1996, Pettersson 1996, Glass & Buenfeld 1997, Alonso *et al* 2002]. Besides, few of these studies include statistical approach to the problem [Breit & Schiesl 1995, Izquierdo *et al* 2004]. Other reasons exist for a non unique chloride threshold value derived from the methodology employed to detect depassivation and the parameter to express the threshold [Hausman, 1967, Lamdberg *et al* 1991, Kayyali & Hake 1995, Arup 1996, Alonso *et al* 2002, Castellote *et al* 2002]. From this analysis it can be concluded that, at present, a significant lack of critical analyses on the chloride threshold is observed resulting in a large uncertainty in the values used for reinforcement. It is therefore a great practical importance to reduce this uncertainty based on a common approach supported by appropriate experimental investigations.

When dealing with prestressing structures the knowledge concerning chloride threshold is practically inexistent; however construction codes include different levels for prestressing steel. In fact present codes specify a lower value for prestressing steel (0.2%) than for reinforcing steel (0.4-0.6%). The reasons for this difference are unclear and should be clarified on the basis of understanding of the corrosion process and experimental determination of chloride levels. Present paper gives an initial attempt to determine chloride threshold values in prestressed concrete beams.

Relatively small samples can be acceptable for reinforcement chloride threshold determination to be used in the laboratory. But for prestressing concrete, not only the steel composition changes, but also the wire works under load (70-80% max. load), what makes unsuitable the use of similar samples than for conventional concrete. Beams are being used in this work having a 1.5 m length of exposed steel wire, which makes feasible to perform several determinations of chloride threshold at the wire level and to perform statistical analyses of chloride threshold levels. Four penetration methods are being used: two Natural methods, ponding and wetting/drying Cycles, one Potentiostatic method, controlling the surface potential of the wire and one Migration method, using an electrical field.

2 EXPERIMENTAL PROCEDURES

2.1 Prestressed Beams Preparation

Prestressed concrete T beams of 1.5m length are being used for the experimental study. The beams were fabricated in an industrial line and cut from a 140m initial prestressed concrete element. Three prestressed ribbed wires of 5mm in diameter were embedded, two at 1.5 cm and separated 5cm and the third wire centred at 8 cm, as shown in figure 1. The beams were fabricated using 380k/m^3 of 42.5 OPC, the slump of the concrete was 1-2 cm (dry) and 40 MPa of compressive strength. After fabrication the elements were left for hardening during 3 days covered with a plastic to avoid drying, then were cut into beams of 1.5m.

Three faces of the T beams were painted with epoxy resin in order to prevent the interaction with the atmosphere. A pool was fixed on the biggest face "Fig 1" in order to introduce the 0.5M NaCl solution for chloride penetration tests. Electrical cables were welded to the wires that appear at the lateral faces of the beams.

Initially water was included in the pool for 20 days and the passive state of the steel wires was confirmed through the measurement of corrosion potential, E_{corr} and corrosion rate, i_{corr}. Mean values of E_{corr} in the order of -175 mV vs. SCE and $i_{corr} < 0.1$ μA/cm^2, (mean $i_{corr} = 0.06$μA/cm^2) indicate the passive state.

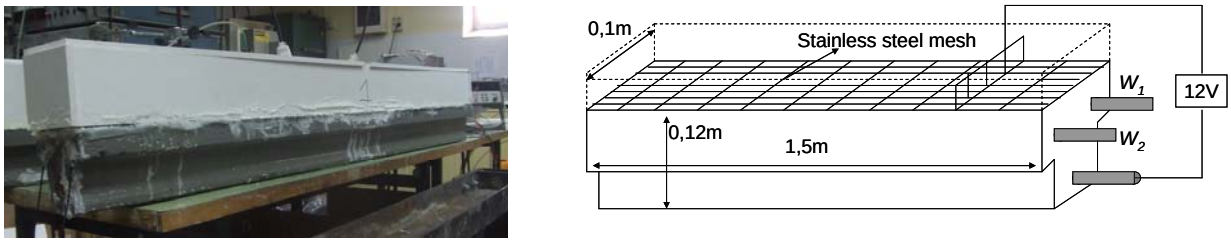

Figure 1. Prestressed T beam dimensions, with a pool fixed at the surface containing 0.5M NaCl (left) and connections for accelerated Cl penetration test (right).

2.2. Chloride Penetration Tests for Chloride Threshold Determination

Four different types of tests are being carried out: 2 considered as natural (ponding and wetting/drying), 1 potentiostatic method and 1 accelerated, the migration induced method.

In the natural-1 method, the pool containing the chloride is maintained continuously and periodically the E_{corr} and i_{corr} of the wires are measured in order to identify the initiation of corrosion. In the natural-2 method, wetting and drying cycles are employed; the pool is maintained with the chloride solution for two weeks and then emptied and leaved for drying during one week. E_{corr} and i_{corr} of the wires are also measured during the wetting period. The criteria for corrosion initiation were: stable measurements of $E_{corr} < -350$ mV SCE or $i_{corr} > 0.2$ μA/cm^2

Potentiostatic method, the wires are continuously polarised at a constant potential, in this case the potential selected was -350mV SCE through a potentiostat and a silver/silver chloride electrode. A stainless steel mesh was used as external counter electrode introduced inside the solution. Periodic monitoring of the current evolving from the system is recorded, for the individual wires and for the whole system. When the system is suffering a sharp and continuous increase of the current above 0.2 μA/cm^2 is considered as criteria for depassivation and pitting corrosion initiation, as demonstrated in a previous paper [Alonso *et al* 2002].

Finally a more accelerated test was employed, the migration induced method, as described in [Castellote *et al* 2002]. In this case an electrical field of 12 V is applied between two counter electrodes. The field has been imposed from an external counter electrode (stainless steel mesh) connected to the negative pole of the power supplier and the rebar embedded at 8 cm was connected to the positive pole, so that chlorides penetration is accelerated from the pool to inside the concrete. The two wires embedded at 1.5cm are affected by the action of the electrical field and suffer an inductive polarisation. During the test a continuous record of the potential of the wires, using Mn/MnO_2 electrode and a multi-channel data logger, was made. The electrical field was switch off when a sharp evolution of the potential of the wire to more positive values is detected, considered as indicative of pitting corrosion; although the electrical field was maintained longer to guarantee that the pits activity is permanent. Also periodically the electrical field is switched off and maintained for 1 hour to reach stable values of E_{corr} and i_{corr} of the wires to contribute to more accurate determination of depassivation time, evolution to more negative potentials in the E_{corr} or to high i_{corr} values are considered indicative of activation of corrosion.

2.3. Chloride Content Measurements

Two methods are being employed to identify chloride penetration:

a) % of free Chlorides at the rebar level, determined through titration of soluble chlorides in water, and expressed by weight of cement.
b) % of total Chlorides, determined by XRF and expressed by weight of cement, used to profile penetration and content distribution at the rebar level

The chloride content was determined in small concrete samples taken 5 mm as maximum from the rebar level and at several points along the beam. Also concrete cores of 5 cm in diameter were taken between the two parallel wires, in order to determine the profile of chloride content and for further calculation of the chloride diffusion coefficient of prestressed concrete.

3 RESULTS AND DISCUSSION.

3.1 Influence of the Method on the Determination of the Onset of Corrosion

The two natural tests used have showed no signs of corrosion initiation after five months of exposure of prestressed beams to chloride penetration in the E_{corr} measurements and neither in the i_{corr}. Values above -350mV, SCE and $i_{corr} < 0.1\ \mu A/cm^2$ respectively were recorded, as shown in 'Fig. 2 left' for wetting and drying test.

With regard potentiostatic test, the initial values of the current measured were around $0.2\mu A/cm^2$ that diminishes within three months up to $0.08\ \mu A/cm^2$. Around four months the current again increases up to $0.3\ \mu A/cm^2$ and maintain till 1 year, as showed in 'Fig. 2 right', however a continuous increase of the current was not detected. Finally after 15 months the potentiostatic polarisation was switch off and the E_{corr} and i_{corr} of the wires was measured in order to better identify the corrosion state. Values of $E_{corr} \approx$ -125 mV, SCE and $i_{corr} \approx 0.05\mu A/cm^2$ were measured which confirm the passive state.

In previous work [Alonso *et al* 2002] was detected that the critical chloride threshold linearly increases for surface potential of the rebar below -200mV/ SCE, (from 0.5-0.7% at -200 mV to 1-1.5% at -350mV/SCE). The reason was attributed to differences in composition and homogeneity of the passive layer as the polarisation potential becomes more negative. Chloride threshold values determined at more positive potentials, > -200mV/SCE, do not affect Cl^- threshold and significantly reduce the test duration for the onset of corrosion. This region of potentials is more representative for passive state of concrete structures at the atmosphere. Further experiments at potential values within the region that do not affect the chloride threshold will be also carried out.

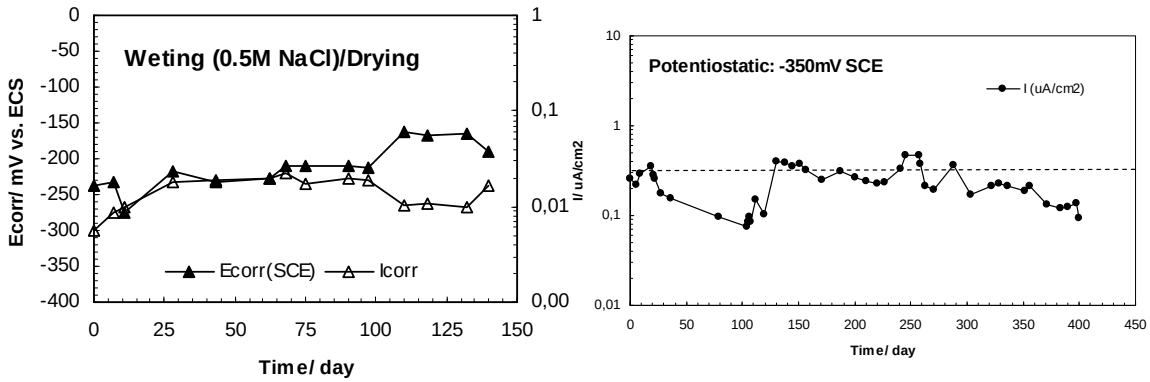

Figure 2. E_{corr} and i_{corr} evolution of prestressed wires exposed to wetting/drying cycles in 0.5M NaCl (left). Current evolution of the prestressed wires of the beam polarised at -350mV/SCE (right).

The migration test has been more accelerated and after 60 days of testing, rebar showed signs associated to pitting corrosion initiation. The inductive potential polarisation (V) measured in the wire evolves from -1V/SCE to +0.5V/SCE, as can be observed in 'Fig. 3' identified as 1st pitting. Simultaneously a decay to more negative values of the E_{corr} of the wire (< -500mV SCE), square points of 'Fig. 3 left', and high $i_{corr} \approx 1$ μA/cm^2, square points of 'Fig. 3 right', were also measured. However if the electrical field is maintained, a new decay of the inductive potential of the wires to more negative values is newly observed, which has being interpreted as a repassivation of the initial pits, also followed by increase of E_{corr} and decrease of i_{corr}. At longer testing times, 140 days, a new evolution of the polarised potential of the wires to more positive values is detected and interpreted as 2nd pitting, which also corresponds with decay of E_{corr} and increase of i_{corr}. These last positive polarisations of the wires are maintained with time and indicate that pitting is permanent.

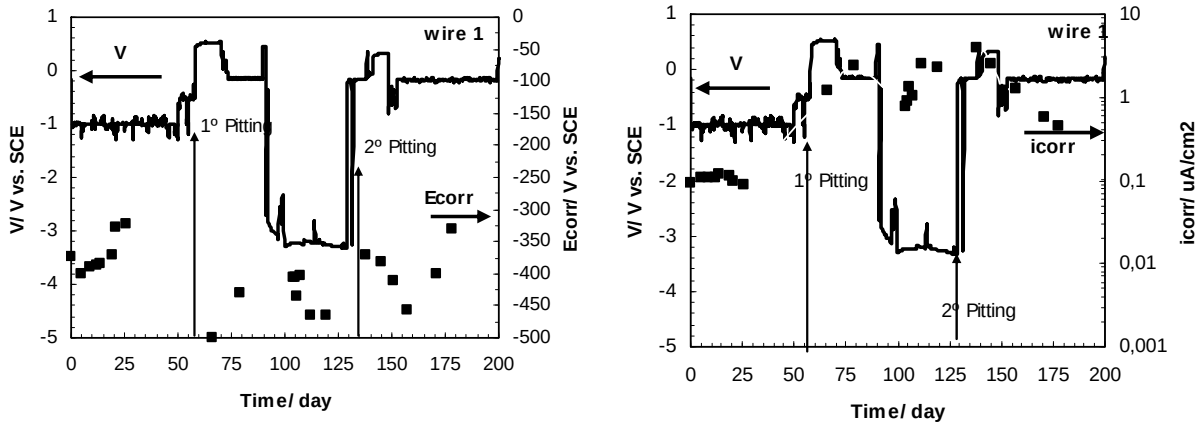

Figure 3. Inductive polarisation potential of beam prestressed wires exposed to chloride threshold migration test. Evolution of E_{corr}, (squares-left) and i_{corr} (square right) at depolarisation.

3.2 Chloride Penetration. Profile and Diffusion Coefficient Determination

The chloride profile was determined in concrete cores taken at 30, 60, 90 and 120 cm length of the beam. The profiles, given in 'Fig. 5 left', show a decrease in chloride content with the concrete depth, at 0.5 cm, 1.2-1.6% total Cl^- by weight of cement, and decreasing to 0.2-0.5 % at 3 cm. The total chloride content expected at the rebar level varies from 1 to 1.4%.

The profiles of the total chlorides represented in 'Fig. 3 left' have being used to determine the non-stationary diffusion coefficient of the concrete of the prestressed beam. The migration diffusion coefficient, D_{mig}, has been determined, from the use of a modified Fick's second law [Andrade *et al*

1994] and following the suggestion of a previous paper [Castellote *et al* 2002] the D_{app} of the prestressed concrete of the beam has been obtained.

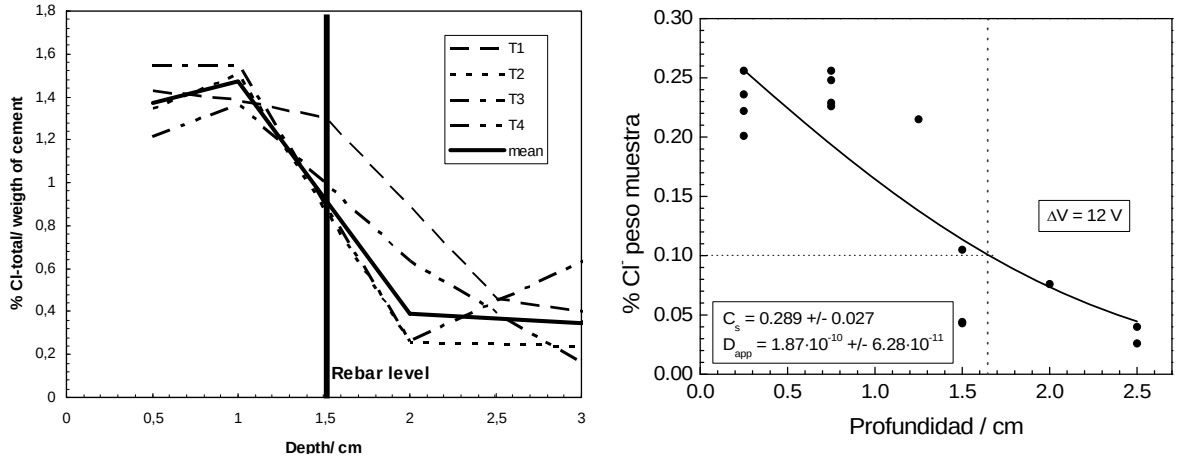

Figure 4. Chloride profiles in the concrete cores, in % total Chloride by weight of cement (left). Chloride profile for apparent diffusion coefficient determination (right)

A mean value for a D_{app} of $2.65 \cdot 10^{-10} \pm 7.32 \cdot 10^{-11}$ has been found. Table 1 shows the D_{app} coefficients for each core and the average. These values are more than one order of magnitude lower to those published in literature for conventional concrete, non prestressed. However further tests are needed from non accelerated chloride penetration methods to confirm previous values.

Table 1. D_{app} of concrete prestressed beam calculated from migration coefficient test

T1 (cm^2/s)	*T2 (cm^2/s)*	*T3 (cm^2/s)*	*T4 (cm^2/s)*	*Media (cm^2/s)*
$4.31 \cdot 10^{-10}$ $\pm 1.68 \cdot 10^{-10}$	$1.91 \cdot 10^{-10}$ $\pm 1.38 \cdot 10^{-10}$	$1.54 \cdot 10^{-10}$ $\pm 1.45 \cdot 10^{-10}$	$2.95 \cdot 10^{-10}$ $\pm 1.67 \cdot 10^{-10}$	$2.65 \cdot 10^{-10}$ $\pm 7.32 \cdot 10^{-11}$

At the end of the migration experiment, the chloride content distribution near the rebar surface was determined at different points along the beam, in order to know the variability of the chloride threshold. The % of total amount of chlorides and the free chlorides were analyzed. “Figure 5 left” shows the results. The average % for free chlorides is 1.37±0.34 and for total chlorides 1.73±0.48% by weight of cement. After broken and observations, the wire surface shows pits with different sizes. These pits are more developed in areas with higher free chloride content.

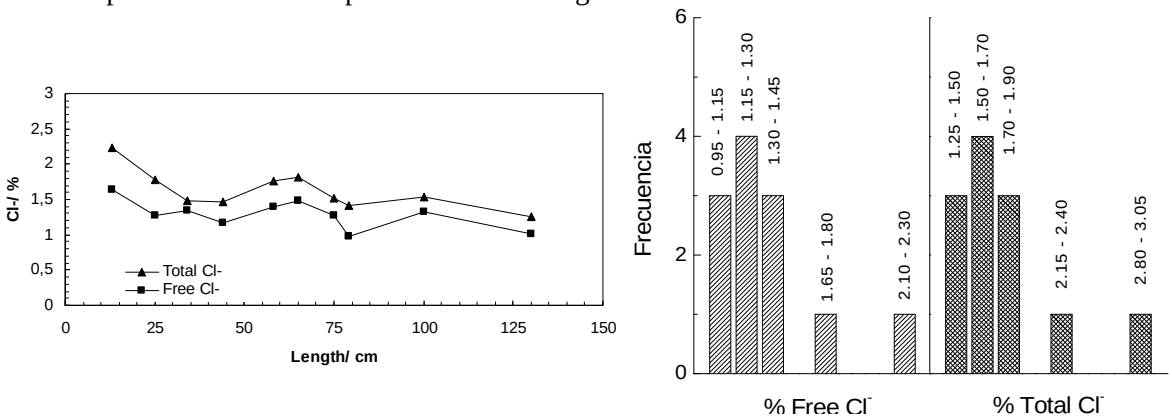

Figure 5. % of total and free chlorides content, in weight of cement at the rebar level (left)**.** Chloride distribution probability at the wire level (right).

The statistical distribution of the chlorides values shows that the higher probability of chloride threshold at the rebar level is around 1.15 to 1.30 for free chlorides and 1.5 to 1.7 for total Cl^-, as shown in "Fig. 5 right". Besides, more than 70% probability of free Cl^- content is among 1 to 1.5, and for total chloride the 80 % is between 1.2 to 2%. However these chloride thresholds can be considered representative if corrosion pits are completely developed and certain penetration of attack is accepted. However lower values should be found if the time for first pitting is considered, as shown in "Fig. 3"

4 CONCLUSIONS

From the preliminary results presented in the paper several conclusions have been derived:

- It has been possible to develop an experimental procedure for determining chloride threshold using real prestressed concrete samples.
- Several methods have been considered based on natural or accelerated determination, which varies significantly the time to onset of corrosion.
- The accelerated method based on migration has been confirmed to be a method able to give information on chloride threshold in reasonable testing time. The method has allowed the simultaneous determination of the time to depassivation at different levels of corrosion.
- The higher dimension of the samples needed for prestressed concrete, which includes large length of wire exposed, allows on the same sample several determinations of chloride threshold at the wire surface and to perform statistical analyses.
- The simultaneous determination of D_{app} is possible from the same test sample.

ABSTRACT

Carbon fiber reinforced polymer (CFRP) materials are currently produced in different configurations and are widely used for the strengthening and retrofitting of concrete structures and bridges. Recently, considerable research has been directed to investigate the use of CFRP strips as near surface mounted (NSM) reinforcement, primarily for strengthening applications. The technique is based on fixing, by epoxy adhesive, CFRP strips into pre-cut grooves made on the concrete cover of the elements to be strengthened. In several cases the NSM technique has shown substantial advantages when compared with externally bonded laminates.

This paper investigates the flexural behaviour of reinforced concrete beams strengthened with NSM CFRP laminate. A simple and direct analytical procedure for evaluating the ultimate flexural capacity of NSM CFRP strengthened reinforced concrete beams is presented. The procedure is derived from equilibrium equations and compatibility of strains and is applicable to both singly and doubly reinforced concrete rectangular sections. Upper and lower limits of NSM CFRP strips that may be bonded into slits made on the concrete cover of a reinforced concrete cross section to ensure ductile behaviour are established. Design charts to facilitate the implementation of the procedure were also developed. The procedure is validated by comparisons with results of some experimental data available in the literature.

1 INTRODUCTION

Fiber-Reinforced Polymers (FRP) materials have been used extensively, in different configurations and techniques, in the last decade for strengthening bridges and buildings. Externally bonded (EB) FRP sheets and strips are currently the most commonly used technique for flexural and shear strengthening of concrete beams and slabs. This method of strengthening has been the subject of extensive experimental investigations, and codes and design guidelines have been published that address many aspects of this technology. Several researchers reported that the failure of concrete members strengthened with EB FRP sheets or strips could be brittle due to debonding and/or peeling of the FRP reinforcements especially in the zones of high flexural and shear stresses [Spadea *et al.* 1998]. To improve the efficiency of this technique, some anchorage systems have been proposed [Khalifa e*t al.* 1999]. However, the reinforcing performance of these composites can be negatively affected by the effect of freeze/thaw cycles, significantly decreased when submitted to high and low temperatures and are also susceptible to vandalism acts.

To minimize these problems, to improve utilization of the FRP materials, and to ensure long service life for the selected system, near-surface mounted (NSM) reinforcement was recently introduced as a promising strengthening technique and a valid alternative to the EB FRP technique for increasing flexural strength of reinforced concrete members [De Lorenzis e*t al.* 2000, Taljesten e*t al.* 2003, El-Hacha e*t al.* 2004]. In the NSM FRP method, grooves are first cut into the concrete cover of an RC beam/slab and FRP bars/strips are then inserted and bonded therein with an appropriate binding agent typically epoxy paste or cement grout. Configuration of the FRP reinforcements used for the NSM technique is controlled by the depth of the concrete cover.

Compared to externally bonded FRP reinforcement, the NSM system has a number of advantages [De Lorenzis & Teng 2007]: (a) the amount of site installation work may be reduced, as surface preparation other than grooving is no longer required (e.g., plaster removal is not necessary; irregularities of the concrete surface can be more easily accommodated; removal of the weak laitance layer on the concrete surface is no longer needed); (b) NSM reinforcement is less prone to debonding from the concrete substrate; (c) NSM bars can be more easily anchored into adjacent members to prevent debonding failures; this feature is particularly attractive in the flexural strengthening of beams and columns in rigidly-jointed. Thus, this method is relatively simple and considerably enhances the bond of the FRP reinforcements, thereby using the material more effectively.

Published literature on the use of NSM FRP rebars and strips for structural strengthening is still very limited when compared with that of EB FRP sheets and strips. This paper presents a design procedure for flexural RC beams with NSM CFRP reinforcement. The procedure is derived from equilibrium equations and compatibility of strains and is applicable to both singly and doubly reinforced concrete rectangular sections. Upper and lower limits of NSM CFRP ratios to ensure ductile behaviour are established. Design charts to facilitate the implementation of the procedure are also presented. Some experimental results currently available on this topic are used as basis and support to the proposed equations.

2 SECTION ANALYSIS

2.1 Failure Modes

The possible failure modes of beams flexurally-strengthened with NSM CFRP reinforcement are of two types: those of conventional RC beams, including concrete crushing or NSM CFRP rupture generally after the yielding of internal steel bars, for which the composite action between the original beam and the NSM CFRP is practically maintained up to failure, and ‘‘premature’’ debonding failure modes which involve the loss of this composite action. Although debonding failures are less likely a problem with NSM CFRP compared with externally bonded FRP, they may still significantly limit the

efficiency of this technology [De Lorenzis & Teng 2007]. In the present analysis, it is assumed that the beam is properly detailed so as to preclude debonding failure modes.

2.2 Assumptions of Present Analysis

The design equations presented herein are based on the following assumptions:

- Linear strain distribution across the section depth.
- Compressive force in concrete, at crushing, is determined by Whitney's equivalent rectangular stress block. The ultimate compressive strain in concrete is assumed to be 0.0035.
- Tensile stresses in concrete, at ultimate strength, are ignored.
- Reinforcing steel is assumed to have elastic-perfectly plastic response.
- CFRP behaves linearly up to brittle failure since its fibres are aligned with the beam axis.
- Perfect NSM CFRP strip bond is considered for strain compatibility equations.
- The governing failure mode is concrete crushing, preceded by steel yielding, prior to CFRP rupture. A minimum NSM CFRP ratio is formulated to ensure this failure mode.

3 DESIGN OF SINGLY REINFORCED RECTANGULAR SECTIONS

The approach developed by Hayder [Hayder & Shariq 2003] is followed here, as closed form equations are formulated to establish a direct procedure for flexural strength design of FRP-strengthened beams. They differ from the current state of the art iterative procedure which may lead to tedious calculations [Chaallal e*t al.* 1998, EI-Mihilmy e*t al.* 2000]. Referring to figure 1, the force equilibrium equation is used to define the CFRP strip ratio as follows:

$$f_c\, a\, b = A_s\, f_y + A_f\, f_f \tag{1}$$

$$A_f = \frac{f_c\, a\, b - A_s\, f_y}{f_f} \quad \text{with} \quad f_c = 0.85\, f_c' \quad \text{and} \quad a = 0.8\, x \tag{2a}$$

$$\rho_f = \frac{f_c}{f_f} 0.8\alpha - \rho_s \frac{f_s}{f_f} \tag{2b}$$

where $\rho_f = \dfrac{A_f}{b\,d}$, $\rho_s = \dfrac{A_s}{b\,d}$ and $\alpha = \dfrac{x}{d}$.

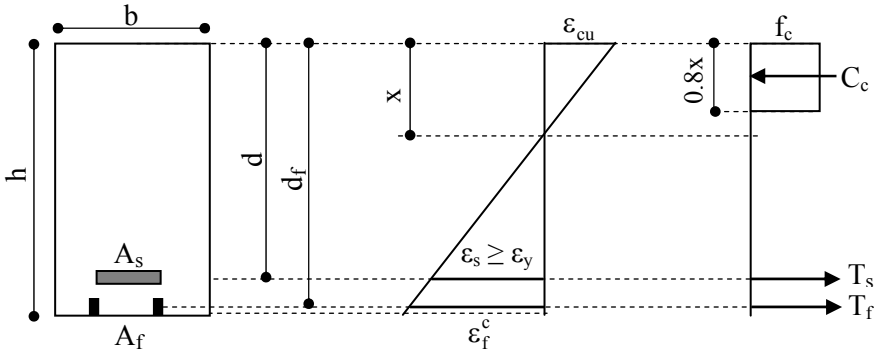

Figure 1. Singly reinforced cross-section with strain distribution and force profile.

Using strain compatibility, the strain in the NSM CFRP strip ε_f^c is given by

$$\varepsilon_f^c = \frac{d_f - x}{x} \varepsilon_{cu} \tag{3}$$

Considering that $\alpha_d = \frac{d_f}{d}$, the above equation is rewritten as follows

$$\varepsilon_f^c = \left(\frac{\alpha_f}{\alpha} - 1\right)\varepsilon_{cu} \tag{4}$$

where ε_f^c is the CFRP strain at failure, considering zero initial concrete strain during strengthening. The actual CFRP strain ε_f^c is found by subtracting the initial concrete strain ε_0:

$$\varepsilon_f = \varepsilon_f^c - \varepsilon_0 \tag{5}$$

Thus, the tensile stress in NSM CFRP strip is

$$f_f = \varepsilon_f E_f = \left(\frac{\alpha_f}{\alpha} - 1\right)\varepsilon_{cu} E_f \tag{6}$$

The expression of the ultimate moment of resistance may be obtained by summing the moment of the forces acting on cross section about the centroid of the concrete stress block

$$M_r = A_s f_y (d - 0.4x) + A_f f_f (d_f - 0.4x) \tag{7}$$

Equation (7) can be expressed in a non-dimensional form

$$\mu_r = \rho_s \frac{f_y}{f_c}(1 - 0.4\alpha) + \rho_f \frac{f_f}{f_c}(\alpha_f - 0.4\alpha) \tag{8}$$

where $\mu_r = \frac{M_r}{bd^2 f_c}$.

Replacing Eq. (1) into Eq. (2) gives

$$\alpha^2 - 2.5\alpha_d \alpha - 3.125\left[\rho_s \frac{f_y}{f_c}(1 - \alpha_d) - \mu_r\right] = 0 \tag{9}$$

Equation (9) directly yields α, which is used to solve ρ_f by substituting into Eqs. (4) and (6).

3.1 Maximum NSM CFRP Reinforcement Ratio

To ensure ductile failure, steel yielding needs to take place prior concrete compression failure. This can only happen if the area of NSM CFRP strip is kept lower than that causing balanced failure (i.e. simultaneous yielding of steel and crushing of concrete). Thus, the maximum NSM CFRP ratio may be expressed in terms of the difference between the balanced and actual steel ratios of the original unstrengthened section, as follows:

$$\frac{\varepsilon_{cu}}{x_{bal}} = \frac{\varepsilon_{cu} + \varepsilon_y}{d} \quad \Rightarrow \quad x_{bal} = \frac{0.0035}{0.0035 + \frac{f_e}{E_s}} d = \frac{700}{700 + f_e} d \tag{10}$$

$$\frac{\varepsilon_{cu}}{x_{bal}} = \frac{\varepsilon_{cu} + \varepsilon_f^{cbal}}{d} \quad \Rightarrow \quad \varepsilon_f^{bal} = \left(\frac{d_f}{x_{bal}} - 1\right)\varepsilon_{cu} - \varepsilon_0 = 0.0035\left(\frac{700 + f_e}{700}\frac{d_f}{d} - 1\right) - \varepsilon_0 \tag{11}$$

$$0.8 f_c\, b\, x_{bal} = A_s f_y + A_f^{bal} E_f \varepsilon_f^{bal} \tag{12}$$

Substituting Eqs. (9) and (10) into Eq. (11) and rearranging:

$$\frac{E_f \varepsilon_f^{bal}}{f_y}\rho_f^{bal} = 0.8\frac{f_c}{f_y}\frac{700}{700 + f_e} - \rho_s \quad \Rightarrow \quad \rho_f^{bal} = \frac{f_y}{f_f^{bal}}\left(\rho_s^{bal} - \rho_s\right) \tag{13}$$

where $\rho_f^{bal} = \frac{A_f^{bal}}{bd}$, ε_f^{bal} is computed by Eq. (10).

It is clear from Eq. (13) that cross-sections originally reinforced with the balanced steel ratio cannot exhibit a pseudo-ductile failure when strengthened with NSM CFRP strips. Fortunately, in current code

practice the steel ratio ρ_s is limited to 75% of the balanced steel ratio [ACI 2002]. This same percentage may be used here to limit the maximum NSM CFRP ratio so that the same type of pseudo-ductile failure is ensured:

$$\rho_s^{max} = 0.75\,\rho_s^{bal}, \quad \rho_f \le \rho_f^{max} = 0.75\,\rho_f^{bal} \tag{14}$$

3.2 Minimum NSM FRP Reinforcement Ratio

As stated earlier, the desired mode of failure is yielding of steel reinforcement followed by concrete crushing prior to NSM CFRP rupture. The latter cannot be guaranteed unless the NSM CFRP stress, at concrete crushing, is lower than its design ultimate strength f_{fu}. This may be conveniently prescribed by keeping the NSM CFRP ratio greater than that minimum needed to attain NSM CFRP design ultimate strength (f_{fu}) upon concrete crushing. Accordingly, the strain compatibility and force equilibrium equations are used to define such a ratio. If Eq. (7b) above yields a lower NSM CFRP ratio, the minimum should be obviously used to avoid any possible NSM CFRP failure.

$$\frac{\varepsilon_{cu}}{x_{min}} = \frac{\varepsilon_{cu} + \varepsilon_{fu}^{c}}{d_f} \quad \Rightarrow \quad x_{min} = \frac{0.0035}{0.0035 + \varepsilon_{fu} + \varepsilon_0} d_f \tag{15}$$

$$0.8\,f_c\,b\,x_{min} = A_s\,f_y + A_f^{min}\,f_{fu} \quad \Rightarrow \quad \rho_f^{min} = 0.8\frac{f_c}{f_{fu}}\frac{x_{min}}{d} - \rho_s\frac{f_y}{f_{fu}} \tag{16}$$

Except for lightly reinforced sections, the second term of Eq. (15) is typically larger than the first term, yielding negative values of ρ_f^{min} which indicate that reaching NSM CFRP design ultimate strength (f_{fu}) prior to concrete crushing is not possible.

4 DESIGN OF DOUBLY REINFORCED RECTANGULAR SECTIONS

The equations governing the NSM CFRP strengthening design for doubly reinforced sections are similar to those of Eqs. (1)–(9) with the contribution of the compression steel included. The strain compatibility is used to define the compressive steel strain, Fig. 2:

$$\frac{\varepsilon_{cu}}{x} = \frac{\varepsilon_{cu} - \varepsilon_s'}{d'} \quad \Rightarrow \quad \varepsilon_s' = 0.0035\left(1 - \frac{d'}{x}\right) = 0.0035\left(1 - \frac{\delta'}{\alpha}\right) \quad \text{with} \quad \delta' = \frac{d'}{d} \tag{17}$$

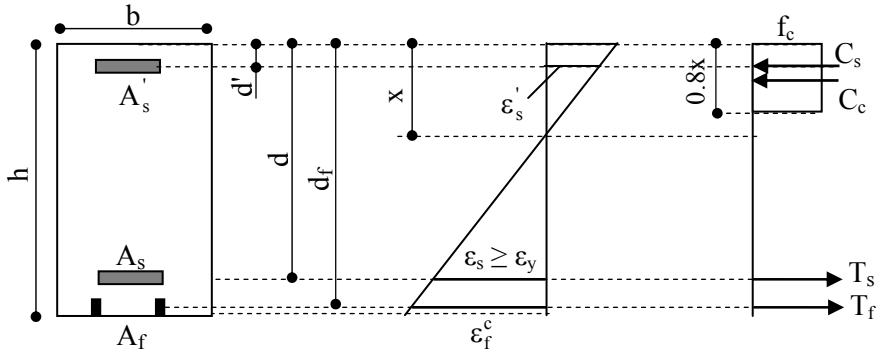

Figure 2. Doubly reinforced cross-section with strain distribution and force profile.

Using the force equilibrium and the sum of moments about the centroid of the concrete compressive force, we obtain the following expressions:

$$\rho_f = \frac{f_c}{f_f} 0.8\alpha + \rho_s' \frac{f_s'}{f_f} - \rho_s \frac{f_s}{f_f} = \rho_{f\,singly} + \rho_s' \frac{f_s'}{f_f} \tag{18}$$

$$\alpha^2 - 2.5\alpha_d\,\alpha - 3.125\left[\rho_s \frac{f_y}{f_c}(1-\alpha_d) + \rho_s' \frac{f_s'}{f_c}\left(1 - \frac{\delta'}{\alpha}\right) - \mu_r\right] = 0 \tag{19}$$

Equation (19) may be directly solved for α if the compression steel has yielded. f_s' is substituted by f_y assuming that $\varepsilon_s' > \varepsilon_y$. The value of α obtained is then substituted into Eq. (17) to verify this yielding. If yielding actually takes place, the solution is complete. Otherwise, Eq. (17) is substituted into Eq. (19) resulting in a cubic expression, which may also be directly solved for α using a scientific calculator.

$$\alpha^2 - 2.5\alpha_d\,\alpha - 3.125\left[\rho_s \frac{f_y}{f_c}(1-\alpha_d) + \rho_s' \frac{f_s'}{f_c}\left(1 - \frac{\delta'}{\alpha}\right) - \mu_r\right] = 0 \tag{20}$$

Once α is found as the lowest positive root of Eq. (20), A_f is determined using Eq. (18).

4.1 Maximum and Minimum NSM CFRP Reinforcement Ratio

The derivation of the maximum and minimum NSM CFRP ratios follows analogous steps to those of Eqs. (10)–(16) yielding the following expressions

- Maximum NSM CFRP ratios: $$\rho_f^{max} = \frac{1}{f_f^{bal}}\left(0.6\rho^{bal} + \rho_s' f_s' - \rho_s f_y\right) \tag{21}$$

- Minimum NSM CFRP ratios: $$\rho_f^{min} = 0.8\frac{f_c}{f_{fu}}\frac{x_{min}}{d} + \rho_s' \frac{f_s'}{f_{fu}} - \rho_s \frac{f_y}{f_{fu}} \tag{22}$$

with $$x_{min} = \frac{0.0035}{0.0035 + \varepsilon_{fu} + \varepsilon_0} d_f \quad \text{and} \quad f_s' = 700\frac{d_f - x_{min}}{x_{min}}$$

5 DESIGN CHARTS

To facilitate the analysis and design of reinforced concrete beams strengthened with NSM CFRP strips, several design charts were developed employing the results of the section analysis previously discussed. The following assumptions were made in the development of these charts:

- Linear strain distribution at failure
- Failure is controlled by the tension failure mechanism
- NSM CFRP strips are bonded to unloaded reinforced concrete beams ($\varepsilon_0 = 0$).

Due to lack of space, the development of the design expressions is presented only for the case of singly reinforced rectangular sections. Referring to Figure 1 and using the same parameters defined in section 3, Eq. (2b) yields to

$$\alpha = \frac{\rho_s f_y + \rho_f f_f}{0.8 f_c} \tag{23}$$

f_f is given by Eq. (6). Substituting this latter into Eq. (23) and taking ε_{cu}=0.0035 and f_c=0.85 f_{c28} leads to

$$\alpha = \frac{\rho_s f_y + \rho_f \left(\frac{\alpha_f}{\alpha} - 1\right) 0.0035 E_f}{0.8 f_c} \tag{24}$$

Rearranging Eq. (24) into a quadratic form and defining ω and ω_f respectively as the mechanical ratio of the reinforcing steel and the CFRP strip:

$$\alpha^2 - \frac{1}{0.68}(\omega - 0.0035\omega_f)\alpha - \frac{0.0035\,\omega_f\,\alpha_d}{0.68} = 0 \qquad (25)$$

where $\omega = \rho_s \dfrac{f_y}{f_{c28}}$ and $\omega_f = \rho_f \dfrac{E_f}{f_{c28}}$

Equation (25) may be used to determine directly the value of α. Substituting Eq. (6) into Eq. (8) and using the parameters ω and ω_f leads to

$$\mu_r = \omega(1 - 0.4\alpha) + 0.0035\,\omega_f \frac{f_f}{f_c}\left(\frac{\alpha_d}{\alpha} - 1\right)(\alpha_d - 0.4\,\alpha) \qquad (26)$$

Considering the section equilibrium, μ_r must be greater or equal to μ_s $(= M_a / bd^2 f_c)$ where M_a represents the design moment. An iterative procedure was employed to determine ω_f for each assumed values of ω and μ_s. The following flow chart resumes the different steps to be carried out to perform the various calculations.

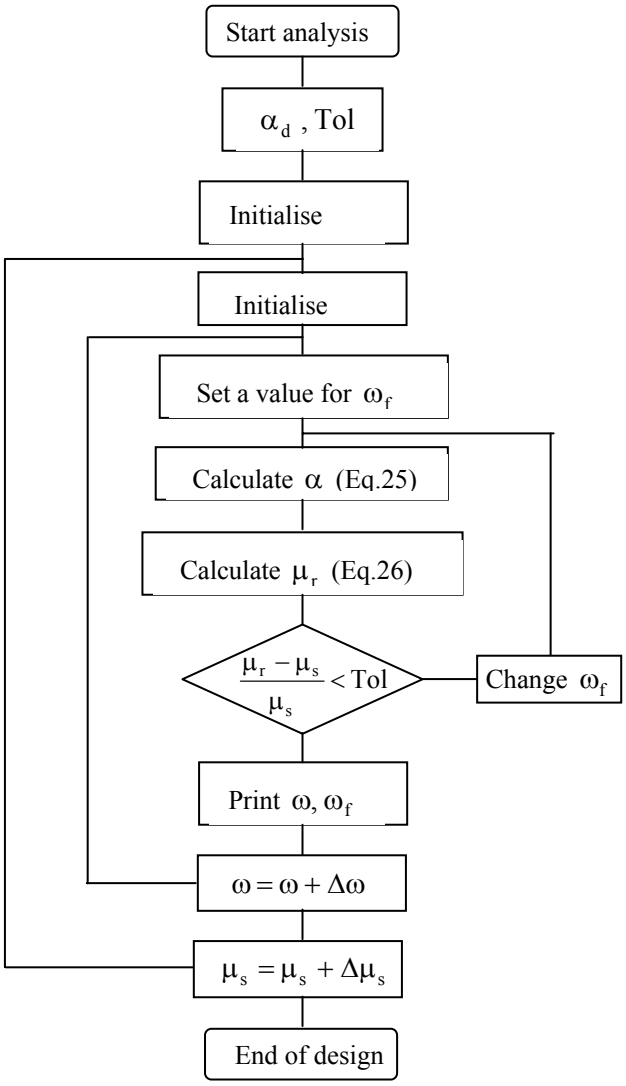

Figure 3. Flow chart of the design procedure for the analysis of NSM CFRP strengthened singly reinforced rectangular section.

The calculations were performed using a computer program developed for this study, and the results are presented in the form of design graphs such as the one presented in Fig. 4. Each family of curves is a function of the ratio d_f/d only. It is interesting to note that these charts are valid for any specific CFRP modulus of elasticity and tensile strength as long as beam failure is controlled by the tension mechanism. Thus, the required NSM CFRP cross-sectional area should be checked against $A_f^{max} (=\rho_s^{max}\, b\, d)$ and $A_f^{min} (=\rho_s^{min}\, b\, d)$ as previously discussed. Therefore, for a reinforced concrete beam requiring an increased moment capacity M_u, the required NSM CFRP cross-sectional area A_f is determined from the following expression:

$$A_f = \rho_s\, b\, d = \omega_f \frac{f_c}{E_f} b\, d \qquad A_f^{min} \le A_f \le A_f^{max} \tag{27}$$

where ω_f is determined from Fig. 4. The exam of this latter reveals that:

- NSM CFRP strips can significantly increase the ultimate flexural capacity of reinforced concrete beams.
- This effect is more pronounced for beams having relatively small steel reinforcement ratios, ρ.
- For any particular reinforced concrete beam, the rate of increase in ultimate flexural capacity decreases as the NSM CFRP strip cross-sectional area is increased.

For the purpose of illustration, design graphs for the case of a doubly reinforced concrete rectangular section are shown in Fig. 5 with $\rho_s^{'} = 0.5\%$, $f_s^{'} = 400\text{MPa}$ and $f_{c28} = 25$ MPa ($\omega^{'} = \frac{\rho_s^{'} f_s^{'}}{f_{c28}}$).

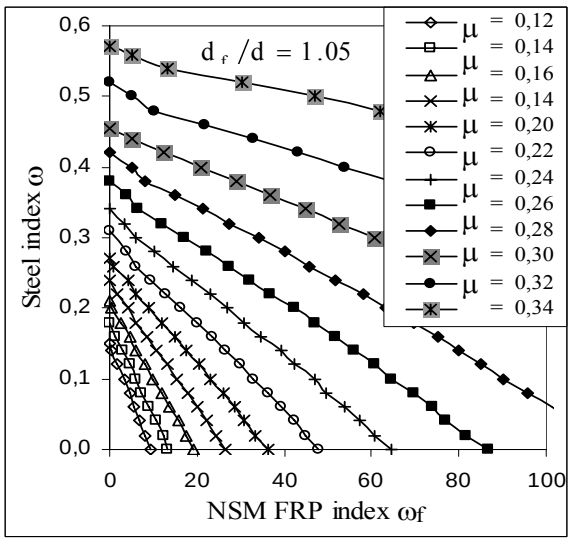

Figure 4. Design charts for singly reinforced concrete rectangular section

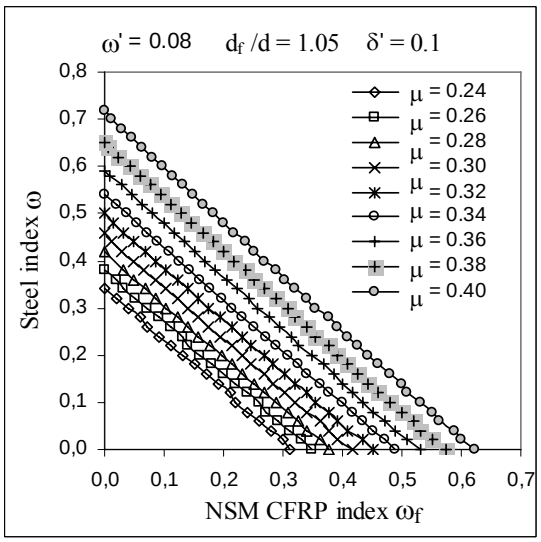

Figure 5. Design charts for doubly reinforced concrete rectangular section

6 SECTION ANALYSIS VERIFICATION

Most of the experimental data available on this topic do not provide all parameters values so as to perform calculations for comparison purposes. The results published by Barros [Barros & Fortes 2005] indicate fortunately all the details regarding tested specimens and materials used. In this respect, a comparison is made and the results are summarized in Table 1. All beams were tested in

Table 1. Comparison of results

Beam Designation	b (mm)	d (mm)	As (mm^2)	A's (mm^2)	f_y (MPa)	f'_y (MPa)	f_{c28} (MPa)	A_f (mm^2)	E_f (GPa)	Exp. ult. load (KN)	Calc. ult. load (KN)
V2R2	100	152	339	402	730	530	48	28.5	160	78.5	75.9
V3R2	100	150	427	402	730	530	43	28.5	160	81.9	83.6
V4R3	100	155	603	402	730	530	46	42.75	160	94.9	108.2

four-point bending over a simple span length. The ultimate load represents the sum of the two equal concentrated loads applied to the beams at failure. The results from this limited comparison clearly indicate that the proposed procedure is quite satisfactory in predicting the ultimate flexural capacity of reinforced concrete beams strengthened with NSM CFRP strips. The absolute average percent difference between the experimental ultimate loads and the ultimate loads predicted by the section analysis procedure was 6.7%, which is very acceptable. In fact, this difference is quite small when one considers the expected variation associated with the behaviour of reinforced concrete structures.

CONCLUSIONS

Strengthening of structures with NSM FRP reinforcement is a technique that represents a feasible and economic alternative to the technique of strengthening structures with EB FRP reinforcement. Research in this field started only a few years ago but has by now attracted worldwide attention. A significant amount of research has been conducted on this emerging technique. This paper presents a design procedure for flexural RC beams with NSM CFRP reinforcement. A simple and a direct approach was developed on the basis of equilibrium and strain compatibility. Design graphs to facilitate implementation of the procedure were also developed. Upper and lower limits for NSM FRP strip cross-sectional area to ensure ductile behaviour of the strengthened beams were introduced. To verify the accuracy of the proposed procedure, comparison of results obtained by the section analysis with some reported experimental results was performed. Good correlation of the predicted results with experimental results was noted.

Effect of Cement Type on the Resistance of Concrete against Rapid Chloride Permeability

Tolga Ilıca [1]
Hasan Yıldırım [2]
Özkan Şengül [3]

T11

ABSTRACT

In chloride containing environment, chloride permeability of concrete is a very important quality parameter affecting the service life of concrete structures. The primary objective of this experimental study was to investigate the effect of different types of cement on the resistance of concrete against chloride penetration. These cements included two different types of granulated blast furnace slag cement (CEM III/A 32.5N and CEM III/A 42.5N), a sulfate resisting cement (SRC 32.5), and a portland cement blended with fly ash, all compared to an ordinary type of portland cement (CEM I 42.5R). For each cement type, four concretes at different strength classes were produced and as a result 20 mixtures were obtained. Workability of the concretes was kept constant. Maximum size of the aggregate and aggregate grading was kept constant in all mixtures. Rapid chloride ion penetration tests according to ASTM C 1202 were conducted. Capillary water absorption tests were also carried out. In order to characterize the concrete quality, compressive strength of the specimens were obtained. The test results clearly demonstrated that the blast furnace slag cements gave the highest resistance against chloride penetration, while the pure portland cements gave the lowest resistance. Sulfate resisting cement also had a low resistance against chloride penetration. Concrete produced using the sulfate resisting cement had substantially higher capillary sorption compared to other mixtures.

KEYWORDS

Cement type, Rapid chloride permeability, Compressive strength, Capillarity.

1 INTRODUCTION

Chloride induced corrosion of embedded reinforcement is the most severe durability problem of concrete structures in marine environment. Concrete composition is one of the main factors affecting the transport of chlorides into concrete. One of the effective ways of minimizing the chloride diffusion of concrete is to substitute portland cement by mineral admixtures [Neville 2004]. These materials are finely divided and can react with calcium hydroxide at ordinary temperatures to form calcium silicate hydrates (ASTM C618, 2000). The most widely used pozzolanic materials are fly ash and granulated blast furnace slag which are industrial by-products. Fresh and hardened concrete properties can be improved by using pozzolanic materials. Utilization of such materials in cement and concrete technology also has important environmental benefits. Since these by-product materials are obtained in very high amounts, storage can also be a major issue. By reducing the clinker amount used, more economical mixtures can be obtained (Aïtcin, 2000).

Pure portland cements are the dominating type of cement in many countries. However, it is expected that the production of blended cements are bound to increase in the years to come (Mehta and Monteirio 1996). Blended cements are produced by replacing parts of the portland cement by various types of pozzolanic materials. For many years, special cements such as granulated blast-furnace slag cements have proved to give a very high resistance of concrete against chloride penetration compared to that of pure portland cements (Bijen, 1998). In recent years, however, more optimized, high-performance cements and combinations of cements with pozzolanic materials have been used for improved durability of concrete structures in severe chloride containing environments.

The main objective of the present project is to study the effect of various types of cements on the resistance of concrete against chloride penetration. In the experimental program four different cements were used to produce concretes. A series of mixtures in which portland cement partially replaced by 25% fly ash, were also produced.

2 EXPERIMENTAL STUDY

2.1 Materials

In the study, four different types of cement were used (Table 1), including two blast furnace slag cements (CEM III/A 32.5N and CEM III/A 42.5N) with 35-40% and 52-58% slag, respectively, a sulfate resisting cement (SRC 32.5) and an ordinary portland cement (CEM I 42.5R) used as reference. For structures in a marine environment, sulfate resisting cement is recommended in many specifications in the country. However, the performance of this cement against chloride effect is not taken into account.

In addition to these cements, the ordinary portland cement blended with fly ash was included in the study. The fly ash used in this study was brought from Catalagzi power plant which satisfies the Class F requirements according to ASTM C 618 [Sengül et al. 2005]. It is known that the pozzolanic reaction of the fly ash is slow and its effect on improving the concrete properties can be limited. In order to obtain the performance of the concrete containing the fly ash equivalent to that of the pure portland cement concrete, 10% of the portland cement was replaced by 25% fly ash by weight.

The grading curve of concrete aggregate was chosen between ISO A16-B16 and closer to B16. In all the mixtures the aggregate grading and the maximum particle size of aggregate were kept constant. The basis of moisture content of the aggregates used in the concrete mixtures was saturated surface dry.

For each cement type, four concretes at different strength classes were produced and as a result 20 mixtures were obtained. The compositions of these concrete mixtures are shown in Table 2. Mixture proportioning was based on previous experience with the cements and trial mixtures to obtain the same compressive strengths. The concrete classes were C25/30, C30/37, C35/45 and C40/50 which are

the most widely used concrete grades in Turkey. These classes were based on the compressive strengths at the age of 28 days. For all the concrete mixtures, a superplasticizer was used to maintain approximately the same slump of 150±10 mm.

Table 1. Compositions of the cements.

Composition (%)	Portland cement CEM I 42.5R	Blast furnace slag cement CEM III/A 32.5N	Blast furnace slag cement CEM III/A 42.5N	Sulfate resisting cement
SiO_2	19.83	26.94	25.38	20.57

Loss on ignition	2.68	2.34	2.55	1.84
Slag content (%)	–	56.00	37.50	–
Blaine fineness, cm^2/g	3350	3593	3593	3226

2.2 Testing Procedures

The concrete mixtures were prepared in a laboratory mixer with vertical rotation axis, from which a number of 150 mm cubes and Ø100 x 200 mm concrete cylinders were produced. After demolding the next day, all specimens were kept in water saturated with lime at 20°C±2°C until time of testing.

The resistance of concrete against chloride penetration was obtained by the rapid chloride ion permeability test according to ASTM C1202-05 standard was applied. This test is based on the electrical conductivity of concrete. The concrete sample was subjected to a potential difference of 60 V and the total charge passing through at the end of 6 hours was measured and expressed in terms of Coulombs.

Capillary water suction and water absorption tests were carried out according to TS 4045 [1984]. The test is based on the water absorption of specimen by capillarity. The test is performed on specimens dried at 50ºC until constant weight. The specimens are covered with paraffin on four of their six faces to ensure that water is absorbed only from the given surface. Specimens are then placed in a container filled with few mm of water and the change in water is recorded at different intervals.

3 RESULTS and DISCUSSION

3.1 Rapid Chloride Permeability

Figure 1 shows the effect of cement type on the rapid chloride permeability of the concretes. The ASTM C1202-05 test is based on the electrical conductivity of concrete. A decrease in the charge value obtained at the end of the test indicates better resistance to chloride ion penetration and thus, lower permeability. As presented in Figure 1, the rapid chloride permeability of the concretes produced with the blast furnace slag cements are substantially lower than those of the other cements. For example, for the concrete grade of C25, the rapid chloride permeability of the pure portland cement concrete is about 6 times higher than the slag cement concretes. Similar results are obtained also for the C30 and C35 concrete classes. As seen in the Figure 1, for the pure portland cement concrete substantial reduction in the chloride permeability was obtained between the C35 and C40

grades. However, at the concrete class of C40, the chloride permeability of the portland cement concrete is still about 3 times higher than those of the slag cement concretes.

Table 2. Concrete mixture proportions (kg/m^3).

Mixture Code	Cement	Water	Fly Ash	w/b	Plasticizer	Natural Sand	Crushed Sand	Crushed Aggregate	Unit Weight

CEM III/A 42.5N-C35	404	194	-	0,48	3.2	419	282	1068	2370
CEM III/A 42.5N-C40	451	203	-	0,45	4.4	408	275	1038	2380

As seen in the Figure 1, partially replacing portland cement by the fly ash had an important effect on the rapid chloride permeability. Compared to the permeability of the pure portland cement concrete, the reduction in the chloride permeability due to fly ash is not significant at the concrete class of C25, but for the other concrete grades, this reduction is more than 50%. At the concrete class of C40, the chloride permeability obtained for the fly ash concrete was close to those of the slag cement concretes.

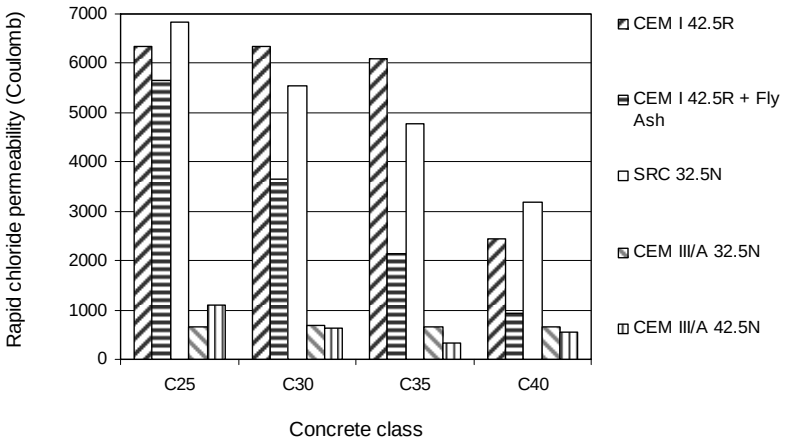

Figure 1. Effect of cement type on rapid chloride permeability of the concretes.

Concretes produced with the sulfate resisting cement were slightly lower than those of the pure portland cement concrete. The rapid chloride permeability of the concretes containing the sulfate resisting cement were about 6 times higher than the slag cement concretes at the C25, C30 and C35 grades and about 3 times higher for the C40 concrete grade. In many construction projects in Turkey, sulfate resisting cements are specified for structures exposed to marine environments. The chloride effect, however, is usually disregarded. These test results clearly indicate that sulfate resisting cements performance is close to portland cement in a chloride containing environment.

As expected, the rapid chloride permeability of the concretes decreased with the increase in concrete strength class. As seen in Figure 1, the chloride permeability of the portland cement concrete was almost the same for the concrete classes of C25, C30 and C35. At the C40 class, however, a substantial reduction was recorded for this type of concrete. The concretes containing the slag cements had very low chloride permeability at all classes, but the changes of rapid chloride permeability of these concretes due to the increase in concrete class were not significant.

The ASTM C 1202-05 suggests values for evaluating the rapid chloride permeability test results. The comparison is based on total charge passing at the end of 6 hours. The chloride ion penetrability is considered high for the test results more than 4000 coulombs. When the test results are between 100 and 1000 coulombs, the concrete can be classified as very low chloride permeability concrete. As presented in Figure 1, the concretes in this study produced with the slag cements can be considered as concretes of very low chloride permeability for all the concrete classes. The lower chloride permeability of the concretes with slag is a result of a denser microstructure. The pozzolanic reaction may cause lower amount of capillary pores and clogging of the pores, which reduces chloride ion transport in concrete [Li and Roy 1986].

As seen in the Figure 2, the concretes produced with the slag cements had very low chloride permeability according to the ASTM C 1202-05 even if they have high water-binder ratios such as 0.68. Except the water-binder ratio of 0.45, the chloride ion permeability of the specimens produced with portland cement and sulfate resisting cement are over 4000 coulombs and these concretes can be classified as concretes with low resistance to chloride penetration. As presented in the figures, the use of fly ash increases the resistance to chloride ion penetration.

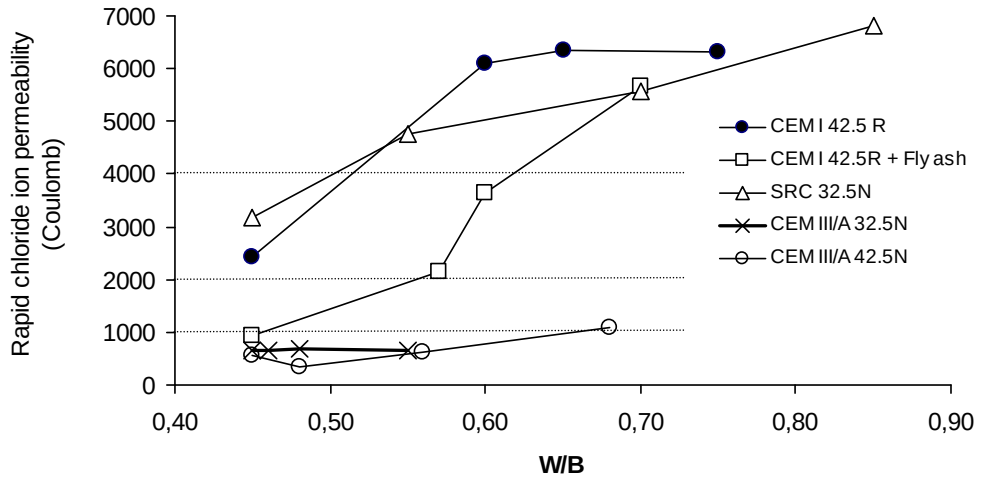

Figure 2. Effect of water-binder ratio on rapid chloride permeability of the concretes.

3.2 Capillary Water Absorption

Capillary water absorption test was carried out to physically characterize the mixtures. This test indicates possible macroscopic pore structure changes as a measurement of the changes in mass for partially submerged specimens. Capillary absorption is the mass of water per unit area that can be

absorbed in the material capillary when the specimen is in contact with water. It represents effective porosity or porosity that is accessible to water and, therefore, to aggressive environmental agents.

The capillary water absorption test is based on the water absorption of the concrete only from a given surface. The changes in weight due to water absorption are recorded at different intervals. The capillary absorption coefficient (k) is obtained from the "weight change per unit area vs. time" graphic. Figure 3 shows the effect of cement type on capillary water absorption of the concretes. An increase in the capillary water absorption coefficient is an indication of the increased water absorption.

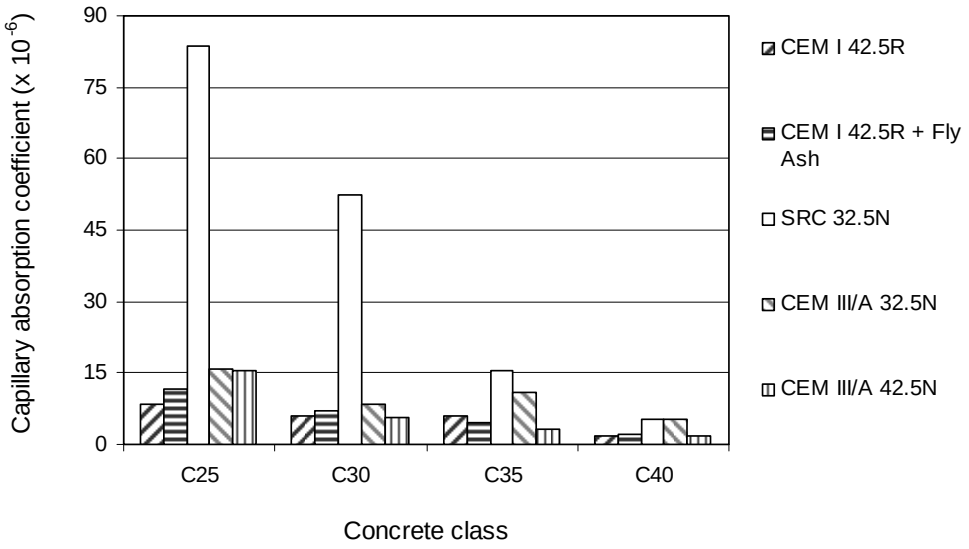

Figure 3. Effect of cement type on capillary water absorption of the concretes.

As seen in Figure 3, the capillary water absorption decreases with the increase in concrete strength class, as expected. This reduction, however, is more significant for the concrete with sulfate resisting cement. The capillary water absorption of the concretes produced with the sulfate resisting cement is substantially higher than those of the other cements, especially for the lower concrete grade. For the concrete class of C25, the capillarity is about 10 times higher than that of the portland cement concrete. At the concrete grade of C40, however, the capillary of the sulfate resisting cement and slag cement 32.5 are almost the same.

Although the concretes produced using the slag cements have substantially lower chloride permeabilities (Figure 1), the capillary water absorption of these concretes are not the lowest. The test results indicate that the capillarity of the concretes with slag cements is similar to those of the portland cement concrete (Figure 3).

3.3 Water Absorption

The specimens used for the capillary water absorption test are also used for obtaining the total water absorption. After the capillarity test, the specimens are immersed into water for 3 days to ensure complete saturation. Based on the dry weight, the water absorption of the concretes was calculated. Pores open to surface affect the water absorption, thus, the water absorption value may be accepted as an indirect indication of the porosity of the specimen. Figure 4 shows the effect of cement type on water absorption of the concretes.

The water absorption test results indicate the high water absorption of the concretes produced using the sulfate resisting cement. Except for the concrete class of C40, this concrete had the highest water absorption which supports the capillarity test results. As seen in Figure 4, the water absorption of the concretes decreases slightly with the increase in concrete class. For a given concrete class, it seems that the effect of cement type is not significant and similar results were obtained. When the rapid

chloride permeability test results (Figure 1) are compared to the capillary suction results (Figure 3) and the water absorption test results (Figure 4), it can be concluded that the better performance of the concretes produced with slag cement is not reflected in the water absorption and capillarity tests.

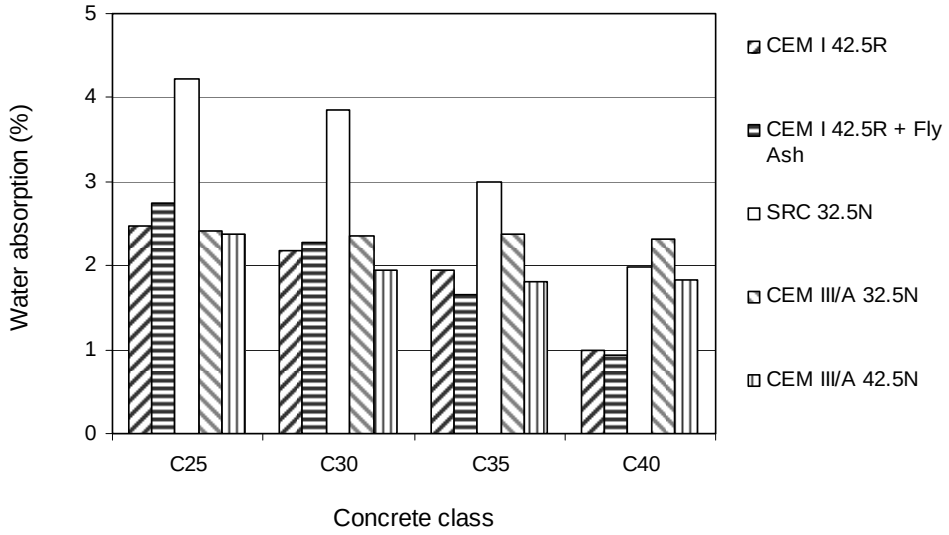

Figure 4. Effect of cement type on water absorption of the concretes.

4 CONCLUSIONS

The experimental investigation was based on a limited number of variables, and the testing was carried out according to accelerated methods. However, based on the test results obtained, the following conclusions appear to be warranted:

1. Concretes produced using the slag cements have substantially lower rapid chloride permeability compared to those of other cements. The concretes produced using the ordinary portland cement had the highest chloride permeability for all the concrete classes. The test results indicate that concretes with the sulfate resisting cement had low chloride permeability performance for all the classes investigated.

2. Concretes produced using the sulfate resisting cement had the highest capillary suction. For the concrete class of C25, the capillary coefficient of this type of concrete was about 10 times higher that of the portland cement concrete. Total water absorption of the concretes with sulfate resisting cement were also the highest among the concretes investigated.

3. The concretes produced using the slag cements have substantially lower chloride permeabilities compared to other mixtures. However, this performance is not reflected in the capillary water absorption test or total water absorption test.

T 11

ABSTRACT

The fly ash effect on the concrete durability was investigated in this study. For this purpose, 12 types of concrete were produced. 4 of them were prepared with only Portland cement, 6 of them were produced by adding fly ash in Portland cement and 2 of them were produced using Portland pozzolana cement. Maximum aggregate size was 16 mm; 7x7x7 cm cubic specimens and 7x7x28 cm prismatic specimens were prepared. On cubic specimens, compressive strength and capillary absorption tests and on prismatic specimens, ultrasonic velocity measurement and flexural tests were carried out. Some of the specimens were put into a solution that includes 10 % sodium sulphate, some of them were placed into lime-saturated water and some of them were kept under a wet burlap. Sodium sulphate solution was renewed at every 21 days.

At the end of 120 days of exposure, the compressive and flexural strengths as well as the weight and ultrasonic velocity of specimens were measured. These values were compared to those of normally cured specimens. According to the results, the resistance loss of the concrete specimens which were produced by fly ash was smaller than those which did not contain any fly ash; high strength concrete specimens were less effected by sodium sulphate solution. The specimens without any fly ash had higher water permeability and they were easily broken and lost weight when kept in the sodium sulphate solution. Parallel to the increasing water/cement ratio, capillary absorption was increased, thus the durability was negatively effected. The results showed that fly ash addition decreased water permeability by filling the pores in the concrete; and the cement paste-aggregate interfacial zone which is the weakest link in concrete could be improved by the pozzolanic and filler effect of fly ash.

1 INTRODUCTION

One of the most important properties of tbe concrete is its durability. Durable concrete should continue to perform its intended functions, maintain its required strength and serviceability , during the specified or traditionally expected service life [1]. Concrete durability has been defined by the American Concrete Institute as its resistance to weathering action, chemical attack, abrasion and other degradation processes such as freeze-thaw damage (physical effects, weathering), alkali-aggregate reactions (chemical effects), sulfate attack (chemical effects), microbiological induced attack (chemical effects), corrosion of reinforcing steel embedded in concrete (chemical effects), abrasion (physical effects), mechanical loads (physical effects), etc.

In the last years, many efforts has been focused on the development of concrete mix design with enhanced durability performances. In the present study, the effect of fly ash on the concrete durability was compared to the effect of Portland and pozzolanic cement.

2 EXPERIMENTAL STUDY

2.1 Materials

It has been used CEM I 42,5 and CEM II 32,5 conforming to TS EN 197-1. Fly ash, procured from Çatalağzı thermal power plant, was used as additive. Its specific surface was 2280 cm^2/g.
The maximum aggregate size was 16 mm; for all the trials, aggregates of the same type and of the same granulometry were used.
A lignosulfonate based plasticizer was utilised as admixture at the rate of 0,4 % of the binder weight.

2.2 Concrete Mixes

12 concrete mixes were prepared, the composition of these concrete mixes are shown in Table 1.

Table 1. Mix Designs

Mixture Code	w/b	Fresh Concrete Unit Weight (kg/m^3)	Cement (kg)	Fly Ash (kg)	Air Content (%)	Admixture (kg)	Sand (kg)	Crushed Sand (kg)	Crushed Aggregate (kg)

3 RESULTS AND DISCUSSION

3.1 Flexural Strength

According to the Table 1 and Figure 1, concrete with low cement content is much more effected by sodium sulphate solution than those with high cement content and compressive strength is decreased parallely. If fly ash is added, the negative effect on flexural strength of sodium sulphate solution is less important.

Concrete with cement content of 300 kg/m^3 and fly ash content of 20% is the more economical and have better strength values.

Table 2. Flexural Strength.

	Flexural Strength (N/mm^2) (120 days)	
Mixture Code	wet burlap	sodium sulphate solution
P250+00	6,6	1,2
P300+00	6,6	4,9
P350+00	7,8	8,8
P400+00	8,8	8,8
P250+10	7,6	3,9
P300+10	8,6	5,7
P350+10	9,0	9,4
P250+20	7,2	5,5
P300+20	8,7	8,7
P350+20	8,8	8,9
T330	4,9	2,8
T380	8,6	6,6

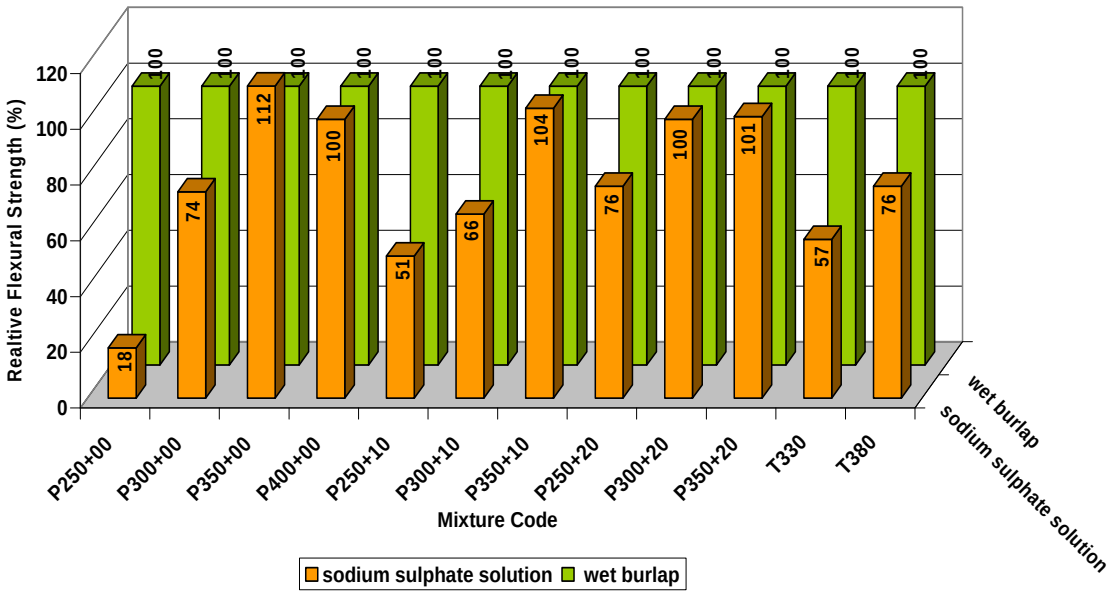

Figure 1. Concrrete Relative Flexural Strengths.

2.3 Compressive Strength

According to the Table 3 and Figure 2, the negative effect of the sodium sulphate solution on the compessive strengths is obvious, this effect is more emphasized for concrete with low cement content.

Against sulphate attack on concrete, the use of concrete with cement content of 300 kg/m^3 and fly ash content of 20% is advised. It is preferable to use concrete with cement content of at least 350 kg/m^3 if no fly ash is added. It is advised not to use Portland pozzolana cement with a cement dosage below 380 kg/m^3.

Table 3. Compressive Strength

		Compressive Strength (N/mm^2) (120 days)		
Mixture Code	w/b	lime- saturated water	sodium sulphate solution	wet burlap
P250+00	0,83	32,8	3,6	33,2
P300+00	0,70	38,7	25,8	38,8
P350+00	0,60	52,7	43,9	52,1
P400+00	0,53	62,2	52,6	59,8
P250+10	0,75	38,2	26,5	37,9

T330	0,65	17,0	15,9	21,9
T380	0,56	40,9	34,5	39,9

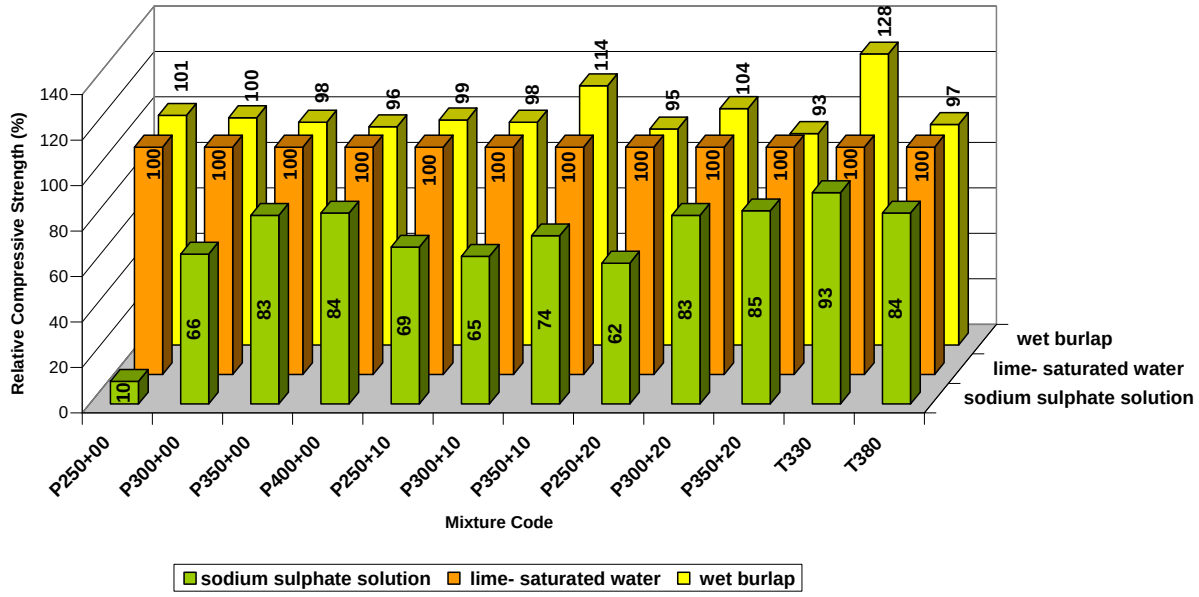

Figure 2. Concrete Relative Compressive Strengths

3.3 Ultrasonic Velocity Measurement

By the ultrasonic velocity measurement which is a non-destructive test method, the velocity of the sound through the concrete is obtained. The velocity data indicates that a condition of craking and deterioration exists in the concrete. If the concrete is porous, the time taken for the sound to pass between the transducers is prolonged , thus the velocity is decreased.

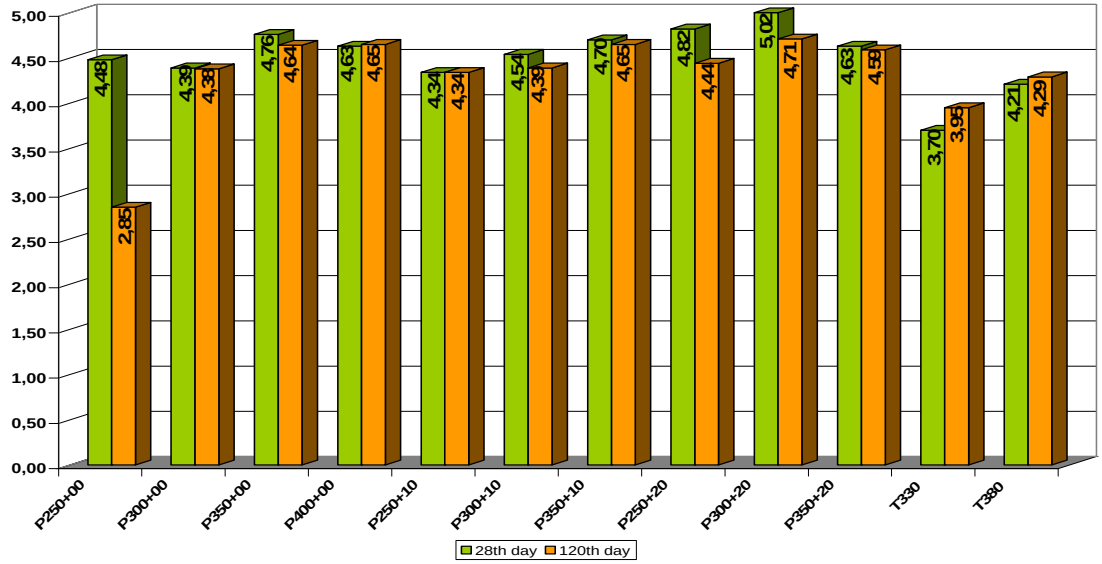

Figure 3. Ultrasonic Velocity Values

From Figure 3 arises that the negative effect of the sodium sulphate solution on the concrete structure is more evident for the sample with cement content of 250 kg/m^3. As the velocity values of other samples are not as much decreased as P250+00, we can conclude that the sodium sulphate has not such a defective effect on the internal structure of concrete with higher cement content.

2.3 Capillary Absorption

The cubic specimens of 7x7x7 cm were cured under a wet burlap during 120 days. Then, they are dried in an oven at 50^{o}C for 24 hours. After reaching the ambient temperature, the lateral surfaces of the specimens were coated with paraphine. The specimens are then placed on a grating in a water vessel, and the weight gains are recorded at 0., 1., 4., 9., 16., 25., 36., 49. seconds.

$$q^2 = (Q/A)^2 \quad (3.1.)$$
$$q^2 = k.t \quad (3.2.)$$

Permeability coefficient of each sample is calculated according to the 3.1. and 3.2. formulas.

As seen in the Figure 4, the permeability coefficient increases with the decreasing cement content. This permeability coefficient increase is more emphasised for the concrete samples with cement content of 250 kg/m^3 and for those containing Portland pozzolana cement. According to the Figure 5, the fly ash has a filler effect on the concrete samples filling the capillary voids, especially for those having low cement content, thus permeability coefficients are less important.

Figure 6 shows that capillary coefficients increase with increasing w/b ratio. This increase is especially emphasized for samples which do not contain any fly ash. It is important to notice that increasing capillary coefficient values have negative effects on the durability.

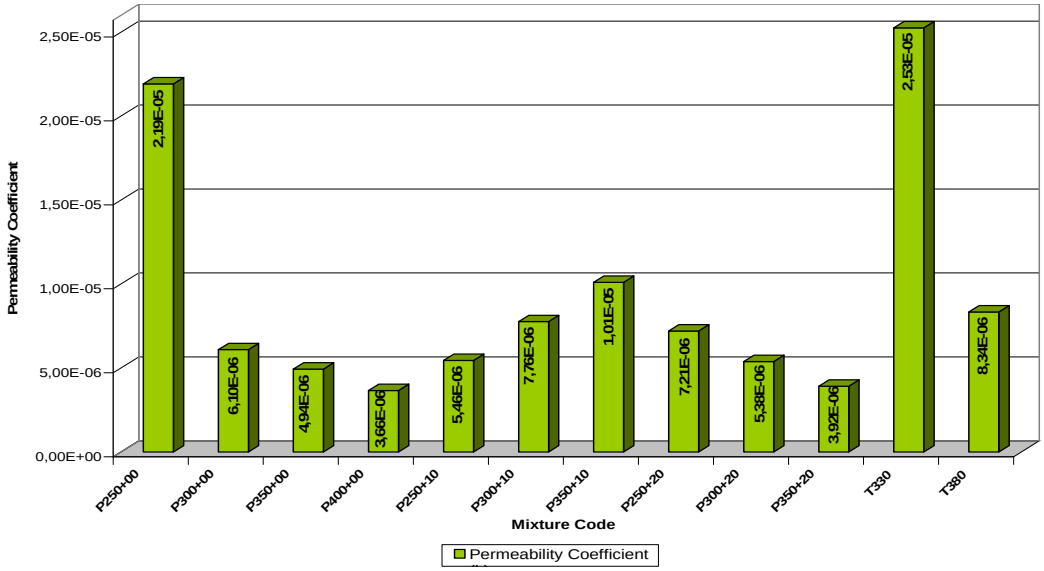

Figure 4. Permeability Coefficients

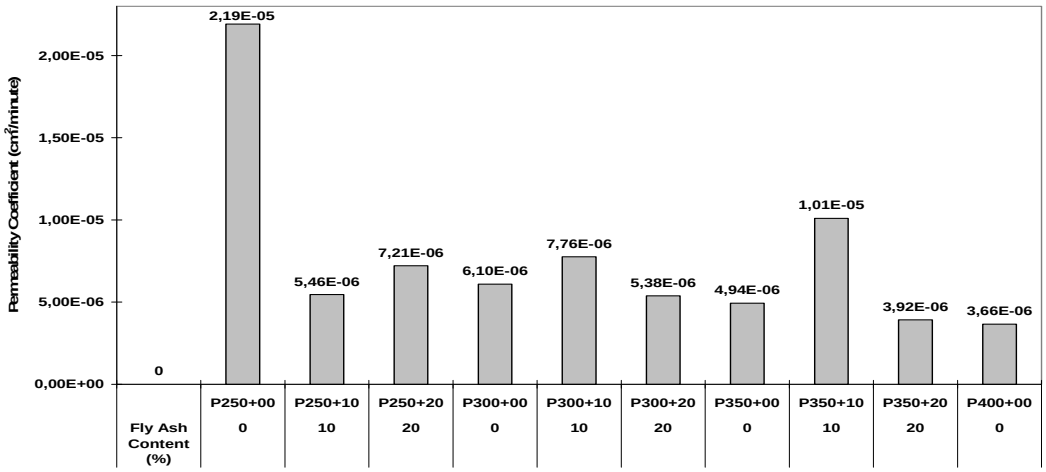

Figure 5. Fly Ash Content and Permeability Coefficient Relation

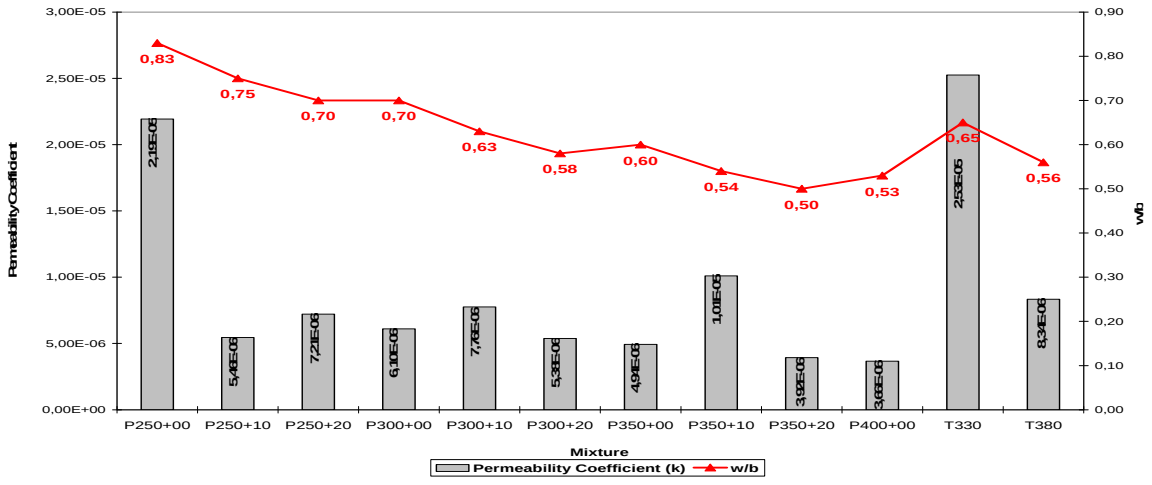

Figure 6. w/b Ratio and Permeability Coefficient Relation.

3 CONCLUSIONS

According to the results, fly ash addition decreases the flexural and compressive resistance loss of the concrete specimens. Concrete with high cement content is less effected by sulphate attack.

The specimens without any fly ash have higher water permeability and they are easily broken and lose weight when kept in the sodium sulphate solution.

Parallel to the increasing water/cement ratio, capillary absorption increases, thus the durability is negatively effected.

These results showes that fly ash addition decreases water permeability by filling the pores in the concrete; and the cement paste-aggregate interfacial zone which is the weakest link in concrete could be improved by the pozzolanic and filler effect of fly ash.

T 11

ABSTRACT

The influence of high temperature on microstructure and mechanical properties of cement paste is vital to characterize fire resistance. Some experimental investigations on the microstructure and compressive strength of pre-heated metakaolin-silica fume blended cement pastes are presented in this paper. The aim of this investigation is to study the effect of substitution of metakaolin (MK) by silica fume (SF) on thermal stability of Portland cement-MK blended pastes. The kaolinite was thermally activated at 850 ^{o}C for 2 hours. The cement pastes were prepared using standard water of consistency. The pastes were kept in moulds at 20 ^{o}C and 100% relative humidity for 24 hours and then hydrated for 28 days under water. The hydrated pastes were exposed for 2 hours to temperature 200, 400, 600 and 800 ^{o}C. The pre-heated specimens were tested for compressive strength, thermal stability, microstructure and phase composition. The thermal shock resistances were performed on cement pastes after hydration. The results of investigation showed that the compressive strength of pre-heated blended cement increases with temperature up to 400 ^{o}C and then, it decreases as the pre-heated temperatures increase up to 800 ^{o}C. The replacement of Portland cement, PC, by 15% MK and 15% SF in cement pastes increases the thermal shock resistance by about 20 times than control

1 INTRODUCTION

When reinforced concrete is subjected to high temperature as in fire, there is deterioration in its properties. Of particular importance are losses in compressive strength, cracking and spalling of concrete, destruction of the bond between the cement paste and the aggregates and the gradual deterioration of the hardened cement paste. Assessment of fire-damaged concrete usually starts with visual observation of color change, cracking and spalling of the surface. The replacement of ordinary Portland cement by pozzolanic material improves mechanical properties and fire resistance Morsy & Shebl [2007], Rojas & Cabrera [2002].

The most common cementitious materials that are used as concrete constituents, in addition to Portland cement, are fly ash, FA, granulated blast furnace slag (BFS) and silica fume. They save energy, conserve resources and have many technical benefits He *et al.* [1994]. Metakaolin, produced by controlled thermal treatment of kaolin, can also be used as a concrete constituent, since it has pozzolanic properties Dunster *et al*. [1993], Sha & Pereira [2001]. According to the literature, the research work on metakaolin is focused on two main areas. The first one refers to the kaolin structure, the kaolinite to metakaolinite conversion and the use of analytical techniques for the thorough examination of kaolin thermal treatment Kakal [2001]. The second one concerns the pozzolanic behavior of metakaolin and its effect on cement and concrete properties Shvarzman *et al.* [2002]. Although there is a disagreement on specific issues, the knowledge level is satisfactory and is being continuously extended.

When fine pozzolana particles are dispersed in the paste, they generate a large number of nucleation sites for the precipitation of the hydration products. Therefore, this mechanism makes the paste more homogeneous and dense as for the distribution of the fine pores. This is due to the reaction between the amorphous silica of the pozzolanic and the calcium hydroxide produced by the cement hydration reactions Rojas & Cabrera [2002]. In addition, the physical effect of the fine grains allows denser packing within the cement and reduces the wall effect in the transition zone between the paste and aggregate. This weaker zone is strengthened due to the higher bond developed between these two phases, improving the concrete microstructure and properties. In general, the pozzolanic effect depends not only on the pozzolanic reaction, but also on the physical or filler effect of the smaller particles in the mixture.

The study aims to investegate the effect of high temperature treatment on the microstructure, mechanical and physical properties as well as the thermal shock resistance of cement-metakoline-silica fume blended pastes.

2 EXPERIMENTAL

The materials used in this investigation were Portland cement with a Blaine surface area of 3000 cm^2/g, metakaolin of Blaine surface area of 3600 cm^2/g and silica fume of very high Blaine surface area 220000 cm^2/g. The chemical composition of starting materials is shown in Table 1. The cement pastes were prepared using Portland cement that was partially substituted by metakaolin and silica fume as illustrated in Table 2. The kaolin was fired at 850 ^oC for 2 hours to give active amorphous metakaolin Dunster *et al.* [1993]. The starting materials were initially mixed with ethanol to attain ascertain homogenity. The pastes were prepared using the standard water of consistency. Table 3 illustrates the used water of consistency for different blended cement pastes.

The pastes were molded into 1 inch cubes for compressive strength determination. The moulds were vibrated for one minute to remove any air bubbles. The samples were kept in moulds at 100% relative humidity for 24 hours, then it was cured under water for 28 days.

Mixes	M0	M1	M2	M3	M4
Water/ Bender	0.25	0.2569	0.2692	0.2885	0.2886

The hardened cement pastes were dried at a temperature of 105 ^oC for 24 hours in an oven. Then, they were kept for 2 hours at temperatures 200, 400, 600, and 800 ^oC. Each tested temperature was maintained for 2 hours to achieve the thermal steady state. The specimens were allowed to be cool gradually inside the furnace to room temperature.

The compressive strength was performed on dried and pre-heated specimens. The crushed samples (dried and fired) result from compressive strength tests were ground for thermal analyses and X-ray diffraction.

Differential scanning calorimetry run were conducted using a Shimadzu DSC-50 thermal analyzer at a heating rate of 20 ^oC/min. The sample chamber was purged with nitrogen at a flow of 30 ml/min. The thermal shock resistance were determined by heating the molded cement pastes after 28 days of curing under water (1" cubes) for 40 minutes at 800 ^oC followed by quenching in water for 5 minutes. Such cycles are repeated until the samples are broken, damaged or deteriorated.

The crystalline phases present in the hydrated product were identified using the X-ray diffraction technique. Nickel-filtered Cu-Kα radiation at 40 KV and 20 mA were used throughout in a Philips PW 1390 diffractometer with scanning speed of 2^o/min. The scanning electron microscope, Philips–XL 30, was used for identification of the changes occurring in the microstructure of the formed and/or decomposed phases.

3 RESULTS AND DISSCUSION

Figure 1 illustrates the development of compressive strength for control and blended cement pastes thermally treated at 200, 400, 600 and 800 ^{o}C for 2 hours. It is evident that, the compressive strengths of control, M0, M1 and M2 cement pastes increase with temperature up to 200 ^{o}C then decrease up to 800 ^{o}C. It also, shows that, the compressive strengths of blended cement pastes, M3 and M4 increase as the treatment temperature increases up to 400 ^{o}C then decrease as the treatment temperature increases up to 800 ^{o}C. Evidently, the increase of compressive strength up to 200 ^{o}C may be due to the additional hydration of unhydrated cement grains as a result of steam effect under the condition of the so-called internal autoclaving effect. The increase of compressive strength of blended cement pastes may be due to the pozzolanic reaction of metakaolin and silica fume with free lime to produce more CSH and CAH phases that deposit in the pore system. The compressive strengths of control, M0, M1 and M2 cement pastes start to decline at 200 ^{o}C whereas those of other blended; M3 and M4 cement pastes even at 400 ^{o}C. This phenomenon is contributed to higher volumes of CSH and CAH phases formed in the blended cement pastes on the one hand and reduction in $Ca(OH)_2$ contents on the other hand relative to those developed in control, M1 and M2 cement pastes. Cement matrix with higher volumes of gel-like hydration products, and lower crystallic $Ca(OH)_2$ contents has improved fire resistance. The decrease in compressive strength with temperature may be due to the dehydration of the calcium hydroxide at about 500 ^{o}C producing CaO and H_2O. Over 600 ^{o}C strength losses are mainly caused by calcium carbonate dissociation and subsequent CO_2 escape from $CaCO_3$. Strength losses of M3 and M4 blended cement pastes are less significant than that of control M0, M1 and M2 cement paste.

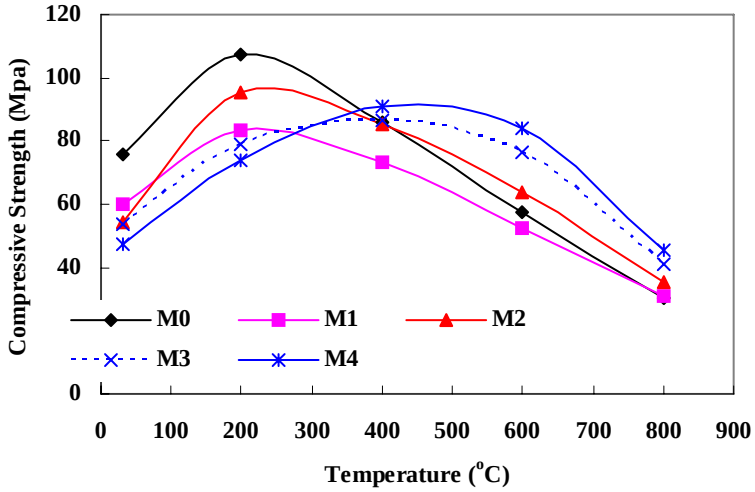

Figure 1. Variation of compressive strength of cement pastes with temperature for different admixtures blended cements.

The formation of CSH as a results of pozzolanic reaction is deposited in porous as well as the filler effect of fine MK and SF. Evidently, this leads to bridge the porous as well as reducing the internal thermal stress. Therefore, the increase of compressive strength can be partially due to the strengthened hydrated cement pastes during the evaporation of free water, which leads to greater Van der Waal's forces as a result of the cement gel layers moving closer to each other Hossain [2006]. Because transportation of moisture in concrete is rather gradual, residual moisture in concrete allowed accelerated hydration at the early stage of heating concretes to high temperatures. Further hydration of cementitious materials is another important cause of the hardening of hydrated cement pastes. The compressive strength of blended cement pastes M3 and M4 has higher values than other control and blended cement pastes up to 800 ^{o}C. This may be due to the principal reaction between the metakaolin ($Al_2O_3.2SiO_2$) and the calcium hydroxide derived from cement additional, cementitious aluminium containing CSH gel, together with crystalline products, which include calcium aluminate hydrates and

alumino-silicate hydrates (i.e., C_2ASH_8, C_4AH_{13} and C_3AH_6). The decrease in compressive strength after 400 °C, may be due to the propagation of microcracks. The crystalline products formed depend principally on the metakaoline/calcium hydroxide ratio and reaction temperature. The formation of CAH and CASH phases, increase the compressive strength.

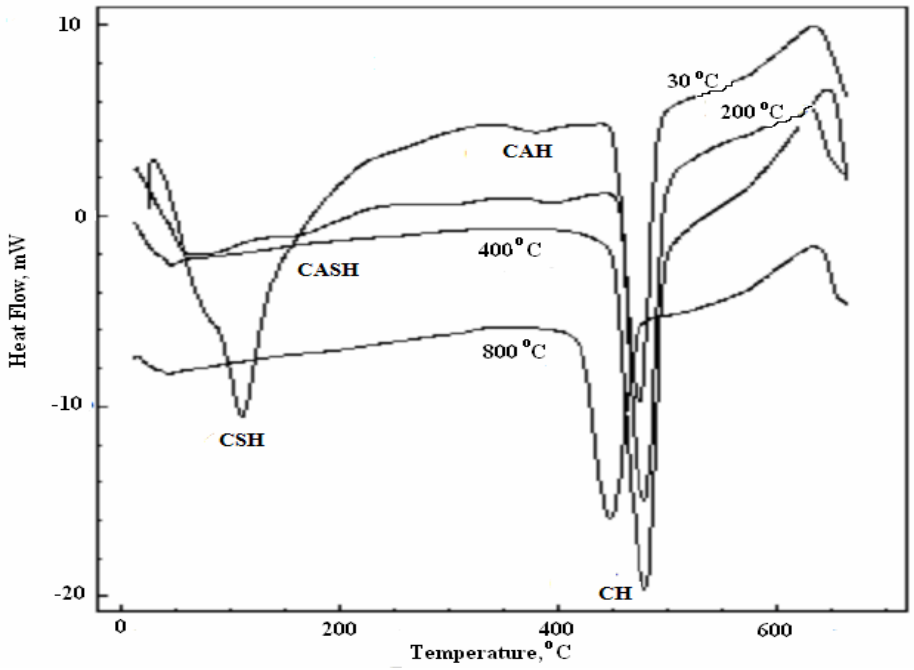

Figure 2. DSC thermograms of the Portland cement paste thermally treated at different temperatures.

The variations of the DSC thermograms of control, M0, and blended cement pastes, M4 at ambient temperature, pre-heated at200, 400 and 800 °C are shown in Figs 2 and 3. Evidently, there are almost four endothermic peaks. The first peak located at about 110-120 °C, is mainly due to the decomposition of calcium silicate hydrates; CSH. The second endothermic peak observed at about 160 °C represents the decomposition of the calcium sulpho-aluminate. The third endothermic peak at about 350 °C is due to the dissociation of C_2SH. The forth endothermic peak was observed at around at 470 °C represents the decomposition of Ca $(OH)_2$. As the pre-heated temperature increases the peak area of calsuim hydroxide increases up to 600 oC and shefted to word lower temperature at 800 °C pre-heated control cement paste, M0, as shown in Fig. 2. This is due to the formation of ill-crystals of $Ca(OH)_2$. Also it is clear that the thermograms of the blended cement paste M4 that pre-heated at 200, 400 and 800 °C show very weak endothermic peaks Fig. 3. It is clear that the calcium hydroxide peak area decreases as pre-heated temperature increases. Evidently, this is due to further reaction between metakaolin, silica fume and CaO at high temperature up to 800 °C. It is obvious that the enthalpy of calcium hydroxide phases in control cement paste, M0, Fig. 2 decreases from 60.22 J/g to 48.58 J/g as the treatment temperature increases up to 800 °C. On the other hand, the enthalpy of calcium hydroxide phase in the blended cement paste, M4, Fig. 3 decreases from 13.06 J/g to 1.9 J/g as the pre-heated temperature increases up to 800 °C. This is due to the formation of ill-crystals (this is indicated by the decrease in enthalpy) of free lime as a result of further reaction of pozzolana at elevated temperatures.

The effects of admixtures on thermal shock resistance of hydrated blended cement pastes are shown in Fig.4. Evidently, the thermal shock resistance increases as the silica fume ratio increases in blended cement pastes. Therefore, the higher replacement of metakaolin by silica fume in investigation blended cement pastes leads to higher thermal shock resistance. This may be due to consumption of free lime released during hydration. During heating, the outer layers of the test specimen tend to expand more than inner layers. Subsequent sudden cooling will unbalance the internal equilibrium, with significant

internal stresses developed as the outer layers attempt to contract relative to the inner Morsy & Shebl [2007]. The differential deformation between the different layers leads to further crack activities. Evidently, the hardened Portland cement paste, M0, can resist only 3 cycle's thermal shock. This is due to the free lime released during hydration of Portland cement. The $Ca(OH)_2$ crystals transform into CaO crystals during heating. Since CaO is often rehydrates in the humid environment and forms $Ca(OH)_2$ again with increase in volume leading to complete failure of the hardened cement paste Morsy & Shebl [2007] [1].

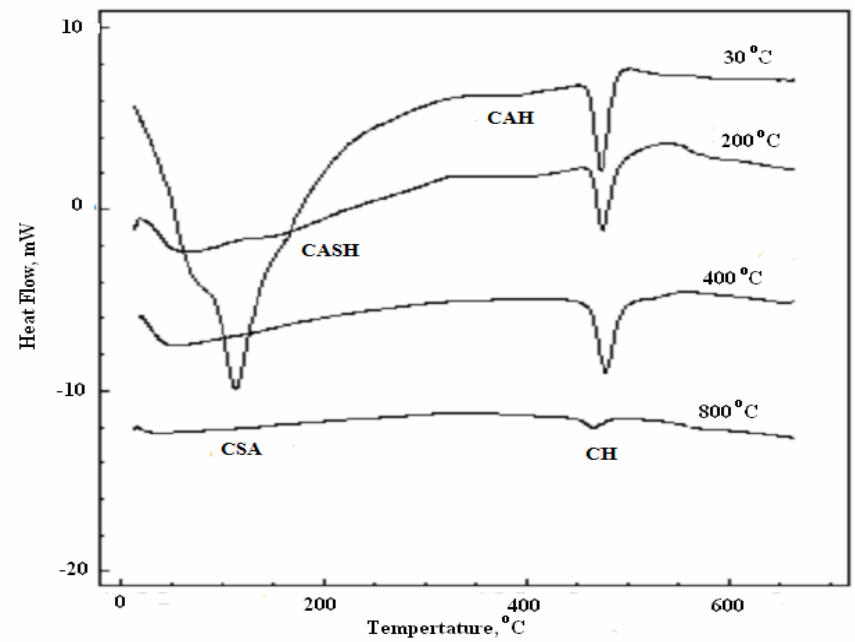

Figure 3. DSC thermograms of the blended cement pastesM4 (70% Portland cement, 15% MK, and 15% SF) thermally treated at different temperatures

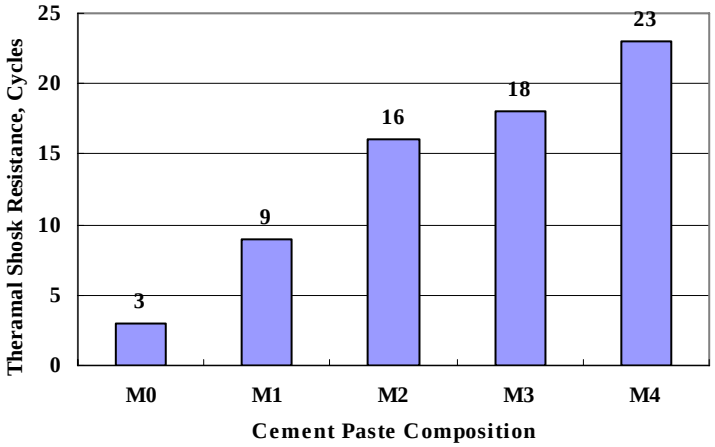

Figure 4. Thermal shock resistance of control and blended cement pastes

The replacement of Portland cement by 30% metakaolin in blended cement paste, M1, leads to increase the thermal shock resistance up to 9 cycle's. This is due to the pozzolanic activity of metakaolin during hydration and at 800 °C, the SiO_2 and Al_2O_3 of metakaolin react with CaO. It also clear that, the replacement of metakaolin by 5% in the blended system, M2; leads to thermal shock resistance of 16 cycle's. The results show that the 30 % wt. replacement of Portland cement by pozzolanic admixture consisting of 15 % wt. of metakaolin and 15 % wt. of silica fume creates the most durable hydrate phase to thermal shocks. Evidently, the thermal shock resistance of blended cement pastes is considerably higher when highly effective microfiller-microsilica is added. Figures 5

and 6 illustrate the XRD patterns of pre-heated control and blended cement pastes. It is clear that, the XRD patterns of the OPC cement pastes pre-heated at ambient temperature, 200, 400 and 800 ^{o}C are presented in Fig. 5. Evidently, the crystalline phase of CH (portlandite) was decreases as the pre-heated temperature increases up to 800 ^{o}C. This is due to thermal decomposition of calcium hydroxide phase at 570 ^{o}C. The replacement of OPC by metakaolin and silica fume is shown in Fig. 6. Basically, the calcium hydroxide phase decreases as the ratio of MK and SF increase, while the weak peaks of CAH and CASH in pastes replaced by SF and MK, slightly increase. The XRD patterns of the hydrate products are plotted in Fig. 6, the MK were replaced by 15% SF. It can be observed that the crystalline peak of CH decreases as the replacement rate increases while the weak peak of CSH and gehlenite hydrate (C_2ASH_8) increases. In Fig.6, the decrease of the CH peak is related with the consumption by pozzolanic reaction of MK and SF Sha & Pereira [2001].

h) SEM micrograph of blended cement paste at 800°C

Figure 7. SEM micrograph of OPC (M0) and blended cement pastes (M4) pre-heated at different temperature.

Figure 7 illustrates the SEM micrograph of pre-heated control and blended cement pastes. Figs (7-a, c, e and g) shows the SEM micrograph of OPC pastes hydrated at ambient temperature and pre-heated at 200, 400 and 800 °C for 2 hours respectively. It is clear that the hydration products formed up to 200 °C having a massive structure of well crystalline C-S-H and sheets of $Ca(OH)_2$ representing the microstructure; Figs (7-a and c). Evidently, the micrograph of sample pre-heated at 400 °C safer partial

decomposition in formed phases. The micrograph of the pre-heated OPC pastes at 800 °C Fig. 7- g; shows a week structure with appearance of micro cracks and pores. However, these leading to a destruction of binding forces as represented by the low compressive strength. On the other hand, the 800 ^{o}C pre-heating was already identified as a critical temperature for the water saturation moisture content of the material and thus for the open porosity as well as the significant increase in porosity due to the $CaCO_3$ decomposition was accompanied by the micro-structural damage of the Portland cement matrix that was also documented in the SEM analysis. Figures (7-b, d, f and h) illustrates the SEM micrographs of blended cement pastes M4, 15% metakaolin and 15 % silica fume, after pre-heated at 200, 400 and 800 ^{o}C. Clearly, the microstructure was relatively compact; the cement binder exhibited a low porosity. Evidently, the microstructure of blended cement paste pre heated at 800 ^{o}C Fig. 7-h; displayed the formation of dense masses of hydration products having micro- and narrow pores. However, these to relatively high compressive strength values as compared with those of OPC paste at 800 ^{o}C.

4 CONCLUSIONS

The main conclusion derived from this study may be summarized as follows

1. The residual compressive strength of the above cement blend paste heated to 800 ^{o}C is higher than the residual compressive strength of the Portland cement. In addition, the microstructure of blended cement pastes, M4, pre-heated at 800 ^{o}C is dense than OPC pastes at the same condition.
2. The replacement of OPC by 15% wt. of metakaolin and 15% wt. of silica fume increase the thermal shock resistance by 20 times than control.
3. The blended M4 can be applied as a fire resistance bonding materials.

Easy Evaluation Method of Self-Compactability of Self-Compacting Concrete

Masanori Maruoka [1]

Nobu Watanabe [4]

T 11

ABSTRACT

The use of self-compacting concrete (SCC) in construction is designed to improve the durability of the structure, by creating as far as possible a comletely filled, voidless and faultless concrete state. However, even with SCC, achieving complete self-compaction is extremely difficult. Therefore, before construction starts, the self-compactability of SCC is examined using, for example, a real-size model formwork in order to determine whether the self-compactability in the construction is adequate. However, the cost of such examinations is high, and so a cheaper and easy examination method is desirable. In this study, we investigated an evaluation method for evaluating the self-compactability of SCC easily by varying several parameters of concrete, mortar and construction properties, such as the rheological properties of mortar, unit volume of coarse aggregate of concrete, and state of obstacle distribution in the formwork. Our cost-effective and simple method enabled pressure force loss of flowing SCC around the ostacles to be evaluated in a formwork. We believe that this method will contribute to the improvement of durability of constructions using self-compacting concrete.

1 INTRODUCTION

If concrete can be poured completely and is voidless and faultless, the durability of a concrete structure will not deteriorate through the influence of, for example, carbonation and freezing and thawing action. However, producing such a state of concrete is difficult and thus deterioration of the durability remains an important consideration. The use of self-compacting concrete (SCC) in construction is designed to improve the durability by creating, as far as possible, a completely filled, voidless and faultless concrete state.

There are currently two estimation methods of the self-compactability of SCC. One involves the SCC filling test using the real-size model formwork modeled from a real structure and determining whether or not the formwork is filled completely or not. The other is a simulation method of numerical analysis. To date, few investigations of the former method have been conducted, and the latter method requires model parameters of the structure as well as parameters of the fresh SCC properties and mix content design of SCC which are very difficult to obtain. Moreover, numerical analysis does not always provide sufficient information.

In this study, we aimed to develop an easy method for evaluating the degree of self-compactability of SCC using a model experiment involving a visualization method of concrete. In this experiment, we use a model of self-compacting concrete that maintains the same fluidity, such as slump flow. The important parameters for this evaluation are unit content of coarse aggregate, rheological properties of mortar, and interspace size of obstacles in the formwork. We alter these parameters and evaluate self-compactability via the “pressure loss” parameter in the model experiment. The results of investigations of this new method are presented and discussed.

2 WHAT IS PRESSURE LOSS ?

We define pressure loss for use in the evaluation of self-compactability of SCC as follows. In the case of SCC flowing in the channel form with steel bars as obstacles (see Figure 1), the stream line of SCC is changed around the obstacle.

If unit coarse aggregate content is small, for example, the unit absolute volume of coarse aggregate is less than about 0.28 m^3/m^3, SCC flow is continued and flows around the obstacle slowly, and there is little height difference between the upstream and downstream surfaces of SCC that is bounded by the obstacle (Case (a) of Figure 1).

If unit coarse aggregate content of SCC is very large, for example, the unit volume of coarse aggregate is more than about 0.33 m^3/m^3, and if segregation occurs, SCC flow stops due to coarse aggregate blockage around the obstacle, such that SCC in the section containing coarse aggregate is changed by the effect of the obstacle (Case (b) of Figure 1). In this case, a difference in surface height is observed.

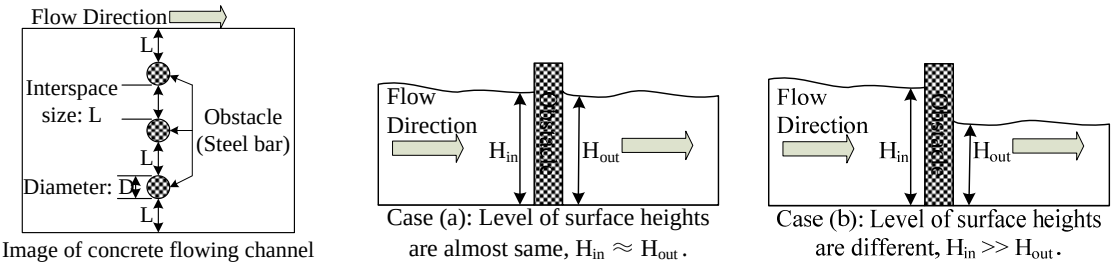

Figure 1. Differences in surface height between upper and lower sections divided by an obstacle.

Pressure loss is calculated by Eq. (1) using the difference in surface height. Then, we considered that the pressure loss value can be used as an index of the evaluation of self-compactability.

$$\Delta P = \rho g \Delta h \quad (1)$$

3 OUTLINE OF EXAMINATIONS

3.1 Examination Method

3.1.1 Measuring Method of Pressure Loss

In this examination, we use a model form made of clear acrylic sheet with obstacles made of pipe, as shown in Figure 2. The method, also shown in Figure 2, is as follows. [1] The gate of the form closes and Tank A is filled with model concrete (see section 3.3 for details). [2] The gate opens and concrete flows out from Tank A to Tank B through the obstacle interspaces. [3] The flow velocity becomes slow and eventually stops. [4] We then measure the height of the concrete surface in Tanks A and B, and calculate the height difference between them Δh, and calculate the pressure loss value ΔP using Eq. (1).

The main parameters for this examination are interspace size of obstacle: *L* (by changing diameter of obstacles; 4 types, 21, 24, 26 and 30 mm diameter) and coarse aggregate volume of model concrete: *Xv* (3 types, 0.26, 0.30 and 0.34).

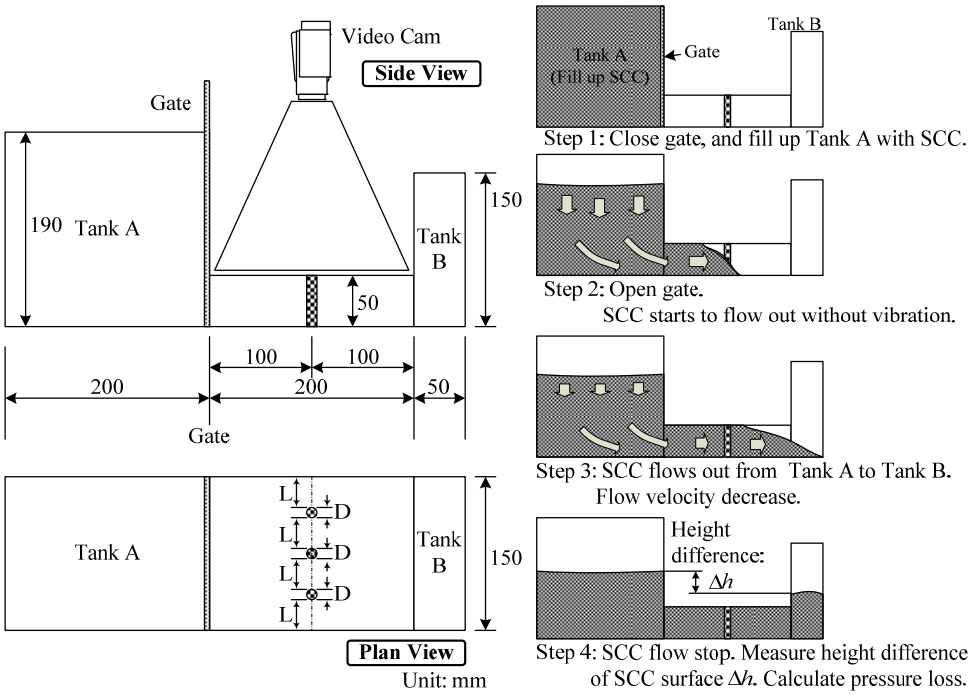

Figure 2. Details of model form and measuring method of height difference Δh between surface of SCC in Tanks A and B.

3.1.2 Visualization Test to Investigate Flow State

Next, we try to estimate the changing coarse aggregate volume divided into two sections by the obstacle. The method is shown in Figure 3. The increase in the volume of coarse aggregate *Xv*' was then measured and calculated. A still image was taken, and Area 1 and Area 2 were defined as shown in Figure 3. Image processing showed the coarse aggregate in white in the image, and the ratios of the white area (contained in Area 1) to Area 1 and the white area (contained in Area 2) to Area 2 were defined as S_1 and S_2, respectively. Then, the difference in the volume ratio of coarse aggregate

between upstream of and downstream of the obstacle ΔXv and the increased coarse aggregate ratio Xv' is given by Eq. (2),

$$\Delta Xv = \frac{S_1 - S_2}{S_1 + S_2} Xv, \quad Xv' = Xv + \Delta Xv = \frac{2S_1}{S_1 + S_2} Xv \tag{2}$$

where ΔXv is the increase in the volume ratio of coarse aggregate, Xv is the initial unit volume ratio of coarse aggregate, S_1 is the area ratio of coarse aggregate in Area 1, S_2 is area ratio of coarse aggregate in Area 2, and Xv' is the volume ratio of coarse aggregate increased in Area 1.

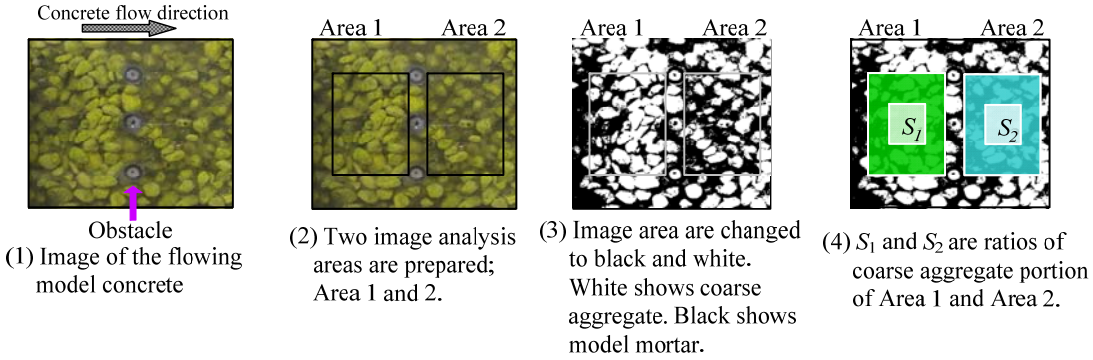

Figure 3. Method of measuring coarse aggregate area using image analysis.

3.2 Materials Used

In these examinations, we must be able to view the coarse aggregate particles, which cannot be done using real SCC. Therefore we use model concrete containing water and a viscosity agent typically used for concrete material as model mortar, and processed lightweight aggregate (density: 1.35 g/cm^3, maximum size: 15 mm) as model coarse aggregate.

The model mortar is therefore almost clear, allowing the distribution of the model coarse aggregate to be observed in the model formwork. In order to capture the coarse aggregate movement data easily, we paint the coarse aggregate yellow.

3.3 Mix Content of Concrete

Mass ratios of the viscosity agent content of the model mortar were 12.5, 15 and 17.5 %. In these conditions, mortar flow with no vibration is almost around 250 mm. The unit volume content of the coarse aggregate was 0.26, 0.30 and 0.34.

3.4 Examination Results

3.4.1 Measuring Pressure Loss

Figure 4 shows the relationship between pressure loss ΔP and interspace size L. These results show that in the case of small L, ΔP increases more than in the case of large L, and this relationship is similar to that obtained for model mortar with a different Xv and viscosity. This means that under the condition of small L and large Xv, it is difficult for the model SCC to flow around the obstacle, and it is considered that the resistance force of the steel bars disturbs and decreases the flow of model SCC, resulting in an increase in ΔP. In the case in which high viscosity mortar is used, ΔP decreases; the occurrence of contact and friction between the coarse aggregate particles decreases, and this has a large effect of the stress transfer mechanism.

3.4.2 Flow State of Coarse Aggregate

In every case we observed that the measured coarse aggregate volume of the upstream section divided by the obstacle was greater than the downstream section. The reasons are thought to be that the stream line of SCC flow around the obstacle changes from being linear to curved and coarse aggregate particles cannot move easily because of the obstacle disturbance and thereby restrict particle movement in the interspaces and the upstream section, making the SCC flow more difficult. In the downstream section, however, where there is no obstacle, the coarse aggregate volume is smaller.
We consider the phenomenon of SCC passing around the obstacle to be an important mechanism when describing increasing pressure loss.

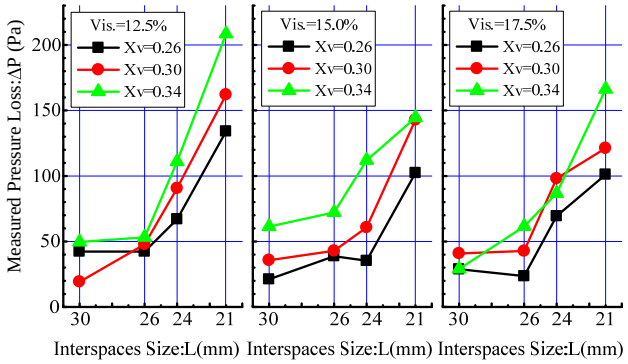

Figure 4 Relationship between interspaces size of obstacle L and measured pressure loss ΔP

4 BUILDING UP THE THEORETICAL AND EXPERIMENTAL FUNCTIONS TO DESCRIBE INCREASING PRESSURE LOSS

4.1 Modeling the Mechanism of Generating and Increasing Pressure Loss

To investigate the mechanism model of generating and increasing pressure loss, we consider the phenomenon of increasing pressure loss when SCC flows through the obstacle interspaces as follows.

[1] Coarse aggregate in flowing SCC is delayed in front of obstacles
When SCC flows through the formwork with steel bars, the flow line of SCC changes from being linear to curved as a result of having to flow around the steel bars, and movement of coarse aggregate contained in the SCC around the steel bars is obstructed and the flow velocity of coarse aggregate is decreased.

We considered one of the reasons causing this phenomenon is coarse aggregate volume change in the SCC. We considered the change to be caused by original coarse aggregate volume *Xv*, increased volume of coarse aggregate *Xv*', interspace size *L*, mortar viscosity, and yield stress. Considering these parameters, we show the relationship between *Xv* and *Xv*'/*Xv* in Figure 5 left side and the equation to explain the phenomenon in Eq. (3) [Kanematsu *et. al.* 1999].

$$\frac{Xv'}{Xv} = \Gamma Xv + 1 \qquad (3)$$

In the case of small *L*, the slant Γ of the relationship is larger than for large *L*. We introduce the idea of relative interspace size *Lr* that is defined in Figure 6 right side and Eqs. (4) and (5). We will verify these relationships later.

$$\Gamma = a \cdot Lr^{-b} \quad (4), \qquad Lr = \frac{L}{L+D} \qquad (5)$$

where a and b are parameters including the rheological properties of mortar, L is the interspace size (mm), and D is the diameter of the obstacle (mm).

[2] Volume of coarse aggregate in front of the obstacle increases
Coarse aggregate particles accumulate in front of the obstacles due to the phenomenon described in [1].

[3] Change in the stress transfer mechanism inside SCC
We consider that, inside the SCC, the sheer stress σ and shearing stress τ act on the surfaces of the coarse aggregate particles, as shown in Figure 6 left side. In the case of SCC having low volume of coarse aggregate particles and high volume of mortar, shearing stress has no influence on sheer stress. However, as the volume ratio of coarse aggregate particles to mortar increases, coarse aggregate particles can come into contact with each other easily. As a result, we consider that the mechanism of the stress transfer model changes and the relationship between σ and τ becomes linear, as shown in Figure 6 center.

[4] Increases in yield stress of SCC and sheer stress at the surface of coarse aggregate particles
The shearing stress increases with increasing sheer stress. Thus, the deformation resistance force of SCC also increases, and the yield stress of SCC increases.

[5] Increasing pressure loss
When SCC flows through the interspaces between the steel bars, it seems a balance of dynamics is arrived at around the steel bars, as shown in Figure 6 right side and Eq. (6). Furthermore, it seems that the force acting on the steel bars from the SCC is related to the decrease in pressure around the steel bars, as described by Eq. (6) for estimating pressure loss. This formula shows that pressure loss increases as the yield stress increases.

Thus, we have derived a model explaining the increasing pressure loss mechanism by means of the above steps [1]-[5].

$$\Delta P = \frac{2D}{D+L}\tau_c \qquad (6)$$

where τ_c is the yield stress of SCC, ΔP is the pressure difference present in the interspaces between the steel bars, D is the diameter of the steel bars, and L is the distance between adjacent steel bars.
In the next section, we will explain about the increase coarse aggregate volume mechanism described in [1], and investigate it through examination.

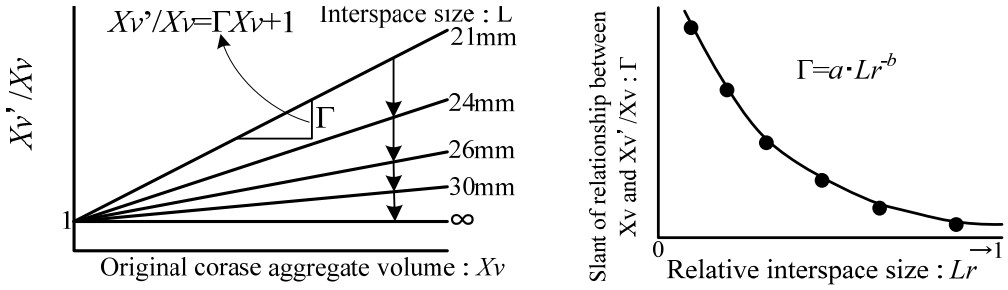

Figure 5. Concepts of relationship between original coarse aggregate volume Xv and relative Xv'/Xv (left side), and relationship between relative interspace size Lr and Γ which is the slant of the relationship between Xv'/Xv and Xv (right side).

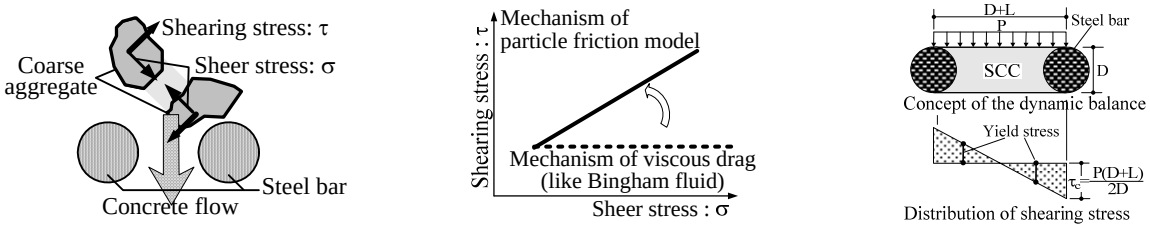

Figure 6. Concepts of sheer and shearing stress (left side), change in stress transfer mechanism (center), and dynamics model of the steel bar interspaces (right side).

4.2 Investiagation of the Model

4.2.1 Relationship between Xv'/Xv and Viscosity of Mortar

The left side of Figure 7 shows the relationship between *Xv*'/*Xv* and *Xv*, as calculated by image analysis. *Xv*' increases with narrowing *L*, and increasing *Xv*'/*Xv* is smaller when high viscosity mortar is used.

The right side of Figure 7 shows the relationship between Γ and *Lr*. Curves indicate the approximate curves of plots in these relationships for each mortar viscosity case applied. In the case of small *Lr*, Γ decreases with increasing mortar viscosity. This suggests that the increase in coarse aggregate volume is controlled partly by increase in mortar viscosity.

Equations in this figure show the approximate curves of the relationship between Γ and *Lr*, and are shown in Eq. (7).

$$\Gamma = \left\{ \begin{array}{l} 0.0189Lr^{-4.34} \left(\eta_m = 0.507\text{Pa}\cdot\text{s}\right) \\ 0.0177Lr^{-4.30} \left(\eta_m = 0.545\text{Pa}\cdot\text{s}\right) \\ 0.0158Lr^{-4.21} \left(\eta_m = 0.748\text{Pa}\cdot\text{s}\right) \end{array} \right\} \tag{7}$$

The left side of Figure 8 shows the relationship between mortar viscosity and coefficient *a*, *b*.
In this test, there are only three types of mortar viscosity, but they have linear relationships. These are shown in Eq. (8).

$$a = -0.01167\eta_m + 0.02447\,, \quad b = -0.5064\eta_m + 4.587 \tag{8}$$

This allows us to explain the increase coarse aggregate is partly due to the influence of mortar viscosity.

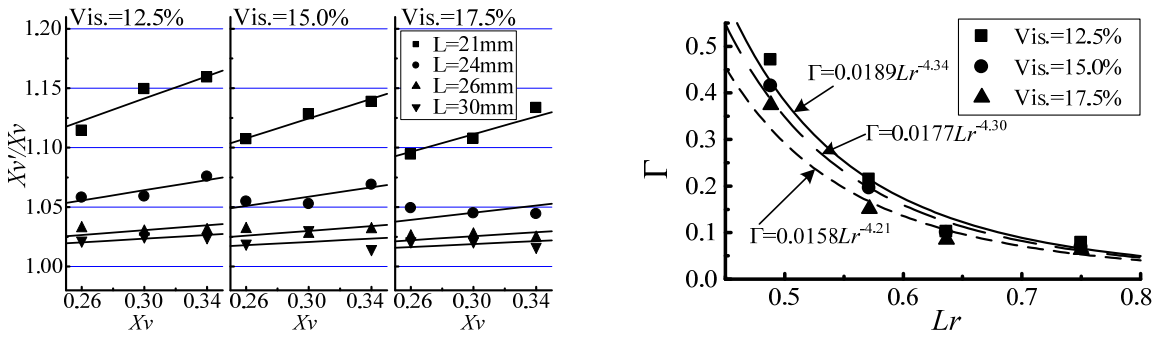

Figure 7. Relationship between relative increase in coarse aggregate volume *Xv*'/*Xv* and *Xv* (left side) and relationship between Γ that is the slant of the relationship between *Xv*'/*Xv* and *Xv*, and relative interspace size *Lr* (right side).

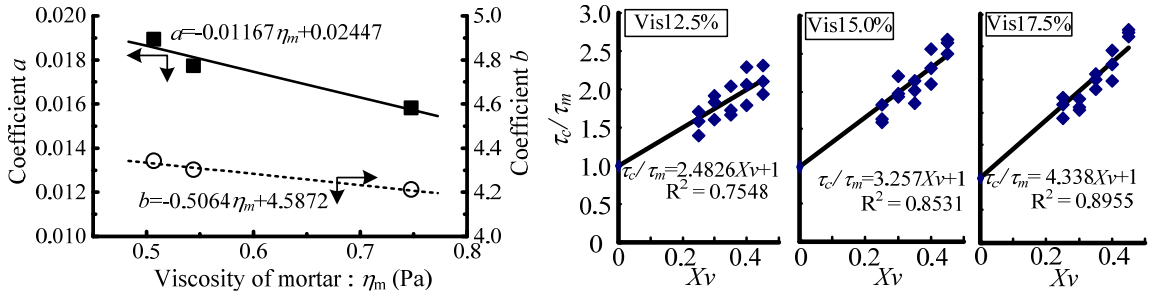

Figure 8. Relationship between coefficients of *a*, *b* and mortar viscosity (left side) and relationship ratio of yield stress of concrete and mortar τ_c/τ_m and original coarse aggregate volume of SCC *Xv* (right side).

4.2.2 Relationship between Yield Stress of Concrete and Mortar and Coarse Aggregate Volume

In this examination, we used a concrete viscometer, and investigated the relationship between relative yield stress of concrete and mortar τ_c/τ_m and coarse aggregate volume *Xv*.

The results are shown in Figure 8. Each relationship has essentially a straight relation, like Eq. (9), and the slants of the lines increase with increasing mortar viscosity.

Thus, there is a relationship between coefficient *c* and mortar viscosity as shown in Eq. (10).

$$\frac{\tau_c}{\tau_m} = cXv + 1 \quad (9), \qquad c = 6.816\eta_m - 0.509 \tag{10}$$

4.2.3 Calculating and Estimating Pressure Loss

We consider that pressure loss can be estimated easily from the aforementioned relationships between the rheological parameters of mortar, coarse aggregate volume, interspace size and diameter of the obstacle.

Equation (11), which has been published previously [Maruoka, et al. 2005], is as follows,

$$\tau_m = -0.553(2R_0) + 203.7\,,\quad \eta_m = 0.0251t_{14} + 0.387\,,\quad \tau_c/\tau_m = (6.816\eta_m - 0.509)Xv + 1\,,$$
$$\Delta P = \frac{2D}{D+L}(cXv+1)\tau_m\,,\quad c = 6.816\eta_m - 0.509 \tag{11}$$

where, τ_m is the yield stress of mortar (Pa), η_m is the viscosity of mortar (Pa*s), R_0 is the radius of mortar flow with no vibration (mm), and t_{14} is the mortar flow through time of the J_{14} type funnel (s).

5. COMPARISON OF MEASURED AND ESTIMATED PRESSURE LOSS

Figure 9 shows the comparative results of measured pressure loss and estimated pressure loss. For low pressure loss (under 200 Pa), the results are similar. However, in certain cases they are dissimilar, i.e., when mortar viscosity is low and interspace size is narrow.

The reason that the model generates pressure loss is in the condition of using low viscosity mortar, where there is large friction between the coarse aggregate particles and modeling this is difficult. Hereafter, we will attempt to improve the precision of the modeling.

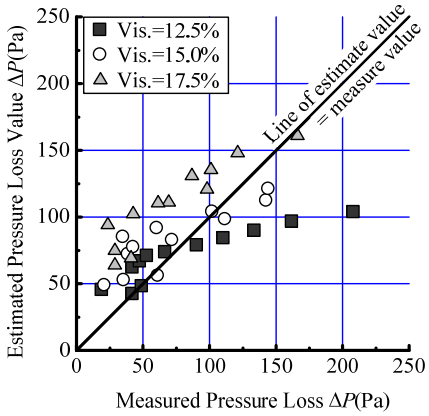

Figure 9. Comparison of measured and estimated pressure loss.

6 CONCLUSIONS

We attempted to estimate the self-compactability of SCC by considering the pressure loss phenomenon. We proposed an easy method for estimating pressure loss, using the rheological parameters of mortar and concrete, coarse aggregate volume and diameter of the obstacle. Using a visualization method to make clear the state of concrete flowing through a channel with obstacles, we detected changes in coarse aggregate volume and observed differences between upstream and downstream SCC flow.

On the basis of the rheological proprties and some derived equations, we estimated the pressure loss, finding that the measured value of pressure loss and estimated value was generally similar, enabling us to estimate pressure loss and self-compactability easily.

T 11

ABSTRACT

Costs for maintenance and repair of conventional reinforced concrete (RC) buildings and structures have become a serious economical, ecological and social problem. A large percentage of worldwide infrastructure needs nowadays repair measures.

This situation motivates great care when developing new construction materials, such as Fiber-Reinforced Concrete (FRC), whose enhanced toughness contributes to more durable structures. In fact, fibers could be introduced in RC structures to reduce the cracking phenomena thus helping the structural durability.

In the present paper, fracture behavior and water permeability of fiber reinforced concrete are studied. The effect of different crack openings is analyzed in order to study its influence on the mechanism of ingress of water.

1 INTRODUCTION

Costs for maintenance and repair of conventional reinforced concrete (RC) buildings and structures have become a serious economical, ecological and social problem. A large percentage of worldwide infrastructure needs repair measures.

The durability of concrete is intimately related to its permeability and the presence of cracks significantly increases the ability of aggressive agents to penetrate into the matrix, accelerating the deterioration processes. This is because concrete is susceptible to degradation through corrosion, alkali-silica reaction, sulphate attack, freeze-thaw damage and other mechanisms that result from the ingress of water [Neville 1981]. Although the permeability of dense concrete with a water-to-cement ratio approximately lower than 0.45, is nearly negligible in an uncracked condition, it becomes significant by the introduction of cracks and increases with the crack width [Ludirdja *et al.* 1989, Wang *et al.* 1997]. In addition, the increased permeability due to cracking, can accelerate other deterioration processes such as freezing and thawing damage.

This situation motivates great care when developing new construction materials, such as Fiber-Reinforced Concrete (FRC), whose enhanced toughness contributes to reduce cracking phenomena [Di Prisco *et al.* 2004, Carpinteri *et al.* 2007]. In a cracked matrix, the presence of fibers improves concrete durability since fibers influence the crack development by causing more distributed cracks with a smaller width. During the last 30 years many different fiber types made from many different materials have been successfully used to reinforce concrete and to enhance its durability [Tsukamoto & Wörner 1991, Aldea *et al*. 2000, Lawler *et al*. 2002].

After decades of research efforts on FRC properties, some structural applications came up and, during the last few years, design guidelines for FRC structures were proposed [Rilem 162 TDF 2002, CNR 2006]. However, the lack of results on durability of FRC does not allow to provide satisfactory information.

In the present paper, early results from an extensive research program (in progress) on fracture properties and water permeability of Fiber Reinforced Concrete are presented. The effect of the level of crack opening is analysed in order to study its influence on the mechanism of ingress of water.

2 EXPERIMENTAL METHODS

2.1 Materials

The concrete mix proportion used for the tests is given in Table 1. The steel fibers used had hooked ends and the characteristics reported in Table 2. The main properties of concrete at fresh and hardened state are reported in Table 3.

Table 1. Mixture proportions.

Materials	
Cement CEM 42,5R II-A/LL	400 Kg/m^3
Water/Cement ratio	0.55
Sand (0-4 mm)	936 Kg/m^3
Gravel (4-10 mm)	643.7 Kg/m^3
Superplasticizer	2.136 Kg/m^3
Fibers	47 Kg/m^3

Table 2. Fiber charachteristics.

Type	*Shape*	*Diameter*	*Length*	*Tensile Strength*
Steel	Hooked	500 μm	30 mm	1200 MPa

Table 3. Physical properties of concrete .

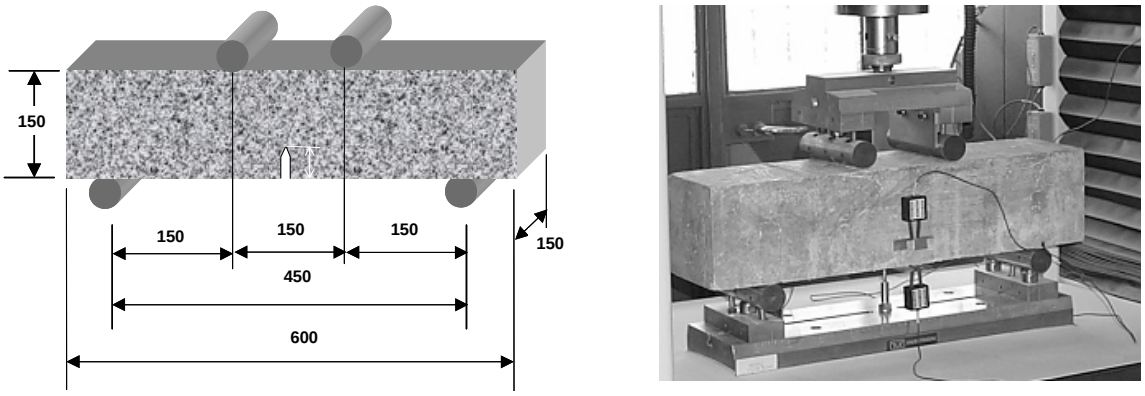
Entrained air (%)	4.9
Slump at fresh state (mm)	265
Compressive strength after 28 days (MPa)	28.93
Tensile strength after 28 days (MPa)	7.35
Dynamic elastic modulus (MPa)	30.96

Workability of fresh concrete was measured by performing a slump test (UNI 12350-2), entrained air was measured according to UNI 12350-7, the compressive strength was measured on cubes (150 mm side, according to UNI 12390-3), the tensile strength was determined by 3 Point Bending Tests (UNI 12390-5) while the dynamic elastic modulus was measured according to UNI 9524 FA-1.

2.2 Fracture Tests

Concrete Toughness was measured according to the Italian Standard (UNI 11039). Four point bending tests were performed on notched beams having a size of 150x150x600 mm and a notch depth of 45 mm 'Fig. 1a'. The Crack Mouth Opening Displacement (CMOD), measured by a Clip Gauge, was adopted as feedback signal. The Crack Tip Opening Displacement (CTOD) was also measured on both faces of the beam during the test 'Fig. 1b'.

Six beam specimens were cast in order to determine the fracture properties of each type of FRC. The latter were determined by using a 250 kN hydraulic testing machine (CONTROLS ADVANT TEST 9) with a closed loop control that permits to compensate the finite stiffness of the load system.



(a) (b)

Figure 1. Geometry (a) and instrumentation (b) of the notched specimen for the bending tests, according to UNI 11039 (2003).

'Figure 2' exhibits typical experimental results from beams tested. Diagrams report the applied load vs. the Crack Tip Opening Displacement (CTOD); it can be noticed that the remarkable residual post-cracking strength of steel fiber reinforced concrete.

'Table 3' summarize the main results from all fracture tests on beam specimens, including the tensile stress at crack onset (f_{If}), the equivalent strength for a crack tip opening displacement (CTOD) in the range 0-0,6 mm ($f_{eq(0-0,6)}$), typical for service loads, and in the range of 0,6-3 mm ($f_{eq(0,6-3,0)}$), typical for ultimate loads.

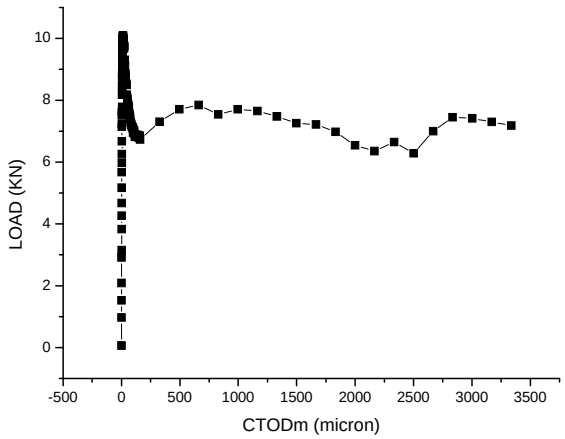


Figure 2. Typical experimental results of fracture tests (Load vs. CTOD).

Table 3. Fracture test results.

	f_{If}	$f_{eq(0-0,6)}$	$f_{eq(0,6-3,0)}$
Mean value (MPa)	2.76	2.05	2.0
Coefficient of variation %	16	29	39

2.3 Water Permeability Test

The concrete specimens for water permeability tests were slices (25 mm thick) cut from cylinders 200mm high with a diameter of 100mm.

The water permeability test was conduced on both cracked and uncracked specimens. Seven cracked specimens were tested. Specimens were pre-cracked by performing splitting tests ('Fig. 3'). Six measurements of the crack width were taken on both sides of the specimens by using an optical microscope ('Fig. 4'); the mean value was assumed as reference crack opening. The mean values of the crack width obtained at the end of the splitting tests are reported in [Table 4].

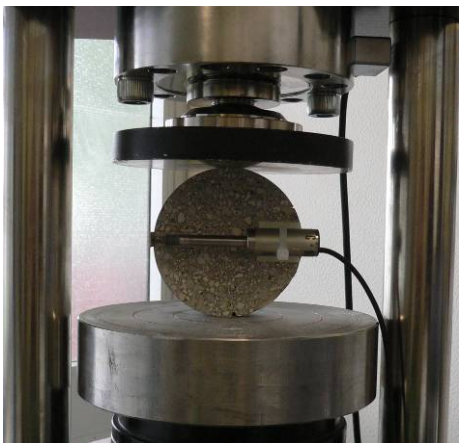

Figure 3. Splitting test performed to pre-crack the specimen**.**

Table 4. Crack width measurements.

Specimen	*Mean value of the crack width*	*Coefficient of Variation %*
A	113.17	24.5
B	26.75	29.2
C	39.05	32.2
D	117.73	45.2

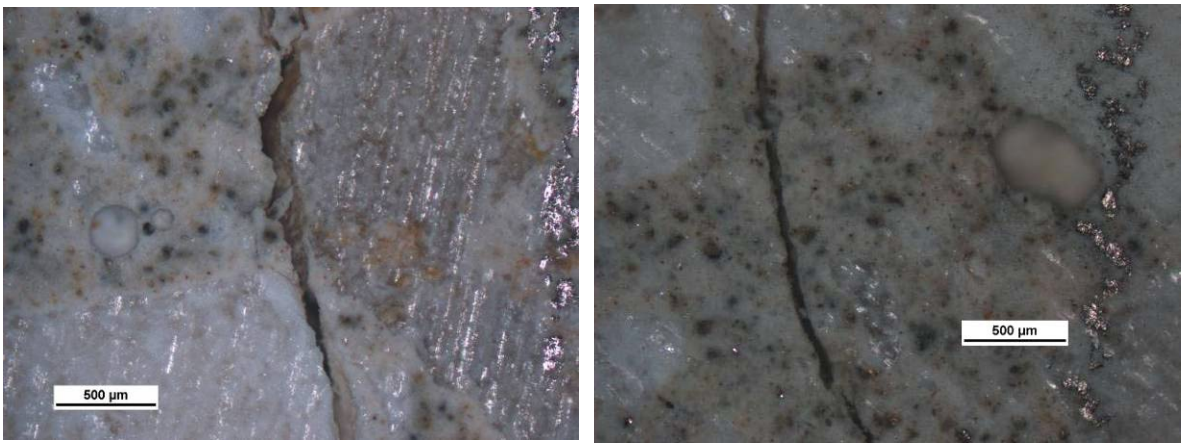
F	106.21	27.5
G	236.23	13.7



(a) (b)

Figure 4. Optical microscope images: (a) crack width of 100 microns; (b) crack width of 50 microns.

All specimens (cracked and uncracked) were conditioned before the water permeability test. The specimen preparation followed the procedure of chloride permeability tests (ASTM C1202-97 "Electrical indication of concrete's ability to resist chloride ion penetration"). Samples were firstly coated with a silicone building sealant on their side surface in order to prevent leakage during the water permeability test; afterwards, they were placed for three hours under vacuum. With the vacuum pump still running, the distilled water stopcock was opened in order to fill the specimen container: this step takes another hour. After the vacuum saturation, specimens were soaked until the water permeability test. After conditioning, the specimens were mounted and clamped in the water permeability test apparatus, as shown in 'Fig. 5'.

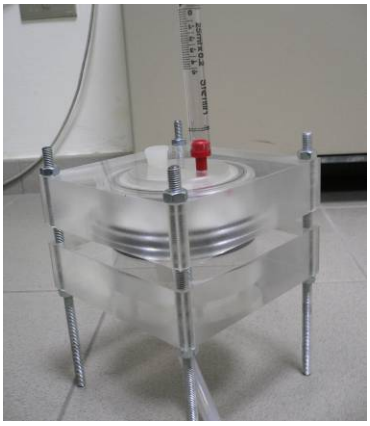


Figure 5. Water permeability cell.

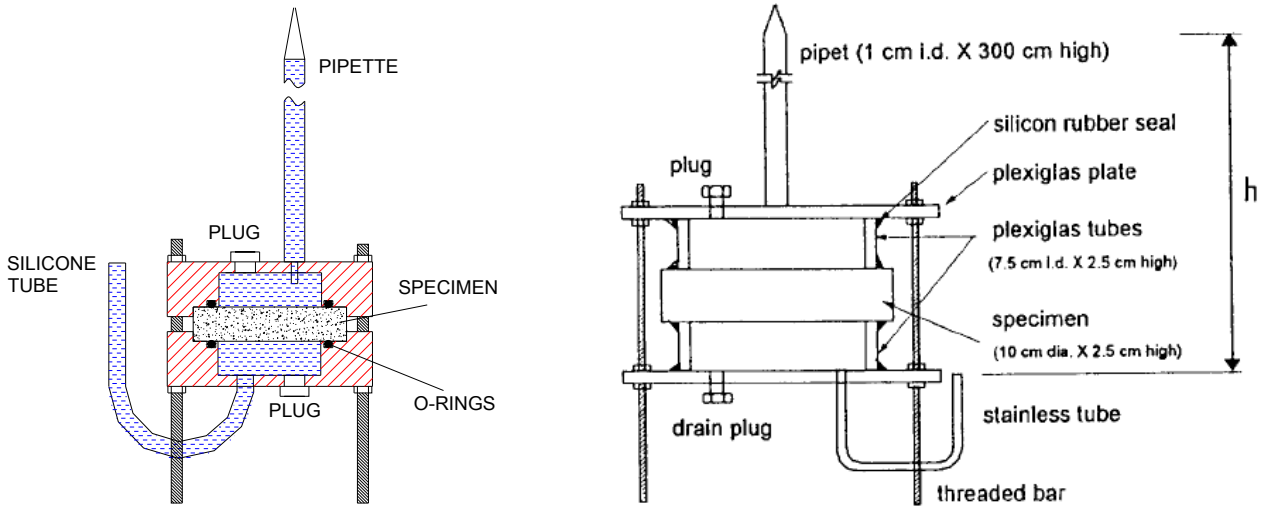
The water permeability cell used in this work ('Fig. 6a') resembles that fully described by Wang et al [1997] ('Fig. 6b'). The cell A and B are slightly different: in the cell A there are two Plexiglas chambers instead of the Plexiglas plates and tubes used in the cell B. In this way it is possible to avoid problems in centering the sample between the Plexiglas tubes of the cell B.



(a) (b)

Figure 6. Comparison between: the water permeability cell used in this work (a) and the water permeability cell used by Wang et al. (1997) (b).

The water permeability test started by filling the pipette with water. The water pass through the specimen under the pressure head given by the difference between the height of water in the pipette and the height of water in the silicone drain tube.

The water flow rate and the procedure of measuring the coefficient of water permeability were different if the specimen was cracked or uncracked.

For uncracked specimens, the water drop was measured once a day in the first week of testing and every two or seven days during the rest of the testing period, in order to minimize the reading errors. After each measurement the water in the pipette was restored to the original level. The test results were plotted with a curve of the cumulative water flow versus time. When the curve becomes linear, a steady state flow is reached and the Darcy's law can be applied to the permeability analysis [Wang *et al.* 1997]. The coefficient of water permeability can be calculated according to the following equation:

$$\frac{dQ}{dt} = \frac{khA}{L}$$

where:

Q is the water flow (cm^3);
k is the coefficient of permeability (cm/sec);
h is the water head (cm);
A is the cross-sectional area of the specimen (cm^2);
L is the specimen thickness (cm).

'Figure 7' shows the curves obtained for two uncracked specimens.

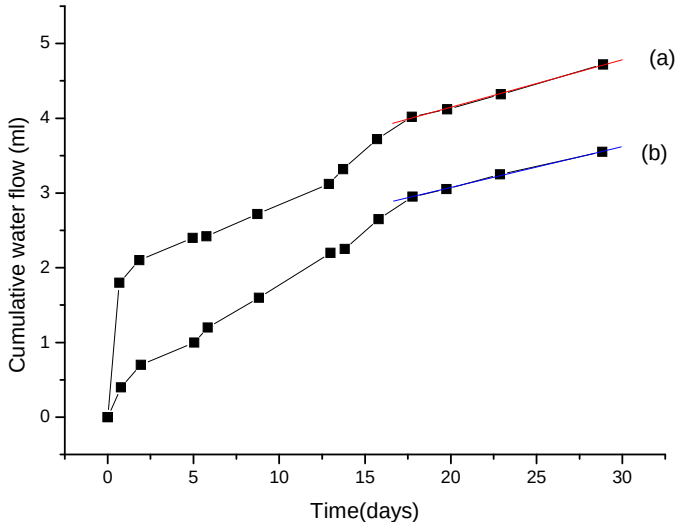


Figure 7: Cumulative water flow vs. time for two uncracked specimens (a, b).

For cracked specimen with a small crack width (specimens B and C), the procedure of measuring the water permeability coefficient was quite different from that used for uncracked specimen. The water flow rate was quite high so the readings of water drop were taken twice a day. Therefore, unlike uncracked specimens, in this case the water head could not be considered as a constant during the test, because the water drop was quite high in the reading time interval. The coefficient of permeability was calculated by integrating the Darcy's law from initial water head h_0 to measured water head h_1, as follows:

$$dQ = -A'dh$$

where A' is the cross-sectional area of the pipette;

$$\frac{\mathrm{dQ}}{\mathrm{dt}} = -A'\frac{dh}{dt} = \frac{khA}{L} \Rightarrow -\frac{dh}{h} = k\frac{A}{A'L}dt$$

$$-\int_{h_0}^{h_1}\frac{1}{h}dh = \int_0^t k\frac{A}{A'L}dt \Rightarrow k = \frac{A'L}{At}\ln\frac{h_0}{h_1}$$

For cracked specimens with a crack width larger than 100 μm, it took less than three minutes for the water to drop from the top to the bottom of the pipette. In this case, the time of the water drop was recorded with a stopwatch and the average of five flow rate, which were all very close, was used for permeability coefficient calculation [Wang *et al*. 1997].

The values of coefficient of water permeability 'k' obtained by using the procedure described above are reported in 'Table 5'.

'Figure 8' shows the relationship between water permeability and crack widths (in 'Fig. 8b' the water permeability coefficient is reported in a log scale). It can be notice that crack openings smaller than 50 microns have a little effect on concrete permeability: the value of k is about 10^{-6} cm/min compared with 10^{-8} for uncracked specimen. The increase in water permeability become significant for specimen with crack openings larger than 100 μm. In this case the order of magnitude of 'k' is about 10^{2} cm/min and become higher for cracks larger than 200 microns (about 10^{-1}). With such high permeability, considerable leaking may occur in the concrete structure during a limited service period.

Table 5. Values of the coefficient of water permeability.

Specimen	*Crack width*	*k (cm/min)*
Uncracked a	-	5.40E-08
Uncracked b	-	6.17E-08
Cracked A	113.17	0.018
Cracked B	26.75	5.70-06
Cracked C	39.05	5.31E-06
Cracked D	117.73	0.022
Cracked E	160.31	0.040
Cracked F	106.21	0.025
Cracked G	236.23	0.25

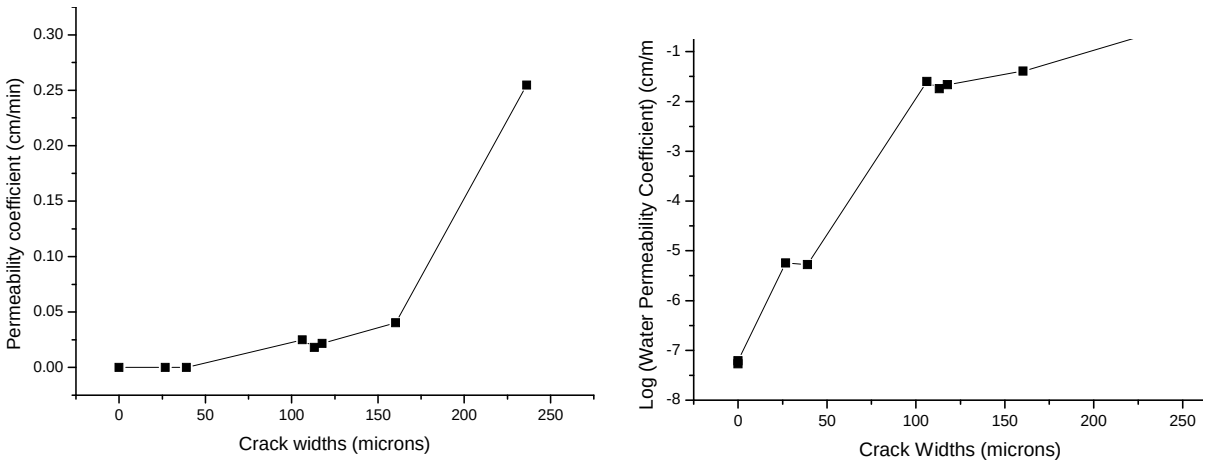

Figure 8. Permeability coefficient vs. crack width.

The results obtained from the present permeability tests on FRC specimens are in accordance with the ones reported in the literature for plain concrete [Wang *et al*. 1997] having similar crack opening: the permeability of cracked concrete with crack widths below 100 μm is nearly identical to that of uncracked concrete. Referring to RC structures, the Italian building code limits the design crack widths in the range 200÷300μm for aggressive and moderately aggressive environmental conditions, depending also on the sensibility of reinforcing steel to corrosion. As the design crack width is affected by a coefficient equal to 1.7, the allowable crack width is below 200 μm. This value is empirical, based on experience, and is in accordance with results obtained herein for FRC.

3 CONCLUDING REMARKS

Fracture behavior and water permeability of Fiber Reinforced Concrete with different crack widths was experimentally studied. Specimens were made of concrete with water cement ratio of 0.55 and a volume fraction of hooked steel fibers equal to 0.6%.

From fracture tests, it was observed that the volume fraction of fibers adopted, significantly improved the material toughness.

Results from water permeability tests indicates that crack openings smaller than 50 μm have a little effect on concrete permeability. The increase in permeability becomes significant for specimens with

crack openings larger than 100 μm where the order of magnitude of the coefficient of permeability (k) is about 10^{-2} cm/min and becomes higher for cracks larger than 200 μm (about 10^{-1}). With such high permeability, considerable leaking may occur in the concrete structure during a limited service period. The results obtained in this work for Fiber Reinforced Concrete are in accordance with those reported in the literature for plain concrete. Although it seems that the presence of fibers doesn't affect the influence of crack width on matrix permeability, smaller crack openings are expected in FRC. However, further research is needed to investigate the influence of the fiber content on the permeability of both cracked and uncracked matrices.

ACKNOWLEDGEMENTS

The Authors wish to express their gratitude and sincere appreciation to the Ministry of University and Research (MIUR) for financing this research work within the National Project (PRIN 2006) "Optimisation of the Structural, Technological and Functional Performance of Construction Methodologies and Materials in Tunnel Linings".

A special acknowledgement goes to Eng. Massimo Borsa of CTG Italcementi Group of Brindisi (Italy) for his valuable help in performing the experiments. The Authors are also grateful to Mr Giuseppe de Rossi (La Matassina Technology s.r.l.) for providing all the fibers.

ABSTRACT

This study investigates the effect of high temperature on some mechanical and microstructural properties of 6 different cement types (CEM I, CEM II/A-P, CEM II/B-P, CEM IV/A-W, CEM IV/B-W, CEM III/A). Blended cements are prepared by adding appropriate amounts of supplementary cementing materials to CEM I. Mortar mixtures prepared in accordance with TS EN 196-1 are cured in water for 28 days and in air for the following 28 days. In addition to control mixture, the specimens are exposed to 150°C, 300°C, 450°C, 600°C and 900°C for 4 hours and are allowed to cool to room temperature. Strength testing is applied to these specimens 24 hours after exposure. Flexural tensile and compressive strength of the mortars are determined in accordance with TS EN 196-1. Blended cements exhibit a higher compressive strength compared to CEM I at high temperatures. Mechanical test results are discussed by considering the microstructural changes in the mortar specimens.

KEYWORDS

Heat resistance, Cement type, Compressive strength, Flexural strength, Microstructure

1 INTRODUCTION

The resistance of portland cement concrete to high temperature depends mostly on the type of the materials used in concrete design. Considering the deteriorations in concrete after exposing to high temperatures, cement paste is the least stable constituent. Chemical and physical deteriorations such as loosing the interlayer and chemically combined water from C-S-H and further decomposition of CH and C-S-H phases takes place in cement paste after exposure to high temperatures. The porosity and mineralogy of the aggregate are other important factors which affect the severity of deteriorations at different temperatures.

Temperature rise has different effects on cement paste [Baradan *et al.* 2002];

- capillary and gel water evaporates at ~100-150^{o}C,
- shrinkage and cracking takes place at ~150-250^{o}C accompanying reduction in tensile strength,
- evaporation of chemically combined water from aluminous and ferrous constituents takes place at ~250-300^{o}C, compressive strength of concrete starts to decrease,
- CH transforms into CaO at ~400^{o}C with accompanying 33% volume reduction,
- C-S-H starts to decompose at ~400-600^{o}C, strength reduction becomes considerable,

Xu *et al* [2001], studied the mechanical and durability properties of concretes incorporating fly ash at 0%, 25% and 55%; w/b ratios of 0.3 and 0.5 after exposure to temperatures of 250^{o}C to 800^{o}C. After exposure to 250^{o}C, plain concretes gained 8-9% compressive strength and fly ash incorporated one gained 10-15% compressive strength compared to the specimens tested before heating. This behavior is attributed to the strengthening of cement paste upon the evaporation of free water, which leads to greater Van der Waals of attraction forces as a result of the cement gel layers moving closer to each other. After exposure to 450^{o}C, the strength loss of fly ash incorporated mixtures was less than plain ones. The beneficial effect of 55% fly ash incorporation was still significant for concretes exposed to 650^{o}C, while the beneficial effect of fly ash diminished after 800^{o}C. It was evident that, C-S-H was decomposed after the exposure temperature of 650°C. The authors also concluded that reduction of CH constituent in fly-ash incorporating concrete increased the heat resistance of concrete by two ways given below:

- the reduction in cracking around CH crystals at ~300^{o}C,
- upon availability of extra water, rehydration of CaO give rise to 44% volume increase, cracking and strength loss at ~400-600^{o}C. The reduction of $Ca(OH)_2$ in cement paste prevents deterioration.

Sarshar and Khoury [1993], investigated the effect of high temperature on compressive strength of pastes and concretes prepared by using ordinary portland cement and cements incorporating 10% silica fume, 30% fly ash and 65% slag. The specimens were cured at 100% relative humidity for 1 year. High temperatures were applied to unloaded specimens after the curing period and compressive strength testing was performed. The authors concluded that plain cement incorporating mixtures started to lose compressive strength after 200^{o}C, the decrease in strength was obvious at 300^{o}C. Concrete and mortar specimens containing fly ash and slag expressed a better performance than plain mixtures and silica fume-bearing mixtures at high temperatures. This behavior was attributed to the fact that mineral admixture-bearing samples had less $Ca(OH)_2$ than plain mixtures.

Savva *et al* [2005] investigated the effect of elevated temperatures on the mechanical properties of blended cement concretes prepared with a siliceous aggregate and a limestone aggregate. Water to binder ratio of the mixes was constant (0.60), blended cements were prepared by using different amounts of two different fly ashes and a natural pozzolan. The authors concluded that concretes with pozzolanic materials showed better resistance at elevated temperatures until 300^{o}C, while they were more sensitive to elevated temperatures above 300^{o}C. Between 100-300^{o}C, the residual strength of almost all the mixtures increased. The effect was more significant for siliceous aggregate-containing concretes. A continuous decrease in the compressive strength of the specimens was observed irrespective of the type of the aggregate at 600^{o}C and 900^{o}C.

The aim of this study is to investigate the effect of elevated temperatures on flexural and compressive strength of 6 different cement types (CEM I, CEM II/A-P, CEM II/B-P, CEM IV/A-W, CEM IV/B-W, CEM III/A). Mortar mixtures were cured in water for 28 days and in air for the following 28 days in laboratory conditions. After curing period, the specimens were exposed to 150°C, 300°C, 450°C, 600°C and 900°C for 4 hours and were allowed to cool to room temperature. The specimens were tested in flexure and in compression 24 hours after exposure. It was concluded that blended cements exhibit a higher compressive strength compared to CEM I when exposed to high temperatures. Microstructure of control and exposed specimens containing CEM I and CEM III-A were observed under ESEM (environmental scanning electron microscope).

2. MATERIALS AND TEST METHODS

2.1 Composition of Binders

The chemical composition of ordinary portland cement (CEM I 42.5R) and mineral admixtures (fly ash, natural pozzolan and slag) are provided from İzmir Çimentaş Cement Factory (Table 1).

Table 1 Chemical composition of CEMI 42.5R, fly ash, natural pozzolan and slag.

Oxide Composition (%)	CEM I 42.5 R	Fly Ash	Natural Pozzolan	Slag
MgO	1.54	1.54	1.27	5.47
Al_2O_3	5.17	23.55	12.22	10.43
SiO_2	18.71	45.98	51.82	41.33
SO_3	2.88	1.47	0.07	0.07
K_2O	0.84	1.8	2.56	1.21
CaO	63.74	18.67	12.32	32.60
Fe_2O_3	2.38	4.91	4.47	1.18
Na_2O	0.30	0.24	1.01	---
Loss on Ignition	3.88	2.31	10.32	---

2.2 Cement Types

The cement types used in this study were prepared by mixing the reference cement (CEM I 42.5 R) with different amounts of mineral admixtures. The contents of different cements are given in Table 2.

2.3 Aggregate (Standard Sand)

The mortars used in this study were cast by using siliceous standard sand in order to compensate the effect of aggregate mineralogy in different mixtures. Standard sand complies with the requirements given in TS EN 196-1.

Table 2 Cement types and their contents

	CEM I 42.5 (reference cement)	Fly Ash	Natural Pozzolan	Slag
CEM I 42.5	100%	0%	0%	0%
CEM IIA-P	85%	0%	15%	0%
CEM IIB-P	70%	0%	30%	0%
CEM IVA-W	70%	15%	15%	0%
CEMIVB-W	55%	15%	30%	0%
CEM III-A	55%	0%	0%	45%

2.4 Mixture Proportions and Test Method

Mortars were cast in accordance with TS EN 196-1 method by using 450 g cement, 1350 g standard sand and 225 g tap water. Six mortar specimens were cast into 40x40x160 mm prismatic molds for each mixture. The demolded specimens were cured in water for 28 days and in air for the following 28 days. The control mixture was tested in 20°C, other specimens were exposed to temperatures of 150, 300, 450, 600 and 900°C for 4 hours and cooled to room temperature for 24 hours. Exposed specimens were weighed before and after exposure to high temperatures.

Strength tests were performed in accordance with TS EN 196-1 by using a test machine of 10 ton capacity which can measure the loads and deflections automatically. Three-point loading was applied in order to evaluate the flexural tensile strength of the specimens. The broken portions were tested in compression as 40x40x40 mm modified cubes.

2.5 Microstructural Investigation

Epoxy-impregnated plane sections were prepared for the microstructural analysis. To obtain the desired smooth surface finish, impregnated specimens were subsequently lapped with 1200 and 4000 mesh bonded Carborundum and polished with 6µm, 3µm, 1µm and 0.25µm diamond paste on a lapping table. Polished specimens were finally rinsed in an ultrasonic bath to remove polishing paste and debris. Surface quality was checked under an optical microscope.

Polished specimens were investigated using a Philips XL30 environmental scanning electron microscope (ESEM). The instrument was operated at 15kV accelerating voltage, beam current 20mA, 0.3Torr pressure and at 10 mm working distance, with these settings applied for imaging.

3 RESULTS AND DISCUSSION

Flexural test results are the average of 6 specimens and compressive strength test results are the average of 12 specimens. Relative compressive strength, relative flexural strength and relative weight loss values were calculated with respect to the control specimen (the specimens tested at 20°C) of each cement type.

Relative compressive strength – temperature relationship is given in Figure 1. The compressive strength of CEM IV/A-W and CEM IV/B-W mortars were slightly increased at 300°C. The relative compressive strength of all mixtures was decreased by increasing temperature and blended mixtures showed higher relative compressive strength values beyond 300°C. The relative compressive strength of all of the mixtures was reduced to approximately 10% at 900°C.

Relative flexural strength-temperature relationship of the mixtures is given in Figure 2. There is a considerable increase in the relative flexural strength value of CEM I mixture at 150°C. Relative flexural strength of all mixtures was reduced at temperatures beyond 300°C. The relative flexural strength of all of the mixtures was reduced to approximately 15% at 600°C, while these values were reduced to about 10% at 900°C. Blended cements are more resistant to high temperatures when compared to CEM I at 450°C. Beyond 450°C, the effect of type of cement on flexural strength of mortars becomes negligible. Figure 3 shows the relative weight loss – temperature relationship. The weight loss of the samples are close to each other for each temperature level, weight loss of all of the mixtures are around 10-12% at 900°C.

Considering the compressive strength-temperature relationships, CEM IV (Pozzolanic) cements containing both fly ash and natural pozzolan and CEM III-A cement containing slag seems to be more resistant to high temperatures when compared to CEM I (plain) cement and CEM II (Portland-pozzolan) cements containing different amounts of natural pozzolan. Similar findings were observed for flexural tensile strength test results which are remarkable at 450°C.

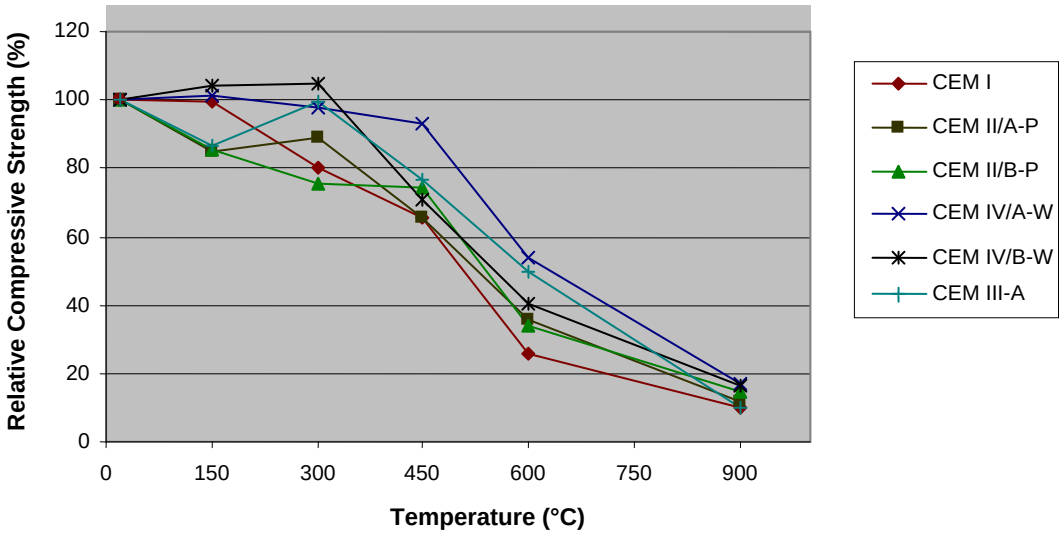

Figure 1 Relative compressive strength – temperature relationship of mortars

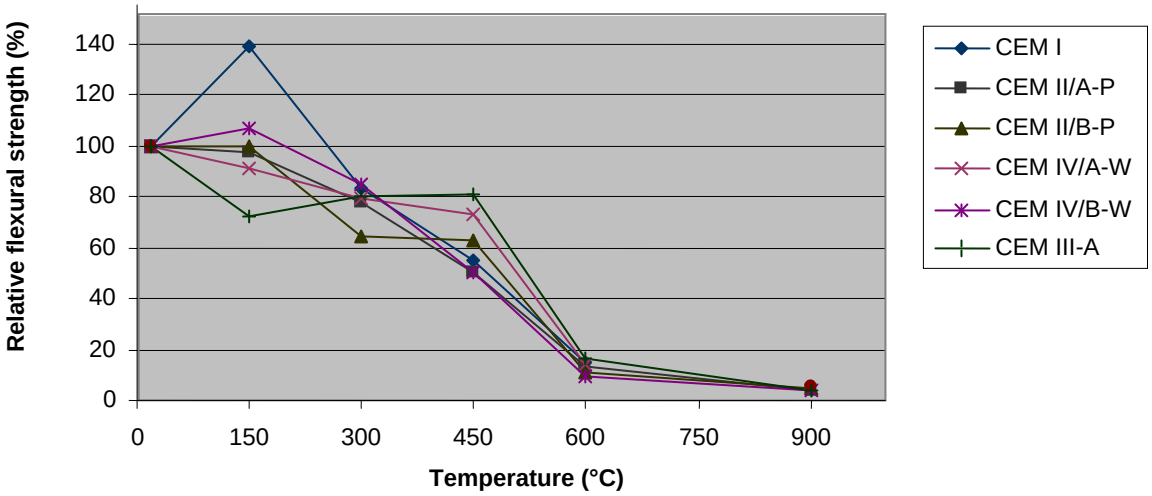

Figure 2 Relative flexural strength-temperature relationships of mortars

Microscopy findings concerning the effect of elevated temperature on the CEM I and CEM III-A mortars is presented in Figure 4. Up to 300°C, no significant structural damage was observed. Bonding between aggregate particles and cement paste was visually in rather good quality. However, significant crack development was observed at the microstructures of mortars exposed to 600°C. Micro cracks were observed throughout the microstructure but the most critical ones were traveling (connecting) individual coarse aggregate particles. De-bonding of the unreacted cement particles was also seen. This effect was probably because of significant volume alteration of hydration reaction products (CH, CSH).

The mineral admixture particles (in this case slag) showed no extensive debonding and appeared to be unaffected by the temperature attack. The microstructural investigation showed that crack size in CEM I paste microstructure was larger in comparison to the CEM III-A paste cracks. Information obtained from microstructural observations seems to support the findings obtained from mechanical tests.

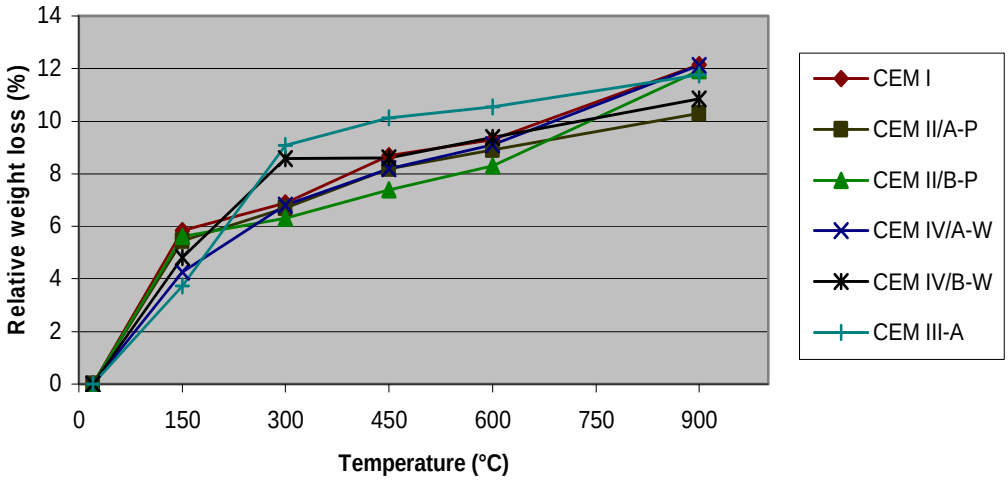

Figure 3. Relative weight loss-temperature relationship.

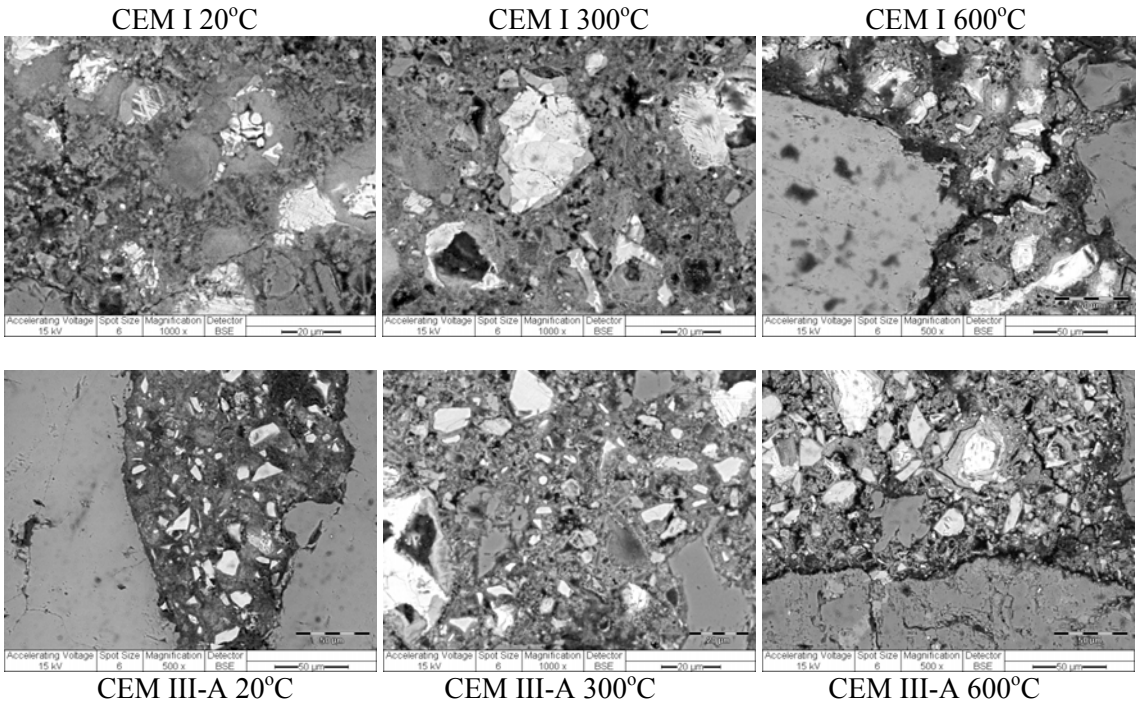

Figure 4. Effect of temperature elevation on the mortar microstructure, CEM I vs. CEM III-A.

4. CONCLUSIONS

- ✓ Relative compressive and flexural tensile strength of all mixtures was decreased by increasing temperature and blended mixtures showed higher relative strength values beyond 300°C.
- ✓ Considering flexural and compressive strength values, CEM IV and CEM III-A type cements are more resistant to high temperatures when compared to CEM I and CEM II type cements.
- ✓ The microstructural investigation showed that crack size in CEM I paste was larger in comparison to the CEM III-A paste cracks.

- ✓ Information obtained from microstructural observations seems to support the findings obtained from mechanical tests.

T 11

ABSTRACT

Using a constant water/cement ratio of 0.42 and different amounts of carbonaceous materials and different curing periods the evolution of the corrosion process in the embedded reinforced bars has been determined. The addition of small quantities of carbonaceous materials to the mixture produces a reduction of the concrete permeability. The higher is the cement paste conductivity, the higher is the instant corrosion rate in embedded steel.

1 INTRODUCTION

There is a wide range of potential applications of general purpose carbon fibers (GPCF). One of the most important is in the construction industry as addition to concrete mixes in order to develop or enhance special properties.

Although the use of carbon fiber materials in the construction industry means a significant cost increase, the highly promising benefits of their use, not only because of the improvement of mechanical properties but also in obtaining more efficient, smaller concrete element sections, make it interesting.

Durability of both the concrete matrix and reinforcements governs the service life of structures. In spite of the above mentioned advantages of carbon fibers, there are very few works published in the technical literature regarding the effect that the addition of different carbon materials produce in the concrete strength properties and the corrosion of embedded steel reinforcement [Hou & Chung 2000, Garcés *et al.* 2005, Garcés *et al.* 2007]. The purpose of the present work is to characterize the durability properties of steel embedded in mortars specimens in which different types of carbon materials have been used.

2 EXPERIMENTAL

2.1 Materials and methods of mortar specimens fabrication

Portland cement type CEM I 52.5 R (CP) and silica sand normalised under UNE-EN 196-1 standard were used for all mortar specimens.

Figure 1 shows the SEM images of the carbon materials used. Note the irregular particle shape. Sofacel graphite powder (PGS) is a commercial brand of Le Carbone Lorraine Company with particle size lower than 0.63 mm. Figure 2 shows PGS in detail. The marked lamellar structure and the rough surface can be observed.

No. 9 Graphite Powder (PG9) is a commercial brand supplied by Superior Graphite Company, particle size lower than 75 µm, also shown in Fig. 2. The morphological differences between PGS and PG9 are notorious.

The graphite electrode maker Grafitos Barco has supplied two types of by-products of the fabrication of furnace conductor electrodes for the steel industry. Both have identical composition and the difference is based on the particle size distribution. PGA type contains a minimum 90% of particles under 50 µm size, whereas PGC type contains a 90% of particles with average size in the range 0.5-1 mm. Table 1 shows the element composition of each type of graphite powder. The high content of carbon in all of them (more than 98%) is to be noted.

Table 1. Chemical analysis of carbon admixtures.

Sample	*Elemental Analysis (% wt.)*			
	C	*H*	*N*	$(S+O)_{dif}$
PGS	99.35	-	-	0.65
PG9	99.00	-	-	1.00
PGA and PGC	98.48	-	0.05	1.47

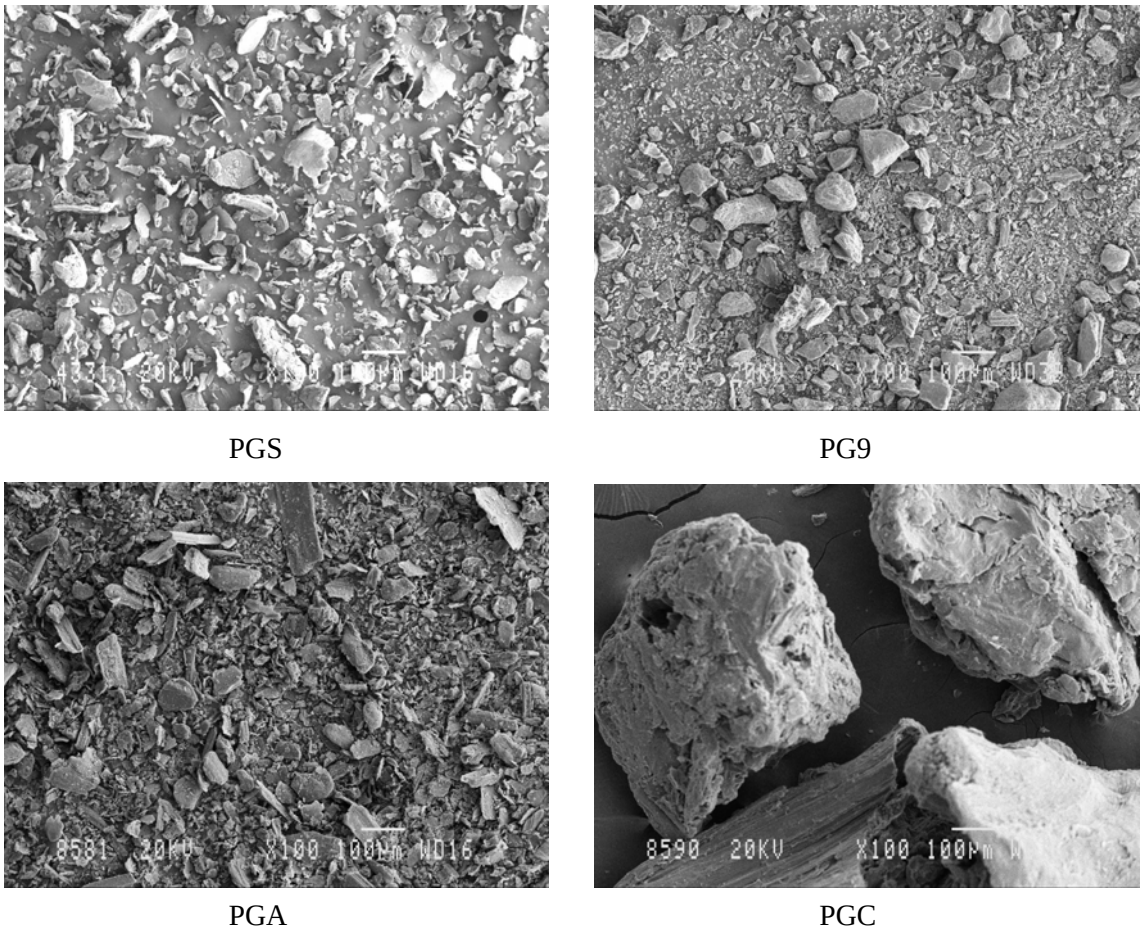

Figure 1. SEM images of carbonaceous materials.

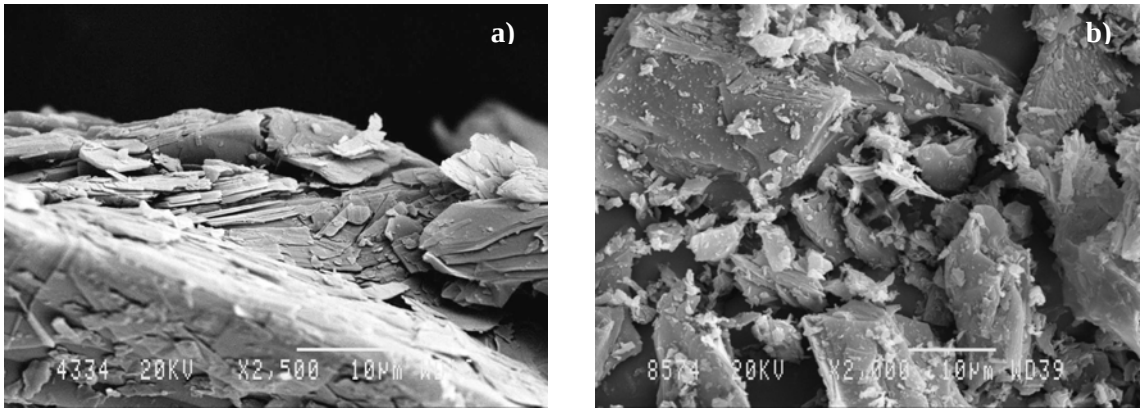

Figure 2. Details of (a) PGS and (b) PG9.

Figure 3 shows the particle grading curves obtained by laser light diffraction of the materials used in mortar fabrication. Only the fraction of sand passing through 0.16 mm sieve was used. The mean size value D50, that is the size value in µm under which 50% of the particles lay, is as follows: 15.9 µm for cement, 28.1 µm for PG9, 28.8 µm for PGA, 41.2 µm for PGS, 79.7 µm for sand and 355.7 µm for PGC. With the exception of PGC all graphite powder types have grading curves laying in between the cement and the sand grading curves. A filler effect can then be expected for those materials.

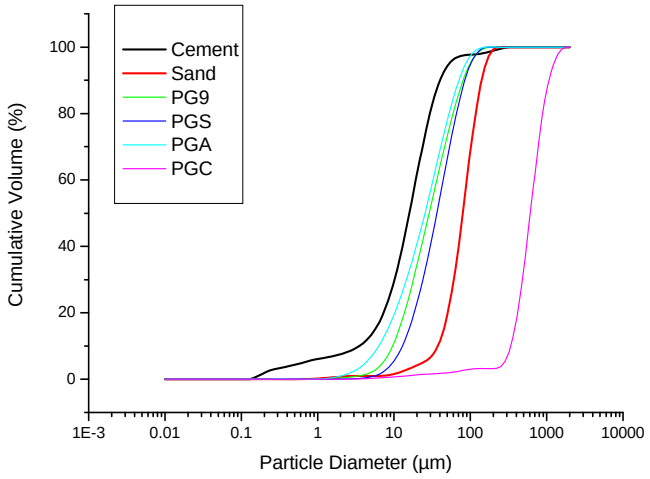

Figure 3. Particle size distributions of the GP types, cement and sand in the experiments.

2.2 Corrosion tests

For corrosion testing the GP ratio used was 1% as addition. Corrosion tests were carried out using mortar prismatic specimens of 80x55x20 mm size. Each specimen contained two cylindrical carbon steel electrodes, 8 mm diameter, and a graphite counter-electrode in the middle. The resulting cover thickness is 6 mm. The steel exposed area is 6.3 cm^2 (two electrodes). The instant corrosion rate Icorr for each electrode was assessed and the average of the two electrodes of each specimens was taken as the result value. Measuring was carried out until stable values of Icorr were obtained.

Corrosion test specimens were cured in a 100% RH chamber, and later, some of them, subjected to haste carbonation (CO_2 saturated atmosphere, 70% RH).The others were partially immersed in a 0.5 M NaCl dissolution simulating seawater.

Half of the specimens were hastily carbonated inside a glass recipient internally filled with a CO_2 saturated atmosphere. In the internal bottom of the recipient a glycerine dissolution kept the inside relative humidity at about 70%. A perforated tray was used to separate and store the specimens above the glycerine dissolution. The progress of the carbonation front was monitored using the phenolphthalein method on separate 80x20x20 mm prismatic specimens. After cutting 1 cm thick slices of the control prisms the carbonated areas were detected by dropping some phenolphthalein on the cut face.

The other half of specimens were hastily carbonated, dedicated to chloride attack study, were placed inside recipients with a 0.5 M dissolution of NaCl simulating seawater. Specimens remained partially immersed in the dissolution leaving only 2 cm of their height above the liquid surface in order to avoid contact of the electrodes with the dissolution. The liquid level was checked periodically and maintained constant. The portions of the electrodes extending outside the mortar were covered with Vaseline to avoid corrosion on this parts.
The electrochemical technique used to asses the instant corrosion rate Icorr of steel was the Polarization Resistance, Rp. After measuring the Rp value the Icorr vas calculated using the Stern and Geary formula [Stern & Geary 1957]: Icorr = B/Rp . Constant B was set to 26 mV for corroding steel and to 52 mV for steel in passive state [Andrade & González 1978].

The value of Rp was measured periodically through the experimental time, along with the corrosion potential Ecorr. At the end of experiments, the total electrochemical mass loss was calculated for each electrode and checked against the gravimetric loss (obtained by weighing). All values of potentials

refer to a calomel saturated electrode. A Princetone 362 EG&G galvanostat was use in the measurements. The result values of Icorr are the average of the measurements of four electrodes (two specimens, two electrodes each). The electrochemical mass loss was calculated by integration of the Icorr vs. time curves and the Faraday Law. The calculated values matched quite well with the gravimetric values, confirming the adequacy of the value used for B.

3 RESULTS

The results of the corrosion behavior of steel embedded in these conductive mortars are shown in Fig. 4 as the evolution of corrosion rate in mortar specimens with additions of PGA, PGC and PG9 types. Initially, the specimens were stored in a 100% RH ambience. Icorr values were monitored periodically since the instant of specimen demoulding until steady values.

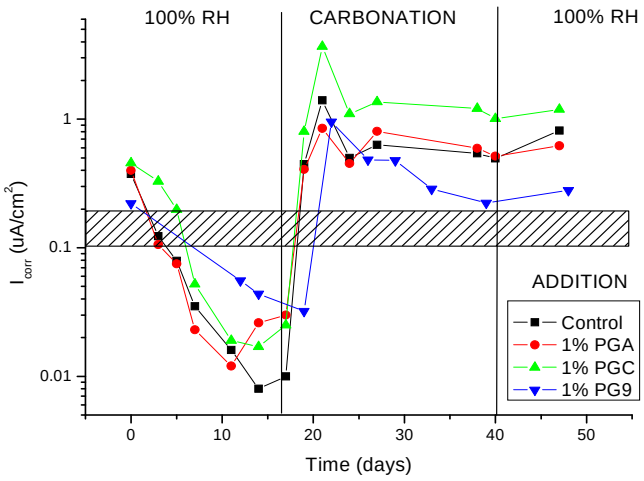

Figure 4. Evolution of corrosion rate in mortars with 1% addition of different GP types and subjected to different ambient conditions: 100% RH, carbonation and again 100% RH.

Under the first 100% RH period, the Icorr values were decreased continuously with the highest values of 0.04 µA/cm^2 for PG9 addition. All values lay under the 0.10 µA/cm^2 threshold, that is in passive state and usually continue so until a change in the conditions occur.

Specimens were then stored in the carbonation chamber and a sudden increase of the corrosion rate was detected in all cases. For example, the PGC addition mortar reached Icorr values of about 4 µA/cm^2. Later on, steady values were recorded but with important difference between some of them. The highest steady value obtained was 1.3 µA/cm^2 for PGC addition specimens. These steady values were almost the same when the specimens were again stored in a 100% RH ambience.

The Icorr values of GP added specimens were similar or higher than the ones of the reference specimens (no GP), except for PG) additions. One possible explanation of it could be the high fineness of this addition and the smaller porosity of the specimens that would compensate the effect of a higher conductivity due to the presence of the carbon material. The lower porosity would mean a limitation of the oxygen diffusion current and consequently of the cathodic reaction.

Figure 5 shows the evolution of Icorr in mortar specimens fabricated with 1% additions of PGA; PGC and PG9 types, cured in a 100% RH chamber and then partially immersed in seawater. Right after demoulding, the first Icorr values were obtained. The recorded values were in the range 0.3-07 µA/cm^2.

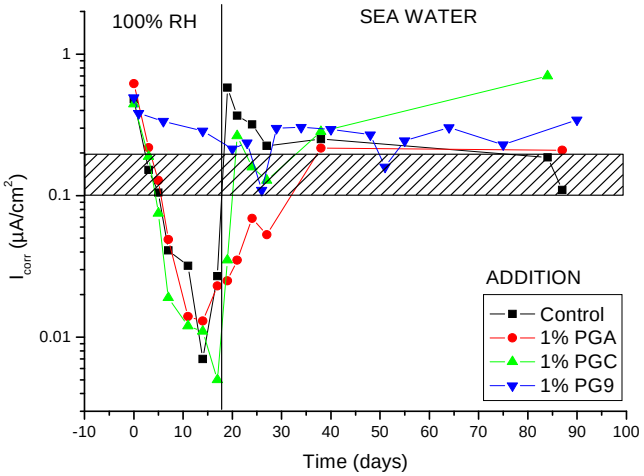

Figure 5. Evolution of corrosion rate in mortars with 1% addition of different types of GP, cured in 100% RH chamber, and later partially immersed in seawater.

In the period of 100% RH ambience the Icorr values were decreasing to values well under 0.1 µA/cm^2, except for PG9 added specimens that provided values in the higher limit of the passivity marking band [Andrade & Alonso 1996, Andion *et al*. 2001].

The immersion in seawater implied in all cases a sudden increase in corrosion rates which after some time reached stationary values.. The PGC type added mortars provided the highest Icorr values of about 0.6 µA/cm^2. The result differences between PGA, PG9 and PGC added specimens can be explained by their different particle size grading curves.

The reference specimens provided smaller Icorr values than any GP added specimen. To explain this, the role of the galvanic couple between steel and the carbon materials is to be considered. The contact of conductive materials of different nobility levels implies that the less noble material will develop a corrosion level higher than the one it would have being alone in the same environment. This would be compensated by a decrease in the corrosion level of the more noble material. The electrons from the oxidation of the less noble material will act as some kind of cathodic protection on the more noble material surface. In our case the more noble material is graphite and the less noble is steel. Consequently the presence of graphite in the mortars contributes to an increase in the Icorr levels registered in steel.

The presence of GP implies an increase in steel corrosion rates due both to the higher conductivity of the mortar and to the galvanic effect that the carbon materials produce on the embedded steel.

4 CONCLUSIONS

1. The higher the carbon material addition content ratio, the higher is the porosity.

2. Tests demonstrate that a increase of the corrosion level occurs when the content ratio of carbon material addition is increased.

Mohammad Shekarchi [1]

T 11

ABSTRACT

Concrete is an inherently brittle material with a relativity low tensile strength compared to its compressive strength. Reinforcing with randomly disturbed short fibers presents an effective approach to the stabilization of the crack system, improving the ductility and tensile strength of concrete. Polypropylene (P.P) fiber reinforcement is considered to be an effective method for improving the shrinkage cracking characteristics, toughness and impact resistant of concrete material. Even though fibers are widely used to improve mechanical properties of concrete, they may affect the workability and the flow characteristics of plain concrete.

Durability characteristics of plain concrete may be improved using polypropylene fibers. Several researchers have been carried out on the mechanical properties of polypropylene fiber reinforced concrete; yet there are a few investigations on the durability properties of concrete containing polypropylene fibers.

In this paper, the effect of adding various percentages of P.P fibers to concrete on the durability of concrete is investigated. Water penetration, gas permeability, electrical resistivity and shrinkage were studied. Results show that adding P.P fibers to the concrete will decrease the shrinkage of concrete significantly. Although using these fibers does not improve the permeability of concrete notably.

1 INTRODUCTION

Rapid development in concrete technology in line with advances in concrete additives has lead in the application of ultra high performance concrete in the field of construction materials. High strength concrete offers more options for the design of tall buildings and makes it possible to be used for long span beam and slab design. Although increasing mechanical properties of concrete such as compressive strength are useful and beneficial, but it reduces the ductility of such concrete which in turn reduces the safety of concrete structures against seismic loads [Tayyib1990].

Adding fibers into the concrete is an efficient method in increasing the ductility of concrete. The most famous of fibers used in the concrete are steel and polypropylene fibers. Thus application of fibers in UHPC is indispensable.

Numerous investigations have been carried out on the application and behavior of the fiber reinforced concrete. Research has been performed on the behavior of fiber reinforced concrete subjected to various load conditions, including flexural and tensile loadings [Khaloo 2005].

1.1 Steel Fibers

The addition of steel fibers significantly improves many of the engineering properties of mortar and concrete, notably impact strength and toughness. Tensile strength, flexural, failure strength and ability to spalling are also enhanced.

Moreover addition of fibers makes the concrete more homogeneous and isotropic material. When concrete cracks, the randomly oriented fiber arrested a micro cracking mechanism and limit crack propagation, thus improving strength and ductility [duzgun et al 2005].

Despite the mentioned advantage of steel fiber, steel fiber could not to be used in the concrete elements which placing in the sever conditions. Durability problems should be concerned when using steel fibers in concrete structures exposed to severe conditions. Constant maintenance and repairing is needed to enhance the life cycle of these structures [Sargaphuti et al 1993].

1.2 Propylene Fibers

Many investigations have performed on the mechanical properties of propylene fiber reinforced concrete.

The results showed that, the use of polypropylene fibers has successfully increased the toughness of concrete. Although polypropylene fibers are characterized by low elastic modules and poor physiochemical bonding with cement paste, it is quite apparent that the load carrying ability of a structure under flexural loading is considerably increased. On the hand, it may be used instead of steel fibers in severe exposure conditions.

Propylene fibers may improve thermal behavior of UHPC although it does not significantly modify the residual mechanical properties of UHPC.

Beside these investigations carried out on the mechanical properties of concrete, There are a few investigations on the durability properties of concrete containing polypropylene fibers. The ability of concrete to withstand the penetration of liquid and oxygen can be described as the durability of concrete [Mahoutian et al 2007].

In this paper, the effect of different percentages of P.P. fiber on durability properties of fiber reinforced concrete is investigated. The effect of fiber on the Water penetration, gas permeability, electrical resistivity and shrinkage of concrete is investigated in this study.

Results obtained from this study indicate that adding fibers into concrete does not significantly improve the durability parameters such as water penetration depth and oxygen permeability, while it reduces shrinkage of concrete.

2 EXPERIMENTAL PROGRAM

In order to investigate the effect of propylene fiber on the properties of fresh and hardened concrete, several mixes of different fiber contents and lengths were designed and tested.

Aggregates used in this experiment are derived from Metosak Company, Iran and are graded in accordance with ASTM C 33. Propylene fiber was provided from Bonyad Alyaf Propylene, Iran.

2.1 *Mix Proportions*

Mix proportions for concrete specimens are shown in Table 1. The water to cement ratio of 0.4 is kept constant for all mixes. Fibers of two different lengths are used in order to investigate the effect of fiber length on workability of fresh concrete. Superplasticizer is used in order to improve the workability.

Table 1. Mix proportions.

	Unit	P_0	P_1	P_2	P_3
Cement	Kg/m^3	350	350	350	350
Coarse Agg.		950	950	950	950
Fine Agg		1000	1000	1000	1000
Water		184	184	184	184
w/c		0.4	0.4	0.4	0.4
SP	Kg/m^3	4.72	4.72	4.72	4.72
Propylene fiber		0	0.9	0.9	3.6
Fiber length	mm	-	12	19	12
Fiber content	%		0.1	0.1	0.4

2.2 Laboratory Tests

To investigate different properties of fresh and hardened concrete containing propylene fibers, laboratory tests according to most well-known standards and recommendations were carried out.

3 FRESH CONCRETE TESTS

3.1 Slump Test

Slump test of fresh concrete is determined regarding ASTM C 143. Although this test is not recommended for Fiber reinforced concrete structures, but it can be used as investigate the effect of adding fibers on the workability of fresh concrete. For mixes containing fibers, the value of slump is determined before and after adding the fibers.

3.2 The Time of Flow Through Inverted Slump Cone

Workability and consistency of fiber-reinforced concrete is best measured by determining the time of flow of fiber-reinforced concrete through inverted slump cone according to ASTM C 995.

The inverted slump-cone time is a better indicator than slump of the appropriate level of workability for fiber reinforced concrete placed by vibration because such concrete can exhibit very low slump due to the presence of the fibers and still be easily consolidated.

Results of these two tests are shown in Tables 2.

3.3 Air Content of Fresh Concrete

Air content of freshly mixed concrete was determined using pressure method in accordance with ASTM C 231. Results are shown in Table 2.

Table 2. Air content, slump and time of flow.

	Units	P_0	P_1	P_2	P_3
Air Content	%	3.9	3.8	3.3	2.8
Slump before adding fibers	mm	90	90	100	105
Slump afteradding fibers	mm	-	25	18	3
Time of flow	sec	-	71	84	188

4 HARDENED CONCRETE TESTS

4.1 Compressive and Flexural Strengths

Compressive strength and flexural strength of concrete specimens of 28 days age according to ASTM C 39 and ASTM C 293 respectively. Results are shown in Table 3.

Table 3. Compressive strength and flexural strength.

	Unit	P_0	P_1	P_2	P_3
Compressive strength at 7 days		39.4	42.3	41.7	38.4
Compressive strength at 28 days	MPa	49	51.8	51.6	49.3
Flexural strength at 28 days		8.7	9.2	8.9	9.7

4.2 Flexural Toughness

Toughness is generally defined as energy absorption capacity of a cracked concrete specimen. Test method in this experiment is in accordance with ASTM C1018. The schematic illustration of the method and calculation is shown in Fig. 1. Toughness indices I5, I10 and I20 correspond to the area under load-deflection curve in steps of 3, 5.5 and 10.5 times of the first crack deflection. Regarding this standard, the indices are calculated as shown below:

$$I_5 = \frac{areaO' ACD}{areaO' AB} \quad , \quad I_{10} = \frac{areaO' ACEF}{areaO' AB} \quad , \quad I_{20} = \frac{areaO' ACEGH}{areaO' AB}$$

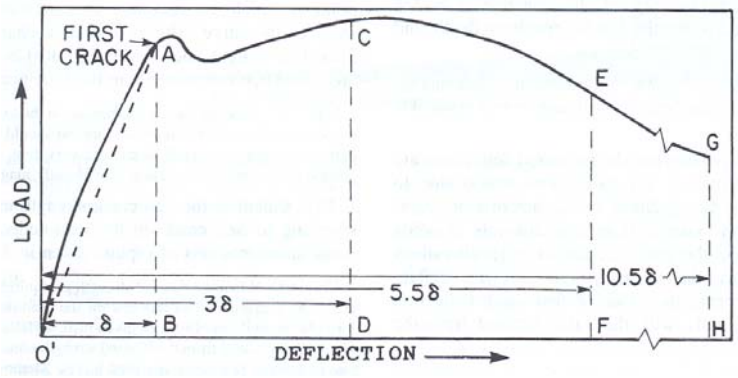

Figure 1. Load deflection curve for concrete specimens under flexural test.

Results obtained from the test are shown in Table 4.

Table 4. Flexural toughness of concrete.

	P_0	P_1	P_2	P_3
Flexural toughness`	0.73	1.22	2.31	2.53
Toughness index I5	-	1.29	1.28	1.25
Toughness index I10	-	-	1.52	1.47
Toughness index I20	-	-	-	1.68

5 DURABILITY TESTS OF HARDENED CONCRETE

5.1 Water Penetration Depth

Water permeability test and determining the depth of water penetrated into concrete is done according to DIN-1048 Part1. The test is carried out on cylindrical specimens of 30 cm height and 15 cm diameter at the age of 28 days. Specimens are kept at water pressure of 1, 3 and 7 atmosphere for duration of 48, 24 and 24 hours sequentially. Results are shown in Table 5.

5.2 Oxygen Gas Permeability Test

Permeability is a microstructure property of concrete which indicates the ability of concrete to bypass a fluid with specific viscosity under a pressure gradient [Bamforth 1987].

The permeability of porous environments is still governed by Darcy's law. Although it has its own limitations and is just valid if:

1- Considering the flow regime laminar.
2- The penetrating fluid should be neutral. There should be no physical or chemical reaction (absorption, capillarity) between the porous milieu and the fluid.
3- The fluid should be incompressible.

Permeability of concrete specimens against oxygen gas is determined in accordance with RILEM-TC116 recommendations. Cylindrical concrete specimens of 30 cm height and 15 cm diameter were tested at the age of 28 days. Results are shown in Table 4.

Table 5. Water permeability test and gas permeability of concrete specimens.

	Unit	P_0	P_1	P_2	P_3
Water penetration depth	mm	13.4	13.5	14.0	14.2
Gas Permeability coefficient * 10^{-17}	m^2	6.485	6.098	7.042	7.872

6 DRYING SHRINKAGE

Determining the shrinkage of specimens was done according to UNI-6555 recommendation. Specimens of 10*10*50 cm were casted in order to measure the shrinkage of concrete within 28 days after casting. Specimens are kept in laboratory condition of Temperature 20 ±1 C0 and the relative humidity of 50 ± 3%. Results are shown in Table 6.

Table 6. Drying shrinkage at the ages of1, 2, 3, 7, 14, 28 days.

	Length change – mm			
Age (days)	P_0	P_1	P_2	P_3
1	-2.92	-0.84	-0.84	-0.76
2	-3.52	-1.54	-1.86	-1.22
3	-3.94	-1.72	-2.48	-2.34
7	-4.66	-2.80	-3.74	-3.54
14	-7.54	-5.48	-5.72	-4.14
28	-8.78	-5.66	-5.88	-5.38

7 CONCLUSION

Results obtained from this study indicate that adding propylene fibers to concrete improves flexural toughness of concrete significantly; while it does not improve other mechanical properties such as compressive and flexural strength.

Adding propylene fibers into concrete has significantly reduced the drying shrinkage of concrete. Although it does not improve durability parameters such as water permeability or oxygen gas penetration into concrete.

ACKNOWLEDGMENTS

Authors should thank Bonyad Propylene Co. for providing fibers required for test preperation.

Sayed Mohamed Abd El-bakey [3]
Esraa Emam Ali [4]

ABSTRACT

Prediction of the early age strength of concrete is essential for modernized concrete for construction as well as for manufacturing of structural parts. Safe and economic scheduling of such critical operations as form removal and reshoring, application of post-tensioning or other mechanical treatment, and in process transportation and rapid delivery of products all should be based upon a good grasp of the strength development of the concrete in use. This research work investigates the use of "*Maturity method*" in estimating the concrete strength and presents a brief review on the previous experimental and theoretical studies carried out on estimating maturity method. An experimental program is designed to estimate the concrete strength by using the maturity method .Where fourty eight concrete mixes are designed. Using available local materials, Ordinary Portland Cement was used with different contents (300, 350,400 and 450 kg/m^3) at curing temperatures (10,25 and 40ºC) and constant water to cement ratio= 0.45, the different mixes are examined woth respect to(compressive strength, indirect tensile strength, flexural strength and elastic modulus).

1 INTRODUCTION

For years, 28-days cube tests have been employed during construction in order to estimate the compressive strength of concrete, since it makes no allowance for the effects of placing, compaction, or curing. Nondestructive in-place test methods have been developed for estimating the compressive strength of concrete in structures. These tests are essential for realistic depiction of the in-place strength in concrete elements. One of the techniques for estimating the strength gain of in-place concrete is the maturity method. This technique is based upon the measured temperature history of concrete during the curing period. The combined effects of time and temperature lead to a single parameter termed "maturity". McIntosh [1], was probably the first to develop a parameter in 1949, which called "basic age", to combine the influence of temperature and time. The basic age was calculated as the multiple of time and temperature above minus 1.1ºC. Numerous maturity functions since the early 1950. Saul [2], proposed the following relation to compute the maturity of concrete.

$$M(t,T) = \sum (T - T_O)\Delta t \tag{1}$$

Where;

M (t, T) = Maturity of concrete as a function of time (t) and temperature (T)
T = Temperature of concrete
To = Datum temperature, and
Δ t = time interval

A model based on the Arrhenius function for thermal activation is widely used in some European countries and also in North America [3].

$$M(t,T) = \int_0^t K.EXP\left(\frac{-E}{RT_k}\right)dt \tag{2}$$

Where;

K = Constant
T_K = Temperature of concrete in degrees Kelvin
E = Activation energy in kilo joules per mol, and
R = Universal gas constant.

Rastrup .[4] presented a time-temperature function of the form:

$$t_1 = 2^{\frac{(T + T_r)}{10}} t_2 \tag{3}$$

Where;

t_1 = Curing time at the temperature Tr
t_2 = The curing time at the temperature T, and
Tr= The reference temperature

The function proposed by Rastrup is based on a well-known physicochemical rule, which states the speed of reaction is doubled when the temperature is increased by 10 ºC.

Nurse [5], used the multiple of the time and temperature above 0 ºC as a parameter to combine the effects of curing history. In this investigation, prism specimens were subjected to steam curing at atmospheric pressure and were tested for strength properties including compressive strength using various types of aggregates and cement.

In 1956, Plowman [6], attempted to develop a relationship between concrete strength and maturity. He used cube specimens that were initially subjected to normal curing for 24 hours prior to being cured at various curing temperatures.

In this study, concrete mixes are designed. Using Ordinary Portland Cement with different contents at curing temperatures (10,25 and 40 ^{o}C) and constant water to cement ratio= 0.45, the different mixes are tested (compressive strength, indirect tensile strength, flexural strength and elastic modulus) with the maturity index [7].

2 EXPERIMENTAL PROGRAMME

The experimental programme includes selection of materials, preparation of mixtures, and testing of specimens.

2.1 Selection of Material

The used cement was CEM I 42.5N according to Egyptian Standard Specification 4756/2005, crushed limestone coarse aggregate according to Egyptian Standard Specification 1109/2001 with maximum nominal size of 14 mm, and sand fine aggregate according to Egyptian Standard Specification 1109/2001, silica fume and fly ash from Mcc. company are also used.

2.2 Perpartation of Mixes

The following Table (1) shows the different concrete mixes used in the experimental programme.

Table 1. Concrete mixes proportions.

Mix no.	Cement content (Kg/m^3)	Coarse agg. (Kg/m^3)	Fine agg. (Kg/m^3)	W/C ratio	Silica Fume (Kg)	Fly Ash (Kg)
1	300	1280	640	0.45	-	-
2	350	1220	610	0.45	-	-
3	400	1154	577	0.45	-	-
4	450	1090	545	0.45	-	-
5	350	1306	653	0.35	35	35

Mixing was done in a standard drum-type mixer. Coarse and fine aggregates were first mixed in dry state until the mixture became homogenous.

For each mix twelve cubes were prepared (15*15*15 cm) for testing compressive strength at (1,3,7 and 28 days) for each degree of temperature (10, 25 and 40°C), also three cylinders (15*30 cm) for splitting tension test, three cylinders (15*30 cm) for determining the modules of elasticity and three beams (10*10*70 cm) for determining the flexural strength of concrete for cement content (350 Kg/m3) at temperature 25°C. During each age of testing the concrete temperature was measured by using a device to monitor and record the concrete temperature at each curing temperature (10, 25 and 40°C) where thermocouples sensors installed at critical location in the specimens.

Figure 1. A device to Monitor and Record Concrete Temperatures.

Figure 2. Thermocouples Sensors Installed in Specimens.

2.3 Determination of Datum Temperature

The testing required to experimentally determine the datum temperature can be performed using mortar specimens, the basic approach is to establish the compressive strength versus age relationships for mortar specimens cured in water baths maintained at three different temperatures.

Two baths should be at the maximum and minimum concrete temperatures expected for the in place concrete during the period when the strengths are to be estimated. The third water bath temperature should be midway between the extremes. (10, 25 and 40 °C).

After knowing the final setting times at the three temperatures, prepare a graph with the reciprocal of strength as the y-axis and reciprocal of age as the x-axis then determine the slope and the intercept of the best-fitting straight line through the data for each curing temperature.

For each straight line divide the value of the intercept by the value of the slope resulting in the k-values which are used to calculate the datum temperature.

Fourty eight mixes were carried out to achieve the strength-maturity relationship at three different curing temperatures (10, 25 and 40 °C).

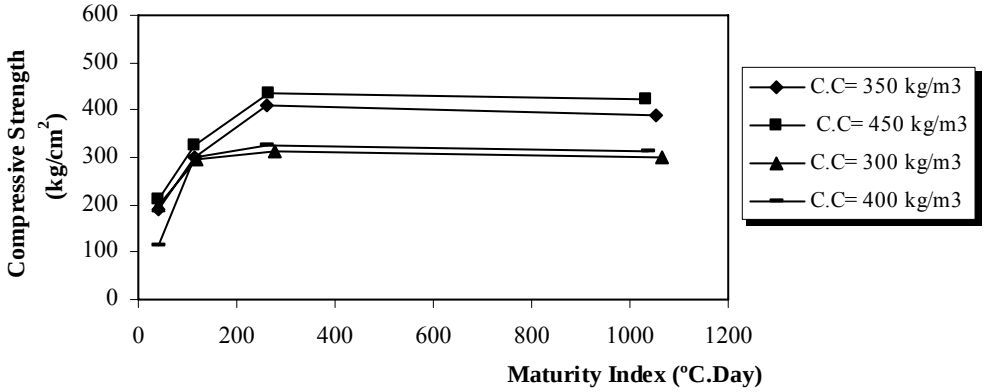
Fig(3-b) Strength-Maturity Relationship at 25°C



Fig(3-c) Strength-Maturity Relationship at 40°C

4EFFECT OF DIFFERENT CEMENT CONTENTS ON STRENGTH-MATURITY RELATIONSHIP.

The strength-maturity relationship for cement contents (350,450,300,400 kg/m^3) and constant w/c=0.45 are as shown in Fig 3 (a ,b and c) and Tables (2 and 3) respectively.

The rate of strength gained is increases at the first 7 days while the rate slow at later ages up 28 days. At mixes which have 0% silica fume and 0% admixtures, at 10°C, the rate of strength gain is smaller compared to the other two degrees of temperatures (25 and 40°C), where for the same mix the 28 days concrete strength at 10°C is more or less equals to the 7 days concrete strength at 40°C, while the slope equals 1.2,1.05,0.48 and 0.53 , (the ratio between the strength and maturity index) for cement contents (350,450,300 and 400 kg/m^3) respectively, it can be seen that cement content 350 kg/m^3 shows the higher slope, while at 25°C and 40°C were (0.22,0.40,0.2 and 0.34) and (0.13,0.14,0.052and 0.10) for cement contents (350,450,300 and 400 kg/m^3) respectively, it can be seen that cement content 450 kg/m^3 shows an increase than the other cement contents.

At 25°C, the strength shows a higher value compared with two degree of temperatures (10 and 40°C) by (8%,8.6%,15% and 10%) and (8%,15.5%,15% and 13.2%), for cement contents (350,450,300 and 400 kg/m^3) respectively.

At 40°C, the rate of strength gain is increased at the first 7 days then decreased at later ages. This is due to the increase of rate of hydration of cement at early ages at higher temperatures which creates a porous concrete matrix hence leading to decrease the compressive strength at later ages.

For maturity index, it increases with an average (1.5 to 5.5 times) as temperature increases from 10 to 40°C for all cement contents.

Table 4. The Splitting tensile Strength Test Results for Cement Content 350 kg/m^3.

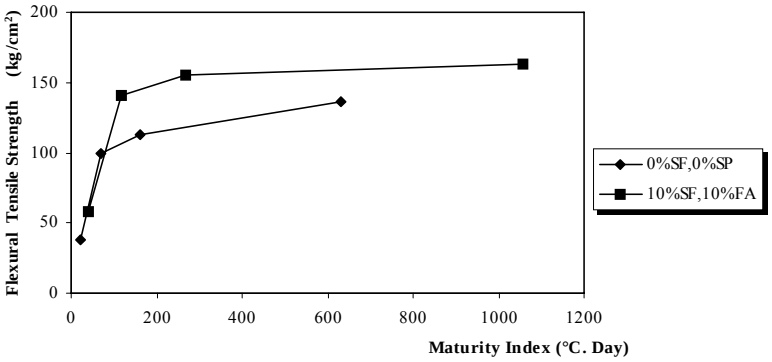
	25	26.5		155.4	269.5
	25	25.8		162.75	1058.4

The splitting strength-maturity relationship Table (4), for cement content 350 kg/m^{3}at temperature 25°C at w/c=0.45 the mix which have 10% silica fume and 10% fly ash shows an increase in strength 37%, while the maturity index increase by 74% from the mix which have no silica fume and fly ash.



(c) Flexural Tensile Strength-Maturity Relationship for C.C=350 kg/m^3 at 25 °C for W/C=0.45

Table 6. The Static Modulus of Elasticity Test Results for Cement Content 350 kg/m^3

Mix Code	Ambient Temp. ˚C	Measured Temp. ˚C	Datum Temp. ˚C	Youngs Modulus (kg/cm^2)	Maturity Index (˚C.Day)
0% SP,0%SF,0%FA	25	25.2	2.7	152	630
10%SF,10%FA	25	25.8	-12	284.7	1058.4

The flexural strength-maturity relationship Table (5), for cement content 350 kg/m^{3}at temperature 25°C at w/c=0.45 the mix which have 10% silica fume and 10% fly ash shows an increase in strength 19%, while the maturity index increase by 67% from the mix which have no silica fume and fly ash.

At w/c=0.45, mix which have 10% SF and 10% FA Table (6), shows an increase in Young's modulus and maturity index (87%, 68%) compared with mixes which have no silica fume or fly-ash respectively.

5 CONCLUSTION

1-The maturity concept can be used to predict strength of concrete at early ages, provided that the actual concrete temperature which used in estimating maturities during the early part of hydration of cement.

2- Compressive, splitting, and flexural strength development of concrete are related to mixture proportioning and curing temperature history.

3- The maturity index increases (1.5- 6 times) as temperature increase from 10 to 40°C depending on the mix proportions.

4- Curing temperature 25°C shows an increase in strength and maturity index for all cement contents (300, 350, 400 and 450 kg/m^3) respectively, while at 40°C at the first 7 days shows a higher increase in strength as the rate of hydration of cement increases hence the strength decrease at later ages.

5- W/C=0.45 shows an increase in strength and maturity index for all cement contents (300,350,400 and 450 kg/m^3) respectively.
6- Critical construction operations should not be initiated on the basis maturity index values and the strength-maturity relationship without further verification that the in place concrete has the expected strength potential.

ACKNOWLEDGMENT

The experimental work was carried out at Housing and Building National Research Centre Laboratories. The great help of the laboratory technical staff is highly appreciated.

Concrete for Durability at Marmaray Project

Serap Erdoğdu [1]
Steen Lykke [2]

T 11

ABSTRACT

The aim of this paper is to present information about the study performed during the construction work of Marmaray Project to obtain the target of 100 years service life of RC concrete structures.

The Marmaray Project in İstanbul includes part of the upgrading of the 76 km commuter rail from Halkalı, in the European end, to Gebze, in the Asian end. This line includes 1.4 km of immersed tunnel, 10.1 km of bored tunnels, 1.3 km of cut and cover tunnel and four underground stations.

Serviceability is influenced from various effects such as cracking, deformation, vibration, durability, water tightness and fatigue. Durability is one of the parameters of serviceability of the structure and therefore during the design stage all parameters were evaluated together in order to check compliance with the service life time requirement which was targeted for the overall project.

In the Project, concrete classes were determined according to the design requirements of typical structures. The composition of the mixture was optimized by pre-testings and trials to resist the relevant exposure conditions that impact concrete's durability. This means appropriate cementitious materials for sulfate ressistance, air void system for freezing and thawing and scaling resistance, adequate protection to prevent corrosion either from carbonation, chloride ingress or depth of cover a low paste content to minimize the drying shrinkage and thermal cracking, and the appropriate combination of aggregates and cementitious materials to minimize the potential for expansive cracking related to alkali silica reactivity.

Methods to be applied during construction for ensuring durability requirements is another step of the studies which are; proper quality control system for constituent materials, hardening and hardened concrete besides curing of concrete and finally adequate repair method.

1 INTRODUCTION

The durability of concrete is one of its most important properties because it is essential that concrete should be capable of withstanding the conditions for which it has been designed throughout the life of a structure. Lack of durability can be caused by external agents arising from the environment or by internal agents within the concrete. Causes can be categorized as physical, mechanical and chemical. Physical causes arise from the action of frost and from differences between the thermal properties of aggregate and of the cement paste, while mechanical causes are associated mainly with abrasion and physical load conditions. Chemical causes are attacks by sulphates, acids, sea water and also by chlorides which include electrochemical corrosion of steel reinforcement.

Durability studies for Bored Tunnels (TBM) and Immerse Tube Tunnel (IMT) which are the major structures of the project will be presented here.

For the bored tunnel, durability was analyzed for the carbonation of concrete and the attack of chloride ion in consideration of the design life of 100 years. As a result, it was confirmed that the carbonation is no problem if the cover is 25 mm or above. However, for the attack of chloride ion it was decided to ensure a cover of 70 mm in all structures potentially exposed to salin water (the Bosphorus Strait). The concrete cover of 70 mm is decided according to the actual measurement value of chloride ion. The result show that chloride ion content in water is extremely small, thus the influence on the tunnel lining is considered to be small. Therefore a concrete cover of 70 mm is used from the strait part to the above mentioned boringhole location. The typical cross section of the Bored and Immerse Tunnel is shown in Figure 1.

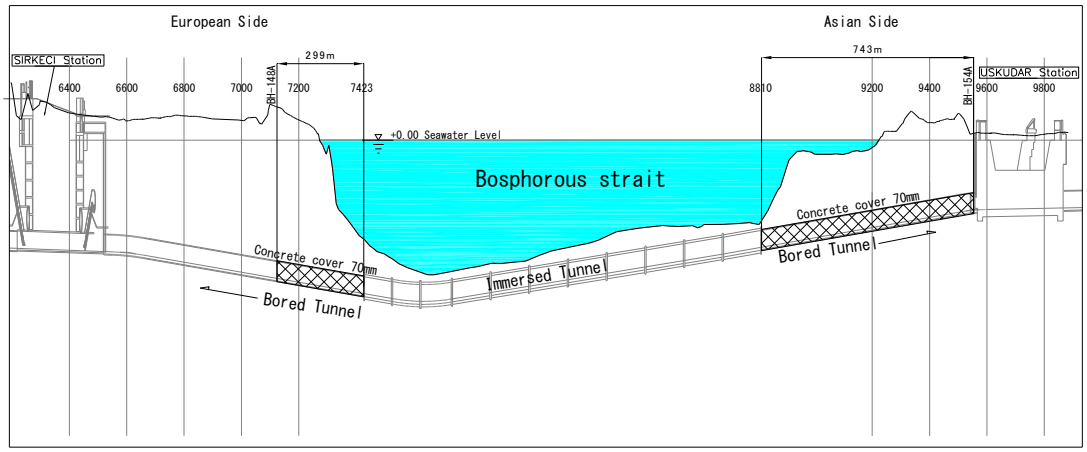

Figure 1. The range in which the concrete cover is 70 mm.

For the Immersed Tunnel (IMM), reinforced structure is enclosed in a steel membrane and waterproofing sheet and isolated from the aggresive environment.

According to British Standard BS 6349 for Maritime Structures, the condition of exposure for the immersed tunnel can be classified as frequently wetted condition, designated as XC2, with the structure totally submerged in seawater at all time. For this exposure condition, the nominal cover required by standard is 50 mm. Although there is an isolation of concrete with a layer of steel membrane and waterproofing sheet, 70 mm minimum cover is appropriate for severe environmental exposure conditions in case the external face of the member should have the waterproofing membrane fail and exposes the concrete structure to seawater seepage. Additionally, steel membrane is protected against corrosion by cathodic protection. Figure 2 shows that the thypical section of Immerse Element.

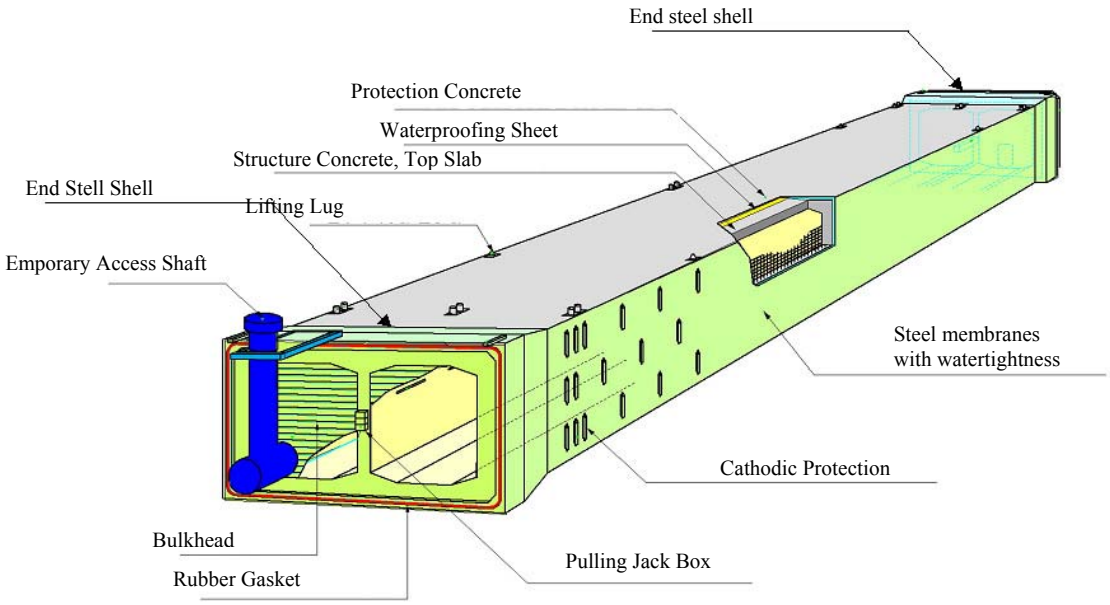

Figure 2. Typical Section View of Immersed Element.

2 DESIGN OF CONCRETE

2.1 Concrete Mix Design

For ensuring durability of concrete, mix design has been optimized according to the following limits;

- Maximum free water/cement ratio : 0.4
- Minimum cement content : 375 kg/m^3
- Minimum strength class : C40
- Minimum nominal cover : 70 mm (external faces), 32 mm (internal faces)
- Maximum crack widths : 0.2 mm (except early-age cracking)

The main characteristics of the mix determined by considering the limitation mentioned above used in the project are;

- High characteristic cylinder compressive strength (fck : 40-50 MPa)
- Low water/cement ratio (Between 0,30 to 0,40)
- Well graded aggregate
- Admixture for water reducer
- Air-entraining admixture
- Supplementary cementitious materials (Fly ash and Micro Silica)

2.2 Pre-testing of Concrete

A comprehensive pre-test programme was developed and executed. A part of the pre-testing was full scale trial casting (FSTC) executed under realistic circumstances. FSTC was not allowed to start until the pre-testing of the concrete mix was completed and should be done using the proposed construction methods and equipment performed by operators and staff whould be involved in the execution of the concreting works.

Following tests were conducted during pre-testings and also production;

2.2.1 Constituent Materials

All tests of constituent materails (Cement , Aggregates (Fine & Coarse), Sand, Fly-Ash, Micro -Silica, Admixtures and Water) according to related standards were realized and certified as Inspection Section.

2.2.2. Fresh Concrete Tests

Workability, Density, Temperature, Air-content

2.2.3 Hardening Concrete Tests

Activation Energy, Compressive Strength Tets, Tensile Strength Test, Modulus of Elasticity, Adiabatic Heat, Early-age Shrinkage, Strains due to Creep, Thermal Expansion, Maximum Temperature.

2.2.4. Hardened Concrete Tests

Compressive Strength, Density, Air Content, Chloride Diffusion, Petrographic Testing (Thin & Plane Section)

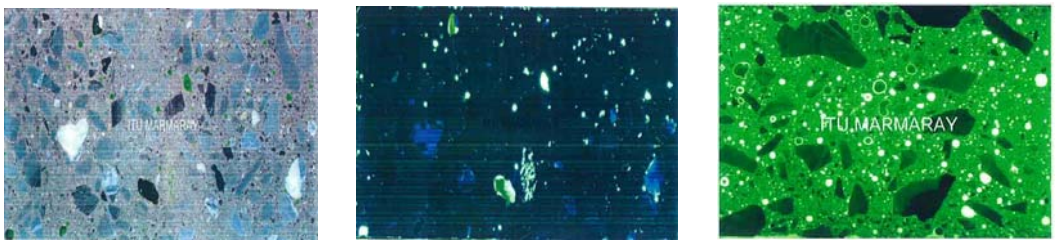

Figure 3. Polished impragneted plane section and thin section analysis.

Concrete Petrography Laboratory which is a part of İTÜ Marmarmaray Laboratory is the first in Turkey. At this laboratory concrete characteristichs are investigated closely during the production. Figure 3 is showing the image of polished impragnated plane and thin section.

3 CRACK CONTROL

Crack control studies of concrete comprises evaporation protection, early age crack control and frost resistance.

3.1 Evaporation Protection

All surfaces of the newly cast concrete is protected against evaporation. The protection is established after completion of compaction and surface treatment is applied to prevent cracking due to plastic shrinkage. The protection against evaporation is maintained until a minimum degree of hydration of 90% has been reached at the concrete surface, except for internal formed surfaces in tunnel items where the requirement for 90% degree of hydration may be replaced by a requirement to reach 96 maturity hours.The degree of hydration in the concrete surface is determined from measurements of the temperature at a depth of a maximum 10 mm, except for construction joints where a maximum depth of 20 mm is allowed. For concrete surfaces cast against formwork, an accaptable evaporation protection to leave the formwork in place.

3.2 Early-Age Crack Control

For hardening concrete structures, early-age cracks may be caused by reastraint to deformations due to combinations of thermal movements, early shrinkage, creep and settlements. Theoratical crack risk must not exceed 0.7. In the project early age cracking is generally not allowed.

For each type of structural element and all water-retaining structures planned risk of early-age cracking are determined through temperature and stress analysis (Figure 4). If cracking occurs, craks are injected in case they exceed the design crack widths.

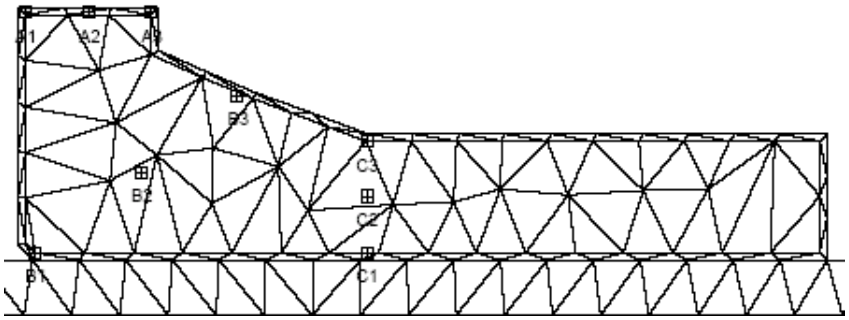

Figure 4. Temperature and Stress Simulation Model.

1) Temperature simulation is based on all relevant input data such as;
- the model (geometry, element mesh and boundary conditions),
- the maturity function for the concrete,
- the documented values for the adiabatic heat development, the content of powder in the concrete,
- the thermal conductivity of the concrete,
- the specific heat of the concrete,
- the concrete density, the fresh concrete temperature,
- the ambient temperature and wind velocity, the temperature, thermal conductivity, specific heat and density of surrounding materials,
- the documented values for the thickness and thermal conductivity of formwork and insulating materials,
- the design and control of arrangements for temperature control,
- the control of curing activities,
- casting sequence.

2) The output from the temperature simulation comprise information such as;
- temperature graphs showing the development of the mean temperatures of the structural elements (figure 5),
- graphs showing the development of the mean temperature of the newly cast items and the mean temperature of previously cast items (Dext),
- graphs showing the temperature difference between the mean temperature of newly cast items and the surface temperature of the newly cast items (Dint),
- graphs showing the maximum temperature in the concrete.

3) Stress simulation is performed using a well-documented computer program based on the Finite Element Method. Stress simulation shall be based on documented values for the thermal expansion coefficient, the E-modulus, the early-age shrinkage and the creep for the actual concrete. Stress simulation is based on all relevant input data such as;
- the model (geometry, element mesh and boundary conditions/restraint)
- the simulated temperatures,
- the documented value for the thermal expansion coefficient,
- the documented value for the thermal expansion coefficient,
- Poission's ratio
- The documented development of the early-age shrinkage,
- The documented development of the parameters that describe the development of strains due to creep.

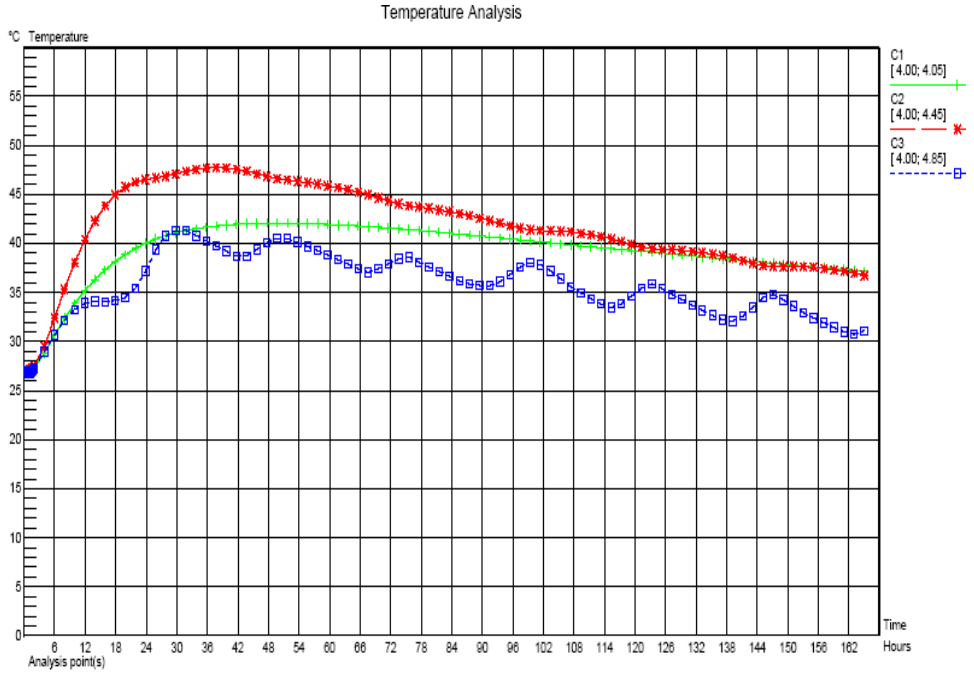

Figure 5. Temperature simulation model.

4) The output from stress simulation shall comprise information such as,
   - a general presentation of the stress level in the structure (iso-curves)
   - the development of the principal tensile stresses in selected points
   - the development of the risk of cracking (P) shall at any time be defined as:

5) The risk of cracking (P) is at any time be defined as:
   P= maximum principal tensile stress / the axial tensile strength
   The maximum crack risk simulation is shown in figure 6.

6) The axial tensile strength of the concrete ($f_{ct,ax}$) is determined from the splitting tensile strength ($f_{ct,sp}$) according to:

$$f_{ct,ax} = 0.9 \times f_{ct,sp}$$

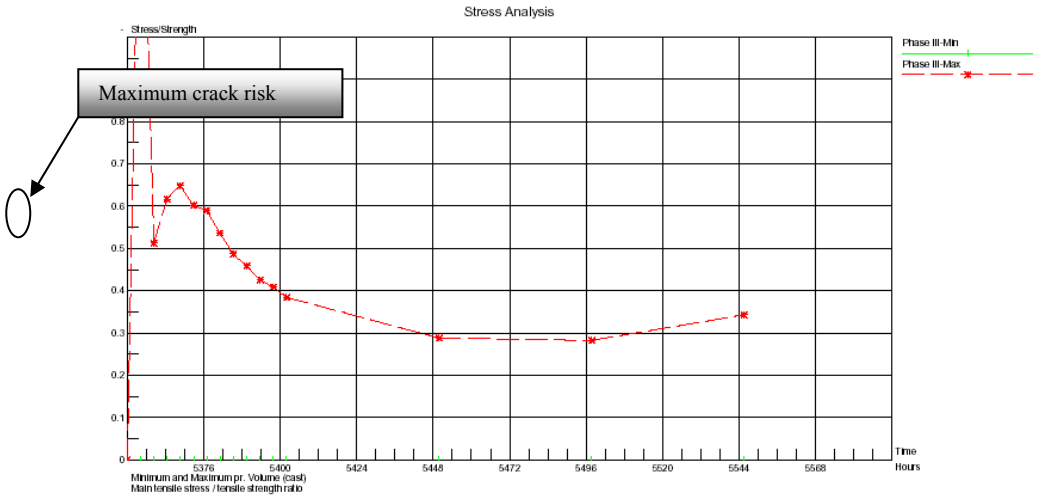

Figure 6. Crack risk simulation.

7) The risk of cracking must comply with the requirements given in Table 1.

Table 1. Overview of Parameters Reletad to Early-Age Cracking.

Location/Structure	Max. W (mm)	Max P	Max D_{ext} (^oC)	Max ΔT_{inc} (^oC)
Tunnels				
- water-retaining parts	0,2	0,70	15	8
- other parts		1,00	20	12
Ramps and C&C				
- water- retaining parts	0.2	0.70	15	8
- other parts		1.00	20	12
Stations				
- water- retaining parts	0.2	0.70	15	8
- other parts		1.00	20	12

8) Based on stress analysis, limiting temperature differences for each structural element are established corresponding to the following two limits;

(a) For structural items that are restrained by neighbouring elements, a maximum temperature difference between the mean temperature of the newly cast element and the mean temperature of previously cast items (D_{ext}) should be defined. The maximum allowable temperature difference during hardening should comply with the requirements given in table 1, regardless of the result of the stress simulation.

(b) For all structural elements, a maximum temperature difference between the mean temperature of the element and the temperature of the element (D_{int}) should be defined. The maximum allowable temperature difference during hardening shall be less than 15 ^oC regardless of the stress simulation.

9) The maximum temperature of the concrete is 50 ^oC in the central part of bottom slabs. If higher than 50 ^oC special consideration of Deleyaed Ettringite Formation (DEF) must be given.

10) A graphical comparison to the requirements is possible. Graphs showing the temperature developments is available on site for execution of the temperature control and other actions related to the temperature and maturity development, e.g. stripping of formwork.

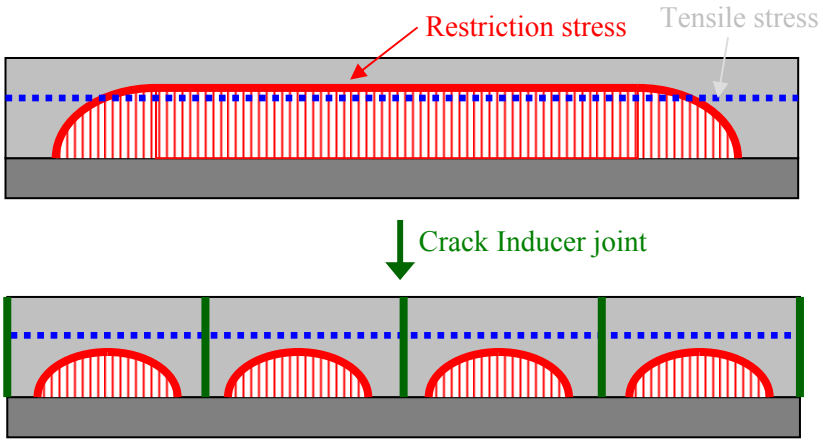

Figure 7. Effect of crack inducer joint.

In the project, temperature and Stress Simulation program is being effectively used in order to determine the casting method. As shown in figure 7, location of crack inducer joints are determined according to the outputs getting from T&S Analysis.

3. 3 Frost Resistance

The concrete is protected against freezing until frost resistance is obtained. Frost resistance is considered obtained when the concrete has reached a compresive strength of 10 Mpa.

In order to provide resistance to the damaging mechanism resulting from freezing is achieved through the use of air-entraining admixtures that stabilize and help distrubute air bubbles within the concrete.

4 CONCLUSION

In conclusion, sub-aqueous tunnels are subject to extraordinary conditions with regard to outside pressure and chemical aggresivity. Therefore, special measures with regard to avoiding or delaying the development of concrete deteriotion and reinforcement corrosion needs to be considered. In this paper, studies regarding the concrete durability have been presented to obtain the target of 100 years of service life of the structures in Marmaray Project.

Rebound and Composition of in-Situ Polypropylene Fibre-Reinforced Shotcrete

Atef Badr [1]
Jeff Brooks [2]

T 11

ABSTRACT

This paper presents the results of an experimental investigation into the rebound of polypropylene fibre reinforced shotcrete (PPFRSC). The effects of polypropylene fibre (PPF), fly ash (FA) and silica fume (SF) on the total rebound material and the composition of the in-situ shotcrete were investigated.

Six mixes were sprayed of which four mixes were initially optimised and investigated by laboratory tests. The remaining two mixes were commercially pre-packed shotcrete mixes. The total material rebound was measured and the factors affecting it were analysed. Samples were taken from the rebound and the freshly placed shotcrete for composition analysis.

About 80 % of the initial PPF dosage did not reach the mould and dropped in the area between the nozzle and the target surface. In general, the total rebound material was combined aggregate, of which the coarse aggregate represented about 60 to 75 %. Consequently, the presence of PPF had no effect on the total rebound material, whereas the coarse aggregate content, experience of nozzleman and binder type had noticeable influences. Mixes without coarse aggregate showed the least rebound. Fly ash was effective in reducing the total material rebound, particularly in the presence of silica fume. A reduction of 35 % and 55 % was observed for mixtures containing FA in the absence or presence of SF, respectively.

The composition of the in-situ shotcrete was significantly different from the proportions of the batched constituents. The in-situ shotcrete had much higher binder content and lower coarse aggregate content. The internal layer of the in-situ shotcrete was affected by the rebound more than the external layer.

1 INTRODUCTION

Fibres offer many advantages over traditional mesh reinforcement in shotcrete as they provide considerable benefits to all end-users including designers, contractors and owners. The most common fibres that are added to shotcrete are mainly steel fibres [Adams 1993; Cengiz and Turanli 2004]. However, using steel fibres has some disadvantages such as, hose wear and high cost. Polypropylene fibres (PPF), in contrast, do not have these adverse effects. Polypropylene fibre reinforced concrete (PPFRC) has an impact resistance and flexural toughness that compare favourably with those observed in concrete made with many other commercial fibres utilised at higher dosage rates [Malhotra *et al.* 1994]. The properties of PPFRC have been extensively researched [Badr *et al.* 2001; Bayasi and Zeng 1993; Zellers and Ramakrishnan 1994; Song *et al.* 2005; Badr *et al.* 2006; Sivakumar and Santhanam 2007]. However, there is very little information about using PPF in shotcrete. In particular, there is almost no information about the rebound of PPF and its effect on the total material rebound and, consequently, the composition of the in-situ shotcrete.

The process of applying shotcrete generally ensures that most of the aggregates and cementitious materials combine to form a mixture, which adheres well to the substrate. Unfortunately, considerable amounts miss the target or do not adhere to the substrate [Wood *et al.* 1993]. Rebound, which is the material that strikes the surface but does not adhere to it, is the most important and significant proportion of the total production losses. The rebound greatly influences the economic efficiency and also has an inconvenient environmental impact [Pfeuffer and Kusterle 2001]. The main questions that always arise with shotcrete applications are related to the amount of rebound [Jolin *et al.* 1999]. In addition to the economical and environmental factors, the amount of rebound and its composition has a direct effect on the composition of the in-situ shotcrete. Therefore, studying the amount of rebound and the factors affecting it are of great interest to the shotcrete industry.

2 MATERIALS, MIXES AND SPRAYING

2.1 Materials

Portland Cement (CEM1), conforming to BS EN 197-1 [2000], was used as main binder in this study. Fly ash and silica fume were used as cement replacement materials. The coarse aggregate used was quartzite natural gravel of 10-mm nominal maximum size. It had a specific gravity of 2.64, bulk density of 1585 kg/m3 and water absorption of 0.60 percent. Quartzite sand which complies with zone M of BS EN 12620 [2002] was used as a fine aggregate, with specific gravity and water absorption of 2.68 and 0.10 percent, respectively. Fibrillated PPF (Figure 1) were used in this study. The fibre has a length of 18mm and an average diameter of 55μm.

Figure 1. Polypropylene fibres used in this investigation.

2.2 Mixes

Six mixes were sprayed in this study. Four of these mixes were initially optimised from laboratory tests. The pre-sprayed composition of these four mixes is given in Table 1. The water content was decided during spraying by the nozelman according to the ease of 'shotability' of each mix.

The remaining two mixes were pre-packed mixes, which are commercially available for shotcrete applications. Both mixes (RDY1 and RDY2) were plain mixes (without fibres). A dosage of 2 kg/m^3 PPF was added to RDY1 in order to compare it to the other fibre-reinforced mixes. However, the producer of mix RDY2 recommended not to add fibres to the mix and, therefore, mix RDY2 was sprayed without fibres. Due to commercial reasons, the compositions of RDY1 and RDY2 are unknown except that both mixes did not contain coarse aggregate.

Table 1. Pre-sprayed mix proportions (kg *per m*^{3}).

Mixes	*CEM1*	*FA*	*SF*	*Gravel*	*Sand*	*Fibre*
CEM0	400	-	-	948	948	-
CEMF	400	-	-	948	948	2.0
FA30	280	120	-	948	948	2.0
FASF	248	120	32	948	948	2.0

2.3 Spraying

Shotcrete panels were produced by the dry process, which was more appropriate for this study due to economical and practical reasons. A dry-process pneumatic spraying machine was used with two rotary feed wheels for mixtures with and without coarse aggregates. For the former mixes, a 38-mm nozzle and material hose were used while a 25-mm nozzle and hose were used for the latter mixes.

Wooden square moulds of 1200-mm side and 100-mm depth were manufactured specially for this investigation. Before spraying, the moulds were positioned as vertically as possible (within 5 to 10°). Polyethylene sheets were placed underneath and around the moulds to collect the rebound.

For the laboratory developed mixes (CEM0, CEMF, FA30 and FASF), all ingredients except water were first mixed in the dry state in a conventional concrete mixer. Where applicable, PPF fibre was added after two minutes of dry mixing, which then continued for another two minutes. The dry mix was then fed through the hopper of the spraying machine, which conveyed the mix pneumatically through the material hose to the nozzle where water was added through the water ring. For all the shotcrete mixes, variations in the spraying process were minimised by keeping the shooting distance between the nozzle and the target-surface around one meter. Also, the spraying angle was as close to 90° as possible, as shown in Figure 2.

Figure 2. Spraying distance and angle were kept around one meter and 90°, respectively.

2.4 Measuring the Rebound and Composition Analysis

On completion of each shotcrete panel, the rebound was collected before starting the finishing process. After weighing the total material rebound, two representative samples were taken from each mix. The shotcrete surface profile was levelled to the edges of the mould using metal trowel. Immediately after finishing, samples of the in-situ shotcrete were taken from different locations.

The fresh samples taken from the rebound material and in-situ shotcrete were used for analysing the composition. A small part from each sample was immediately weighed and dried using a microwave oven to determine its water content, as recommended by BS 1881-128 [1997]. The remaining concrete was washed with an excessive amount of water and drained to separate the aggregate, which was then weighed to determine the total aggregate content in the sample. Using sieve analysis, the combined aggregate was then analysed to estimate the fractions of fine and coarse aggregates.

3 RESULTS AND DISCUSSION

3.1 Total Material Rebound

The total material rebound is shown in Figure 3. The values are given as a percentage of the finished in-situ shotcrete and also as a percentage of the total sprayed materials. The rebound values obtained for the different mixes are in good agreement with values reported by other investigators for dry-process shotcrete [Wood *et al.* 1993; Austin *et al.* 1996].

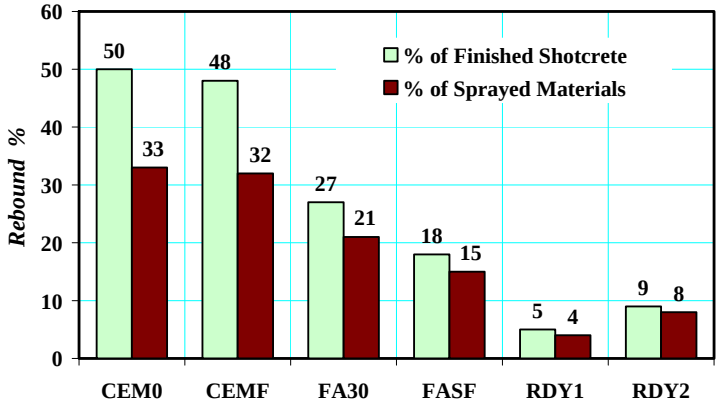

Figure 3. Total rebound as percentages of the finished shotcrete and of the sprayed materials.

It can be seen that the two ready-mixes RDY1 and RDY2 showed the least rebound due to the absence of coarse aggregate. In addition, since the nozzleman was familiar to spraying those mixes regularly his experience may have been a factor in reducing their rebound. The effect of the experience of nozzleman was previously reported [Adams 1993; Lars 1996]. The rebound of mixes containing fly ash (FA30 & FASF) was the best among the laboratory developed mixes.

The presence of PPF had no effect on material rebound, as the difference between the rebound of the control mix CEM0 and its counterpart fibre reinforced mix (CEMF) was negligible, as shown in Figure 3. Fly ash and silica fume effectively reduced the total material rebound. The use of fly ash reduced the rebound of the sprayed materials by about 35 % compared to the CEMF mix. Fly ash was even more effective in the presence of silica fume as the combination between them resulted in a reduction of about 55 % so that the rebound was only 15 % of the total sprayed material.

3.2 PPF Rebound

Most of the polypropylene fibres did not reach the target surface. On exiting from the nozzle, PPF separated from the concrete mixture due to the insufficient wet mixing. Consequently, and as a result of a different density, PPF gained a lower velocity compared to other constituents. Therefore, a considerable amount of PPF dropped down between the nozzle and the target surface, as shown in Figure 4. It was estimated that only 20 % of the fibres reached the mould. It can also be seen from the same figure that other constituents rebounded adjacent to the mould, unlike the fibres. The authors suggest that producing PPFRSC using the wet-process could probably eliminate this problem. It is expected that PPF would not be separated from a well-mixed matrix. However, the dry-process should still be able to produce this type of concrete if the initial fibre dosage was much higher the original fibre content. A factor of 5 could be used as a rough guide. Although this might appear a high factor, the low cost of PPF would not cause a noticeable increase on the total cost of the shotcrete.

It should be mentioned that the problem of embedding fibres in fresh-shotcrete is common regardless of the fibre type. For example, high number of steel fibres in the rebound and the insufficient adhesion of steel fibres to the shotcrete are always observed and have been subject to theoretical studies in attempts to understand and minimise this problem [Burge 1986; Cengiz and Turanli 2004].

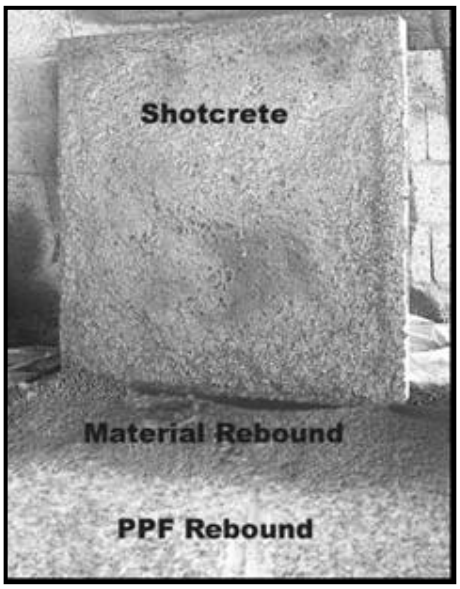

Figure 4. Material and fibre rebound.

3.3 Composition of the Rebound

Individual constituents rebound by different amounts due to their different sizes and densities. Samples from the rebound material were analysed in order to estimate the amount of each constituent. The estimated quantities were used to calculate important ratios such as coarse aggregate-to-rebound (g/R) and fine aggregate-to-rebound (s/R), as shown in Table 2.

The composition of the rebound was mainly combined aggregate with a high percentage of gravel. On average the combined aggregate in the rebound was about 80% of the total rebound material. About two-thirds of the combined aggregate in the rebound consists of coarse aggregate, which represented more than 50 % of the total rebound material compared to 27% fine aggregate in the rebound. Therefore, the gravel-to-sand ratio in the rebound was 2:1, whereas it was 1:1 in the pre-sprayed mixture. This can be attributed to the fact that heavier particles rebound more than the lighter sand grains and cementitious materials. This finding explains the low rebound values for the ready-mixes RDY1 and RDY2 as they did not contain coarse aggregate. However, it can be seen that neither PPF nor the binder type has clear effect on the total aggregate content in the rebound.

Table 2. Constituents of the rebound materials.

	Composition (kg *per* m^3)				*Ratios*			
	Binder *(b)*	Gravel *(g)*	Sand *(s)*	Water (w)	*(g+s)/R*	*g/(g+s)*	*g/R*	*s/R*
CEM0	433	1361	757	63	0.81	0.64	0.52	0.29
CEMF	564	1277	646	95	0.74	0.66	0.49	0.25
FA30	520	1178	796	90	0.77	0.60	0.46	0.31
FASF	383	1602	544	69	0.83	0.75	0.62	0.21
Average	475	1355	686	79	0.79	0.66	0.52	0.27

3.4 Composition of the in-Situ Shotcrete

Samples of fresh in-situ shotcrete were analysed and the proportions are shown in Table 3. Comparing Table 3 to Table 1, it can be seen that the in-situ concrete proportions were different from those of the batched concrete. The shotcrete had much higher binder content and lower coarse aggregate content. The average binder content was about 700 kg/m^3, which is 75 % more than the intended 400 kg/m^3. This very high binder content could provide potential for alkali-silica reaction and early cracking through high heat of hydration [Cabrera and Woolley 1996]. It can also be noticed that the increase of the binder content was at the expense of coarse aggregate, which on average decreased to 592 kg/m^3, whereas the average fine aggregate content actually increased slightly from 948 to 994 kg/m^3.

Table 3. Composition of the in-situ shotcrete.

	Composition (kg *per* m^3)				*Ratios*	
	Binder *(b)*	Gravel *(g)*	Sand *(s)*	Water (w)	w/*b*	*(g+s)/b*
CEM0	727	487	1079	179	0.25	2.15
CEMF	730	585	916	202	0.28	2.06
FA30	749	674	924	159	0.21	2.13
FASF	605	623	1057	174	0.29	2.78
Average	703	592	994	179	0.26	2.28

The w/*b* ratios of in-situ shotcrete varied from 0.21 to 0.29, with an average of 0.26, which can be considered as low values. This, in fact, is the main advantage of the dry-process because a high workability is not a requirement as the case for the wet-process.

There was no significant difference in the w/*b* and *(g+s)/b* ratios for mixes CEM0 and CEMF, indicating that PPF had no effect on the composition of in-situ shotcrete. As with conventional concrete, fly ash reduced the water demand for the shotcrete. However, adding silica fume to the fly ash mix resulted in a w/b ratio equal to that of the CEMF mix.

It was interesting to notice that the internal layer of the in-situ shotcrete was affected more by the rebound than the external layer. Most aggregate rebound from the first layer, as the particles hit the hard substrate with high velocity and rebound. The first layer forms a relatively soft substrate for the next layer and, therefore, the rebound from the external layer was less, as can be seen from Figure 5 (the yellow line indicates the demarcation between the first and subsequent layers). It can be seen that the internal layer (mould side) had very little aggregate compared to the external layer (spraying side).

Figure 5. Composition of external and internal layers of the FASF in-situ shotcrete.

4 CONCLUSIONS

For the shotcrete mixes and PPF used in this investigation, the following conclusions can be made:

- About 80 % of the initial PPF dosage did not reach the mould and dropped in the area between the nozzle and the main rebound material, which was next to the target surface. Consequently, the addition of PPF had no effect on the total rebound material, whereas the binder type had an obvious influence.

- Fly ash was effective in reducing the total rebound, particularly in the presence of silica fume. FA reduced the rebound by 35 % and 55 % in the absence or presence of SF, respectively.

- The sprayed materials rebound by different amounts due to different sizes and densities. The composition of the rebound was mainly aggregate with high percentage of coarse aggregate. On average, the combined aggregate was about 80 % of the total rebound material, of which the coarse aggregate represented about two-thirds. Neither PPF nor the binder type had a clear effect on the total aggregate content in the rebound.

- The composition of the in-situ shotcrete was significantly different from the proportions of the batched constituents. The in-situ shotcrete had much higher binder content and lower coarse aggregate content. The internal layer had less aggregate compared to the external layer.

- PPF had no effect on the composition of in-situ concrete, whereas the binder type has noticeable effect on the water-to-binder and aggregate-to-binder ratios.

ABSTRACT

In the last decade fibre-reinforced polymer (FRP) composites have been successfully used for confinement of reinforced concrete (RC) and masonry columns. Their high mechanical properties, light weight and low installation costs have contributed to making the wet lay-up wrapping one of the most affordable techniques for column confinement. Although previous studies have demonstrated the high performance of FRP strengthening systems, several concerns are related to the long-term behaviour of wrapped columns, which has limited implementation. Environmental effects, such as freeze-thaw cycles, wet-dry cycles, ultra violet (UV) radiations exposure, high temperatures and de-icing salts, may affect the material properties and the structural response of the wrapped elements. In this paper an experimental work is presented in order to study the long-term behaviour of Glass FRP-confined columns. A commercial GFRP system was used to wrap thirty-two small-scale concrete cylinders that were subjected to extreme conditions such as freeze-thaw cycles, immersion in water and saline solution, immersion in alkaline or HCl solutions. Epoxy adhesives, cured at four different temperatures, used for FRP bonding, were also studied after immersion in water, diffusion properties were measured after different times of exposure, also changes in glass transition temperature were monitored by using a differential scanning calorimeter. Changes in mechanical and physical properties of FRP-confined cylinders and adhesives are discussed herein.

1 INTRODUCTION

When structural deficiencies are present in the columns of a reinforced concrete (RC) building, collapse of the entire structure happens without system redundancy. These dangerous occurrences may be due to insufficiencies caused by incorrect design assumptions, deterioration in section capacity due to steel corrosion, vehicular impact damage, construction defects or damage caused by seismic forces.

Although several experimental studies demonstrated the effectiveness of FRP-confinement in repairing damaged or inadequate compressed concrete elements, important questions related to long-term behaviour and durability were not adequately highlighted. Knock-down factors to address environmental conditioning are an important design consideration for long-term performance, thus research efforts are needed in this field.

Environmental agents, over time, may reduce the durability in infrastructure applications including bridges and marine structures. The most important effects that need to be investigated are those related to low temperatures in cold regions, aggressive environments such as marine or industrial areas, de-icing salts that are used to avoid frost in infrastructures, fluid penetration and absorption such as rain waters, thermal cycles, typical of seasonal changes.

Earlier studies revealed that external agents can significantly reduce the effects of confinement, due to material degradation, embrittlement of the resin and fibres and chemical attack that reduces the effectiveness of reinforcement [Toutanji and Balaguru 1999]. In particular it was observed that different resin systems and wet-dry cycling affect the ductility of Glass FRP (GFRP) confinement, reducing the ultimate capacity by 18% [Toutanji 1999]. Freeze-thaw cycles combined with moisture showed reduction of more than 30% in the ductility of GFRP-confined concrete [Karbhari and Eckel 1994]. The effect of freeze-thaw cycling was found to be very low in a dry environment; only the radial strain is affected, resulting in more brittle failure modes [Karbhari et al. 2000]. Combined effects, including moisture and freeze-thaw cycling, different pH environments, were investigated and reduction in mechanical properties was found to be more than 20% of the compressive strength and axial strain, while a reduction of 50% was found in radial strain [Kshirsagar et al. 2000]. According to the results obtained by Corvaglia et al. [2006] it was highlighted that durability of FRP-confined concrete is related to three main issues: type of aggressive environment; constituent materials of FRP systems; wrapping technique used for confinement.

In this study a set of forty-eight concrete cylinders were tested in compression. The experimental variables were different geometry and different exposure programs. The effects of aggressive fluids and low temperature were studied for FRP-confined concrete and for the epoxy adhesive. Thus the scope of this research is defined by the possible effects of external aggressive agents on retaining of carrying capacity and structural ductility of FRP-confined concrete columns. Experimental results furnished in this research may be taken into account for future calibration of existing guidelines, including environmental factors that can be addressed to particular service conditions.

2 EXPERIMENTAL PROGRAM AND TEST SET-UP

The experimental program consisted of specimen preparation, a period of accelerated aging, mechanical and physical tests. A laboratory-protocol was used to investigate the durability effects on conditioned cylinders and FRP specimens under different conditions. Compression testing was used to measure the possible changes in mechanical properties of FRP-confined concrete, while differential scanning calorimetry (DSC) was used to measure possible changes in resin properties, such as glass transition temperature, that may assist in understanding the degradation processes that occurred in the FRP layer. Tensile tests according to ASTM D3039 were used for characterization of FRP systems. Mechanical properties of FRPs in the following will be related to the thickness of dry sheets. The variables investigated were geometry of concrete cylinders (full-core and hollow-core), accelerated

aging, including immersion in water, also followed by freeze-thaw cycles, immersion in aggressive solutions (acidic, alkaline, saline). In all cases the conditioning regime of cylinders did not take place in presence of axial stress (i.e. sustained loading). However, it may also be noted that in real RC columns the stress in FRP jacket is negligible under service conditions. Unconditioned specimens and unconfined concrete cylinders were also tested as control specimens. Four compressive tests were made for each type of control and conditioned cylinder.

Concrete cylinders were poured with the same mix at the same time, a low quality concrete was chosen in order to simulate more real conditions (20 MPa of compressive strength). Forty cylinders were cast with a diameter of 150 mm and height of 300 mm; eight cylinders were cast with the same geometry but with hollow core, having a wall thickness of 50 mm.

E-glass fibre sheets were used for external strengthening; mechanical properties of GFRP were measured by tensile tests that were conducted according to ASTM D-3039. Testing was performed in displacement-control mode on a 150-kN universal testing machine, with a crosshead displacement rate of 2 mm/min. An electrical extensometer was used to measure the strain of CFRP under tensile force. Average experimental results (with standard deviation) were: tensile strength 1957 MPa (173 MPa), Young modulus 86 GPa (6 GPa), ultimate strain 2.29 % (0.003 %). Tensile tests of epoxy adhesive were also conducted according to ASTM D-638. Average experimental results (with standard deviation) were: tensile strength 22 MPa (5 MPa) and tangent modulus 2 GPa (6 GPa). Flexural tests, according to ASTM D-790, were performed to measure the flexural properties of the resin, the average strength was 56 MPa (2.7 MPa), the modulus was 1.84 GPa (0.16 GPa).

The strengthening process was done using the manual wet lay-up technique, in a laboratory environment with a controlled temperature of 21 °C and 45% of relative humidity. The same experienced worker applied the composite jackets in order to reproduce the same conditions for all specimens, since the comparative aspect of the results was the main issue. Properties of the epoxy adhesive were studied also in terms of absorption capacity; twenty-five circular plates of resin (diameter was 80 mm and thickness was 5 mm) were cured at different temperatures: 20°C, 30°C, 40°C, 55°C. All specimens were immersed into distilled water for 1440 hours at 40°C; weight measurements were made every 72 hours, except for the first ten days, in which the possible weight increase was measured every 12 hours. A supplementary group of five resin specimens that was cured at 20°C, after immersion in water was also subjected to 166 freeze-thaw cycles, with a range of temperature from -15°C to 25°C. Weight increase law that was recorded was about the same for all specimens, as it is illustrated in Figure 1. According to these results a diffusion coefficient was computed, and an average value of $D=3.36 \times 10^{-3}$ mm^2/hrs was found. Assuming a saturation point of 90% and a thickness of 2 mm for the FRP cured sheet, from the Fickian diffusion law, it was found that a period of 1010 hours is necessary for the saturation of the epoxy adhesive at 40°C.

Differential scanning calorimetry (DSC) was used to measure the glass transition temperature (T_g) range of the resin cured at room temperature (21°C), and activation of T_g resulted at 56°C. Therefore, a conditioning temperature of 40°C was chosen, since it resulted far from possible thermal degradation of the resin or thermal activation of post-cure polymerization.

GFRP confined cylinders were subjected to different exposure programs, each group was made by four samples. Two groups were immersed into distilled water at 40°C for a period of 2600 hours, one of them was also subjected to 80 freeze-thaw cycles from – 8 °C to +8 °C, the duration of a single cycle was of 24 hours.

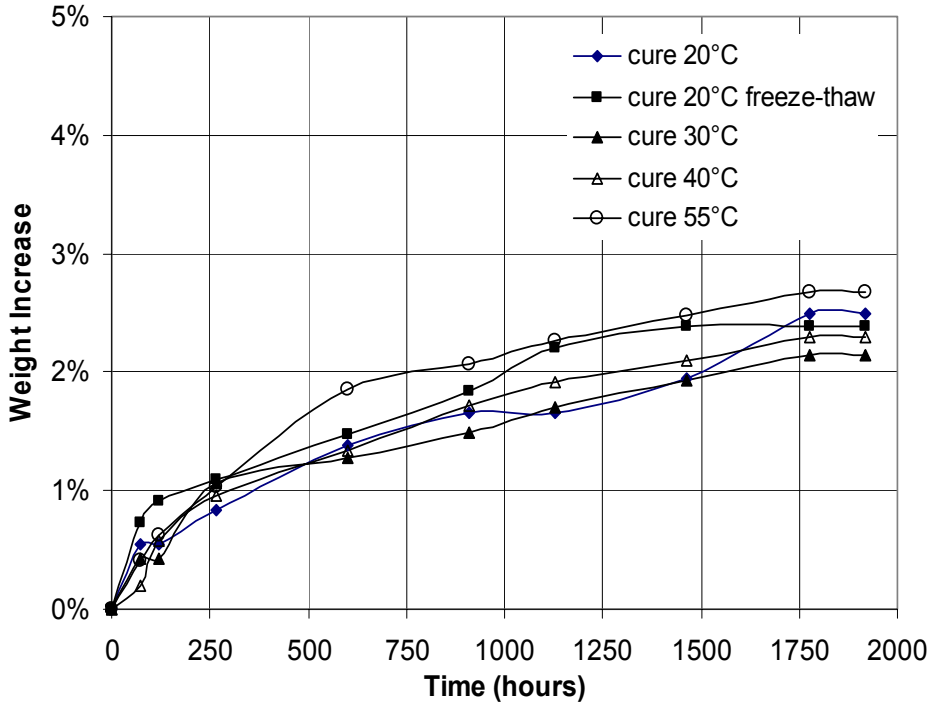

Figure 1. Water absorption in epoxy resins cured at different temperatures.

A third group of cylinders was immersed in a HCl aqueous solution (pH=3.0) at 40°C for 2600 hours. Four groups of cylinders (two with full core and two with hollow-core) were immersed in a NaCl aqueous solution (5% weight) at 40°C for 2600 hours; one group for each type was also subjected to 80 freeze-thaw cycles from – 8 °C to +8 °C, the duration of a single cycle was of 24 hours. The last group of cylinders was immersed in alkaline solution (0.16% $Ca(OH)_2$+1%Na(OH)+1.4% K(OH) in weight) at 40 °C for 2600 hours. Table 1 shows the details of the experimental program.

Table 1. Experimental program for GFRP-confined cylinders.

Specimen	# of samples	Geometry	Strengthening	Exposure
C	4	full-core	unconfined	laboratory - control
H	4	hollow-core	unconfined	laboratory - control
C-F	4	full-core	1 layer GFRP	laboratory - control
C-H	4	full-core	1 layer GFRP	laboratory - control
W	4	full-core	1 layer GFRP	distilled water 40°C 2600 hrs
W-FT	4	full-core	1 layer GFRP	distilled water + freeze-thaw cycles
HCl	4	full-core	1 layer GFRP	HCl solution 40°C 2600 hrs
NaCl	4	full-core	1 layer GFRP	NaCl solution 40°C 2600 hrs
NaCl-FT	4	full-core	1 layer GFRP	NaCl solution + freeze-thaw cycles
HC-NaCl	4	hollow-core	1 layer GFRP	NaCl solution 40°C 2600 hrs
HC-NaCl-FT	4	hollow-core	1 layer GFRP	NaCl solution + freeze-thaw cycles
A	4	full-core	1 layer GFRP	alkaline solution 40°C 2600 hrs

Plain and wrapped concrete cylinders were tested under axial compression using a 3000-kN compression machine in load-control mode. Two LVDTs were used to monitor the relative displacement between the extreme faces of the cylinder. Four strain gauges, two in the longitudinal

and two in the hoop direction, were applied on each cylinder at mid-height to measure load vs strain values.

In all specimens the FRP wrap did not cover the full height of the cylinder. This avoided that the axial load be applied directly on the FRP resulting in local buckling of the composite close to the loaded surfaces. Thus a narrow gap was left between the end concrete surfaces and the extreme composite fibres.

3 RESULTS AND DISCUSSION

Differential calorimetry tests revealed that after immersion in water, and after freeze-thaw cycles the glass transition temperature showed a difference respect to the control samples within a range of 4°C. Thus it is assumed that the wet conditioning did not produce any significant change in the properties of adhesive, respect to a premature glassy/rubbery transition.

It was observed after different cure temperatures in a range from 20 °C to 55 °C, so the tested epoxy adhesive may be applied at room temperature, higher temperatures of cure did not showed to activate an higher rate of polymerization.

Compressive tests on plain concrete cylinders showed a strength of 26.5 and 26.1 N/mm^2 respectively for full and hollow-core samples. Confinement with one layer of GFRP produced a dramatic increase in mechanical properties, it was expected due to the low quality of plain concrete: an average increase of about 70% was observed in both cases. Axial strain at ultimate crushing state was more than 4 times that of unconfined cylinders. Those results are very encouraging since both ultimate capacity and ductility are enormously modified with a single layer. Long-term behaviour showed that this advantage may be lower since a damage of the FRP-confined system may occur.

Immersion in water produced a reduction of about 20% in ultimate load, while the presence of freeze-thaw cycles after wet exposure showed a positive effect as shown in Figure 2 and in Table 2. Reduced capacity is due to a degradation of the confinement effect that is practiced by the FRP jacket, in this case the presence of an aqueous solution may have produced a damage at fibre/matrix interface that modifies the stress distribution inside the composite cylindrical layer.

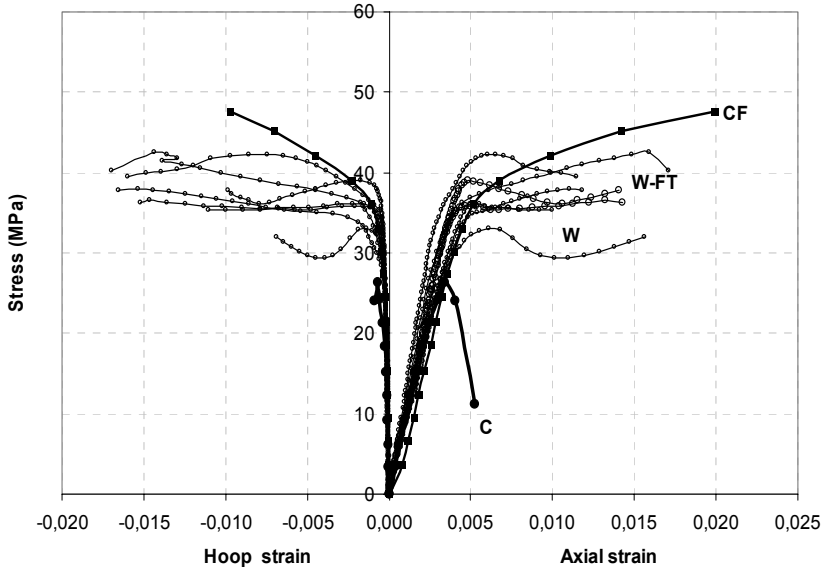

Figure 2. σ-ε curves for specimens immersed in water (W and W-FT).

Cylinders subjected to immersion in acidic solution showed a reduction in their capacity. The difference between control and aged specimens in terms of ultimate load was almost the same observed for specimens immersed in water, while a significant reduction (more than 40 %) was recorded for axial displacement. This indicates decay in terms of enhanced ductility due to the presence of the GFRP. Curves in Figure 3 and average results of Table 2 illustrate the experimental results for this group of specimens.

GFRP-confined concrete subjected to marine environment (NaCl solution), that is typically very aggressive for steel rebars, when concrete has an undesired porosity, showed a moderate reduction in terms of ultimate compressive strength (about 20% for both full and hollow-core cylinders). Additional freeze-thaw cycles that were applied after immersion in NaCl of hollow-core cylinders did not produce any effect, as seen in Figure 4 and Table 2.

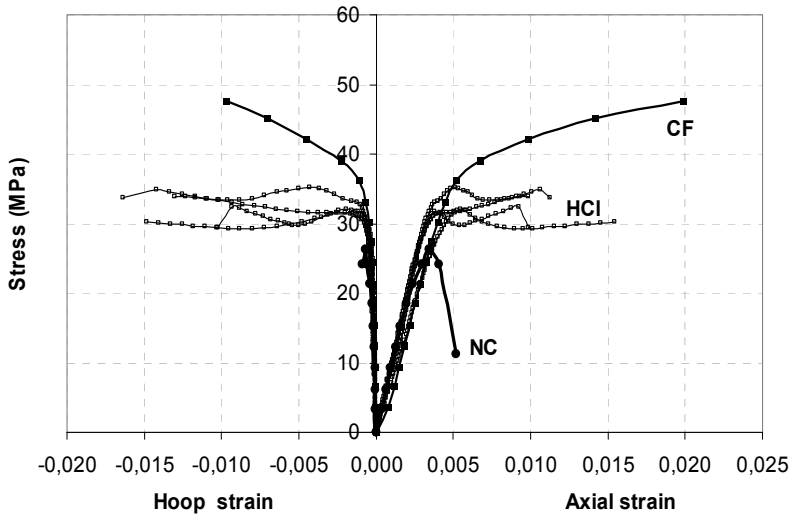

Figure 3. σ-ε curves for specimens immersed in HCl solution (HCl).

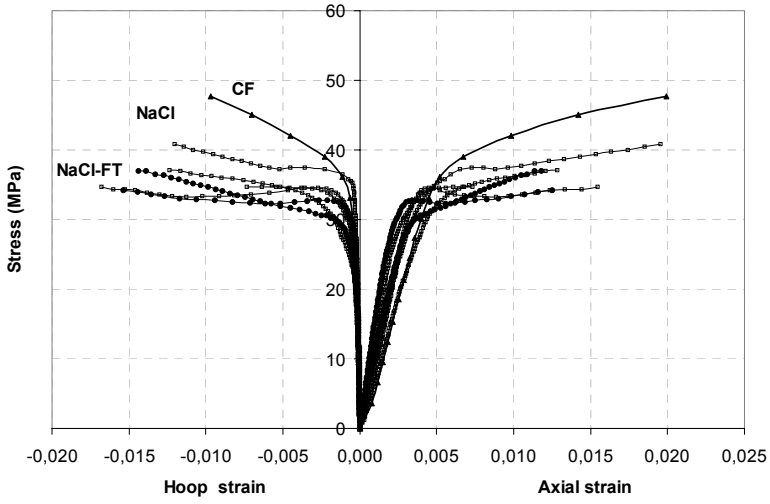

Figure 4. σ-ε curves for specimens immersed in NaCl solution (NaCl and NaCl-FT).

The alkaline attack to E-glass fibres resulted the most dangerous for GFRP-confined concrete since the average compressive strength was 29.8 MPa that is very close to that of unconfined concrete. The alkaline environment produced a chemical attack, so it can be assumed that the presence of alkaline ions produced an embrittlement of the glass fibres and damage at the fibre resin interface level produced by the growth of hydration products. These effects lead to a dramatic loss in tensile strength and interlaminar transverse properties of the GFRP jacket.

Also the ductility, measured as deformation capacity until failure, was very close to that of plain concrete, therefore the effects of confinement were negligible after alkaline conditioning. It is clear from the observation of Figure 5 and Table 2, where experimental results are reported in form of average values.

From the mechanical tests it was observed that wet environment may produce a saturation of the resin that influences the ultimate properties, this may be due to a change in interface properties. When different types of ions are present, the chemical attack is extended to the fibres, which are prone to premature failure. It was seen in fact that immersion in water, saline and acidic fluids reduces the mechanical performance of GFRP-confined concrete, while the presence of an alkaline solution erases the advantages of external confinement.

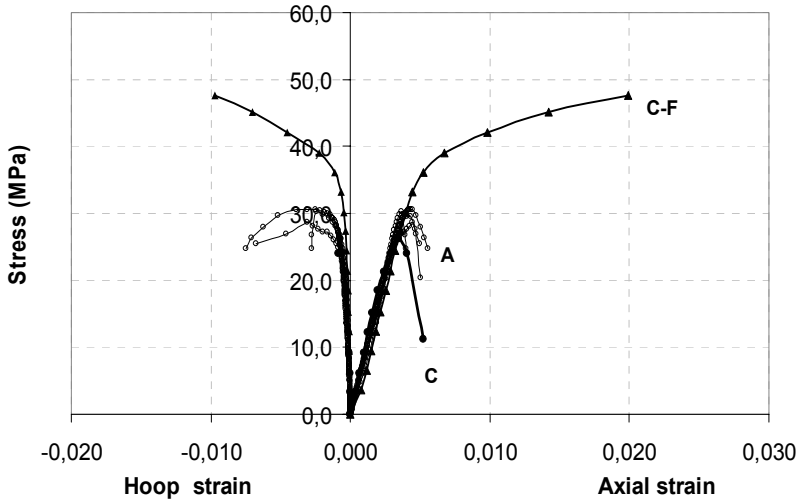

Figure 5. σ-ε curves for specimens immersed in alkaline solution (A).

Table 2. Experimental results for GFRP-confined cylinders.

Specimen	f'_{cc} (N/mm^2)	ε_{axial} %	ε_{radial} %	$f'_{cc\text{-}AGED}/f'_{cc}$	$\varepsilon_{acc\text{-}AGED}/\varepsilon_{acc}$	$\varepsilon_{rcc\text{-}AGED}/\varepsilon_{rcc}$

A	29.8	0.49	0.57	0,67	0,25	0,61

where:
f'_{cc} is the average value of the compressive strength of the specimens
ε_{axial} is the average value of the ultimate axial strain of the specimens
ε_{radial} is the average value of the ultimate hoop strain of the specimens
$f'_{cc\text{-}AGED}/f'_{cc}$ is the ratio between the strength of aged specimens and strength of control specimens
$\varepsilon_{acc\text{-}AGED}/e_{acc}$ is the ratio between the axial strain of aged specimens and that of control specimens
$\varepsilon_{rcc\text{-}AGED}/e_{rcc}$ is the ratio between the hoop strain of aged specimens and that of control specimens

4 CONCLUSIONS

An experimental study has been presented in order to investigate important issues related to the long-term behaviour of GFRP-confined concrete. A preliminary study was made to understand the properties of the epoxy adhesive since this is the matrix that should be able to protect the glass fibers from external agents.

Glass transition temperature was measured for different temperatures of polymerization and after different conditioning programs. Significant changes were not observed in terms of glass transition.
Results of gravimetric tests after immersion in water at 40 °C were calibrated in order to obtain the diffusion properties of the resin and its capacity respect to reach a saturation point.

Based on these preliminary results different exposure programs were applied to GFRP-confined concrete cylinders that were aged in aqueous solutions at 40 °C for 2600 hour, including saline ions, acidic ions and alkaline ions. Freeze-thaw cycles were also applied after conditioning in wet environment.

A moderate reduction (about 20%) was observed in terms of ultimate strength and ultimate axial strain, in all cases, except for alkaline solution, which produced a dramatic drop of mechanical properties. In this last case the properties of aged GFRP-confined concrete resulted close to that of plain concrete. Freeze-thaw cycles did not affect the mechanical properties.
Authors know that accelerated extreme conditions reproduced in laboratory are more dangerous than those that affect structural systems in real applications, but the results of this study help to individuated which conditions are more critical in presence of E-glass fibres. Results may be considered very helpful in calibrating durability safety coefficients that are present in current design guidelines.

ABSTRACT

Energy, natural resources and environmental protection are the most important factors for the sustainability of technology. The production of Portland cement constitutes about 8% of the total CO_2 emission in the world today. The production of boron modified active belite (BAB) cement reduces the emission of CO_2 by up to 25% and saves a significant amount of energy due to low clinkering temperatures around 1325°C. These two factors are the main propulsive forces for the trial production of this cement. The production process of BAB cement is still in the test scale, however, first findings of the technical characteristics of the BAB cement are very noticeable. In this paper, by using boron modified active belite (BAB) and normal Portland cement, produced in Goltas Cement Factory, some chemical, physical and mechanical tests were carried out to investigate characteristics of the cement and concrete phases and evaluate the results in this first part of the research. In the second part of the research, besides some other tests, the microstructure of concrete made with BAB cement will be investigated mostly. BAB cement was standardized by Turkish Standard Institution as a type of Portland cement called "boron modified active belite cement" It has been found out that BAB cement has very low heat of hydration and less than 52,5 Cal/g at 7 days. Moreover, its early strength at first 7 days is less than that of normal Portland cement, however, beyond 7 days it gives same levels of strength values up to 28 days and later ages displays higher strength values than the normal Portland cement. In the durability part of tests like water permeability and chloride penetration resistance tests, concrete specimens made with BAB cement indicated more resistance as comparing to the specimens made with normal Portland cement even at lower cement contents.

1 INTRODUCTION

Boron modified active belite (BAB) cement, a hydraulic binder, is finely ground and an inorganic material and forms cement paste hardening with hydration reactions when mixed with water. This cement paste maintains its strength and stability by the means of stable hydrate phases formed after hydration. This definition is completely compatible with Portland cement definition in TS EN 197-1 standard. Main component of BAB cement clinker is di-calcium silicate (α and/or α'-C_2S modifications), which is in active belite phase. Other mineralogical components are tri-calcium aluminates (C_3A) and tetra-calcium alumina ferrite (C_4AF) phases. Difference of BAB cement clinker from Portland cement clinker is that the main component is hydraulically high active belite phase instead of the alite phase. Hydraulically hardening of BAB cement rely on hydration of active belite phase, but other cement phases can also play some roles in the hardening process.

According to the results of tests carried out on boron modified belite (BAB) cement produced by adding one of the boron ores, Colemanite, to other cement raw materials (e.g. farine), it has been determined that C_3S phase, formed at high ratios in normal Portland cement, did not form at all or formed in very small amounts. At the same time, when producing BAB cement, the production temperature in the rotary kiln does not exceed 1325°C and as such, a decrease of about 25% in CO_2 emission is observed. In BAB cement, instead of C_3S (alite), one of the polymorphs of C_2S, having α or α'-C_2S crystal structure forms; this belite phase is quite active and stable phase. It is for this reason that this cement has been named as boron modified active belite cement (BAB).

In this research, the chemical, physical and mechanical properties of boron modified active belite (BAB) cement were examined. The composition of BAB cement contains about 3.0% (wt.) of B_2O_3 (boric oxide). The chemical composition of boron modified active belite cement has no C_3S, there is active and stable structured α and/or α'- C_2S crystal phase in extremely high amounts and the rate of hydration is significantly higher than cement containing the β-C_2S phase; consequently this results in the formation of a more compact and more dense concrete microstructure. In normal conditions the hydration of the β-C_2S phase of cement is very slow as compared to that of C_3S and gaining strength values is lately. However, the final strength is the same or greater than that for C_3S. Reaction of the β-C_2S (or the α- or α'-C_2S phases) and the reaction of the C_3S phase with water can be summarized as follows:

$2C_3S + 6H_2O \rightarrow C\text{-}S\text{-}H\ (C_3S_2H_8) + 3Ca(OH)_2$ (Fast Reaction)
$2C_2S + 4H_2O \rightarrow C\text{-}S\text{-}H\ (C_3S_2H_8) + Ca(OH)_2$ (Slow Reaction)

The hydration reaction of C_3S with water forms 2 times more $Ca(OH)_2$ than that of C_2S. Calcium hydroxide constitutes about 20% or 25% by volume of Portland cement paste. This component is the weakest component in the concrete and it mostly tends to gather on the interfacial and transition zone between the aggregate and cement paste. Failure in concrete generally begins on the surface between aggregate and cement paste and continues. Another negative aspect with normal Portland cement (including C_3S) is that high calcium hydroxide formation leads to increase of porosity ratio of concrete. However, in concretes made with BAB cement with high α and/or α'- C_2S, the ratio of calcium hydroxide will be rather low and this will lead to less porosity ratios (capillary pores) and therefore strength and durability of concrete will be higher with a more dense structure.

The fineness of BAB cement is a critical parameter because the strength development depends on the degree of fineness. In this research, the degree of fineness of BAB cement and normal Portland cement were chosen to be almost the same. The degree of fineness of both cements was around 3300 cm^2/g. For mass concrete structures the fineness of BAB cement is considered acceptable at around 3500 cm^2/g. However, when high early strength values are needed in structures such as concrete bridges, concrete roads and residence buildings and the like, it is possible to attain early strength development when using BAB cement as compared to normal Portland cement by increasing the fineness value of the BAB cement to 4000 ± 50 g/cm^2. Moreover, without increasing the fineness of the cement, high early strength values can easily be accomplished by using concrete chemical admixtures.

2 MATERIALS

Cement: All chemical, physical and mechanical tests of cements and all concrete tests were conducted on BAB and CEM I 42,5R Portland cement conforming to TS EN 197-1 and manufactured at the Goltas Cement Factory, Isparta, Turkey. The results of chemical analysis of the BAB cement is given in Table 1 and the results of the physical and mechanical tests of four different Blaine values of BAB cement are given in Tables 2 and 3. Moreover, some mechanical test results of normal Portland cement (CEM I 42,5R) conforming to TS EN 197-1 and very finely grounded Denizli BAB cement were given on Table 3.

Table 1 . Results of Chemical Analysis of Goltas BAB Cement.

Results of Chemical Analysis of BAB Cement, %	
Silicon Dioxide (SiO_2)	19.1
Aluminum Dioxide (Al_2O_3)	4.68

Aggregate: In concrete tests, three classes of crushed aggregate (two classes of coarse and one class of fine aggregate) were used. Some physical tests results about the aggregates are given on Table 4.

Table 4 – Some physical test results of aggregates used in concrete specimens.

Classes of Aggregates	Specific Gravity	Water Absorption (%)	Aggregate Ratios Used in Concrete Mixes (%)	Fineness Modulus of Fine Aggregate
Coarse Agg. 1 (15-30 mm)	2,71	0,2	25,0	In Concrete F.M.= 2,63
Coarse Agg. 2 (7-15 mm)	2,70	0,3	25,0	
Fine agg. (0-7 mm)	2,70	1,2	50,0	2,57

3 EXPERIMENTAL STUDY

Cement Tests: the chemical, physical and mechanical tests conducted on both BAB and normal Portland cement produced at the Goltas Cement factory gave quite significant findings. All the results obtained with both cements are given in Tables 1 to 3. The most important characteristic of the BAB cement is that it has a very low heat of hydration even less than very low heat cement. The heat of hydration measurements were carried out with an isothermal conduction calorimeter for the BAB cement, normal Portland cement and Portland cement plus fly ash and the results are given on Figs 1 and 2.

Concrete Tests: with the lights of cement test results, concrete tests were started. In concrete tests, by using both BAB and normal Portland cement produced at Goltas Cement factory, same kinds of tests were conducted and the results were compared with each other. In concrete tests, especially durability aspect and strength development of samples were investigated. All concrete mixtures prepared in the laboratory are given on Table 5 in detail.

Table 5. Cement, mixing water contents and w/c ratios of concrete designs prepared in the laboratory. No chemical admixture was used in the mixtures.

Concrete Code	BAB or CEM I 42,5R Portland Cement Content, kg/m^3	Water Content kg/m^3	Water/Cement Ratio
BAB Cement Concrete with Slump 15 cm (Water Bleeding Exist)			
BD-1	250	200	0,80
BD-2	275	200	0,73
BD-3	300	200	0,67
BD-4	325	200	0,62
BD-5	350	200	0,57
BD-6	375	200	0,53
BD-7	400	200	0,50
BD-8	450	200	0,44
Normal Portland Cement Concrete with Slump 15 cm (Slump Loss Exist)

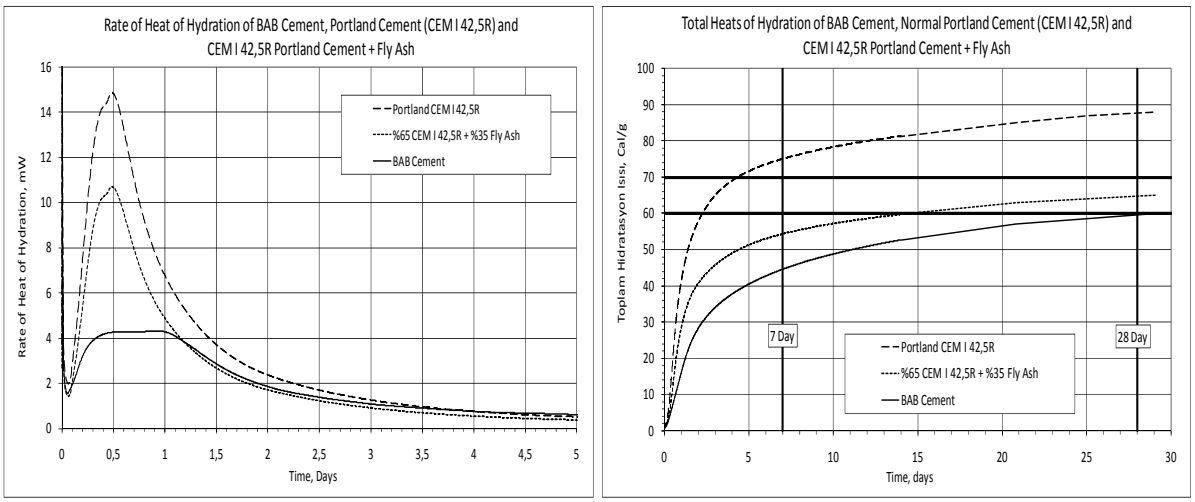
BD-10	300	190	0,63
BD-11	350	190	0,54
BD-12	400	190	0,48
BD-13	450	190	0,42

Note: BD and ND abbreviations define different concrete mixtures as BD: BAB cement concrete mixtures and ND: normal CEM I 42,5R Portland cement concrete mixtures.

Concrete tests were carried out at the same amount of cement contents and same slump values with both cement types and all concrete mixes were made without using any chemical admixtures. The results of concrete mixes with different chemical admixtures will be given in the second part of research. At the beginning, the slump values of concrete mixes were chosen to be between 13 and 15 cm for pumpable concrete. However, it was observed that concrete mixes with BAB cement with a slump value of 15 cm showed some bleeding after moulding due to the slow hydration of BAB cement. Because the rate of hydration of C_2S containing BAB cement is slow and for this reason concrete mixes were not being subjected to any slump loss for a period of time and there was a long enough time to work with the concrete to be placed in a structure. For this reason it was decided that new concrete mixes should be made to obtain a slump value of 10 cm without showing any bleeding. With this method, 5% less mixing water was used in the concrete mixtures made with BAB cement resulting in a reduced w/c ratio. Whereas the concrete mixes with slump values of 15 cm were made with a mixing water dosage of 200 kg/m^3, the concrete mixes made with BAB cement and a slump value of 10 cm were made with a mixing water dosage of 190 kg/m^3. In the meantime, concrete mixes made with normal Portland cement with a slump value of 15 cm showed a significant level of slump loss, however, concrete mixes made with BAB cement with a slump value of both 10 cm and 15 cm did not show any significant slump loss for about 30 min.

4 TEST RESULTS

Tests results obtained from both types of cement and concrete phases are given in this section. A comparison among measurements for the development of heat of hydration over time for the BAB cement, normal Portland cement and Portland cement plus fly ash using an isothermal conduction calorimeter at constant temperature of 20 C are given in Figures 1 and 2. In technical specifications for mass concrete, values for the heat of hydration are limited to 60 Cal/g and 70 Cal/g for 7 and 28 days respectively. In any case, the rate of heat of hydration of BAB cement at early age is very low and the cement significantly reduces the adiabatic temperature rise of concrete. Given this property, BAB cement has many advantages in terms of economical, technical and logistical points of view as compared to other types of cement and binders. In Figures 1 and 2, the rate of heat of hydration and total heat of hydration results of BAB cement, normal Portland cement and normal 65% Portland cement plus 35% fly ash are given comparatively.



Figures 1 and 2 . The results of the rate of heat of hydration and total heat of hydration of BAB cement, CEM I 42,5R Portland cement and 65% CEM I 42,5R+35% Fly ash with I.C. Calorimeter.

The heat of hydration of BAB cement is very low in comparison with other types of cement and binders. For this reason, BAB cement can be utilized in all mass concrete structures without taking any extra precautions such as the installation of pre-cooling and post-cooling systems.. On the other hand, the

strength development of BAB cement is also in good levels except for at early ages. In later ages, the strength of BAB cement exceeds that of normal Portland cement as can be clearly seen in Figure 3.

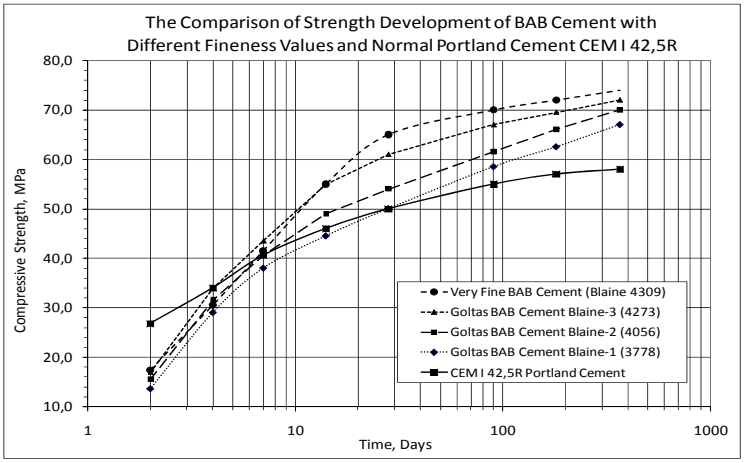


Figure 3. The strength developments of BAB cement with different Blaine fineness values and normal Portland cement.

Some experiments have been carried out with BAB cement in its concrete phase especially intended for measuring its durability and performance properties and considerable results have been attained. Studies were carried out with both cement types for quite a wide range of cement dosages (between 250 kg/m^3 and 450 kg/m^3) and tests were made for measurement of strength development, water permeability and resistance against chloride penetration. In Figures 4 and 5, the 7 and 28 day compressive strength values of concrete with different cement contents and with a slump value of 15 cm made with BAB cement and normal Portland CEM I 42,5R cement are given. The compressive strength changes with cement contents as is evident from the Figures. In Figures 6 and 7, values for concrete strength development for concrete having a 10 cm slump and made with BAB cement as compared to with a 15 cm slump made from normal Portland CEM I 42,5R cement. For these two cement types, a gap has been observed between the 7-day strengths of concrete specimens with 15 cm slump values. For the 28-day strengths, this gap disappears and the values were noted as almost the same. Moreover, concrete strength values of 10 cm slump concretes made with BAB cement are higher than concrete strength values of 15 cm slump concrete specimens made with normal Portland CEM I 42,5R cement at both the 7 day and 28 day cure.

Water permeability tests were carried out on concrete samples made with different cement contents of BAB cement and normal Portland cement according to EN 12390-8 Standard. From this work, a relation was obtained (shown in Fig. 8) that relates depth of water penetration to cement content. It has been determined that the degree of water permeability of concretes made with BAB cements is less than that of concretes made with normal CEM I 42,5R Portland cement. While concrete with 250 kg/m^3 cement content and with 10 cm slump value made with BAB cement was determined as almost impermeable against water and harmful chemicals, concrete made with BAB cement and 15 cm slump was determined almost impermeable to water. However, when concrete made with normal CEM I 42,5R Portland cement was examined, it has been determined that only concrete with 300 kg/m^3 Normal Portland cement content and higher cement contents are almost impermeable against water.

In Table 6, tests results for resistance to chloride penetration conducted according to ASTM C1202-05 are given. Results for concretes made with BAB cement with slump values of both 15 cm and 10 cm and concretes made with normal Portland cement with a slump value of 15 cm are provided. As can be clearly seen in Table 8, concretes made with the BAB cement are more resistive to chloride penetration than those made with normal CEM I 42,5R Portland cement. The resistance to chloride ion penetration of concrete made with normal Portland cement at 400 kg/m^3 cement content resulted in a high permeability class, whereas in comparison,, concrete made with BAB cement, even a lower

cement contents of 250 kg/m^3,resulted in a moderate permeability class. As a result, concrete made with BAB cement appears more durable than that made with normal Portland cement. The reasons for this were explained in detail in the introductory section. The theory and the test results gave quite parallel findings.

5 RESULTS AND DISCUSSION

The partial test results of both cement and concrete with BAB and normal Portland cement showed that this new BAB cement could be used in all massive concrete and in some conventional concrete structures where durability is of main concern. Despite the fact that early strength development seemed to be disadvantageous as comparing to normal Portland cement, however if necessary, by taking some precautions, this obstacle can be overcome most likely. During the pre-tests, a few chemical admixtures such as set-accelerator and high range water reducer were tried in concrete castings in order to investigate the early strength development of BAB cement concrete at 1, 3, 7 and 28 days. With a set-accelerator chemical admixture 5,0 MPa, 18,0 MPa and 29,0 MPa compressive strength values were obtained at 1, 3 and 7 days respectively. Also with a high range water reducer chemical admixture 8,8 MPa, 31,2 MPa and 54,2 MPa compressive strength values were obtained at 1, 3 and 7 days respectively. If needed Blaine value of BAB cement can be increased by up to 4300 cm^2/g in order to obtain higher early strengths of concrete. Moreover, dynamic modulus of elasticity, velocity of longitudinal pulses and transit times were measured on both concrete specimens made with either BAB or normal Portland cement. The first results showed that there is no significant difference between the concrete specimens made with both cement.

In the second part of the research, a more detailed research will be conducted; in particular, focus will be placed on characterising the microstructure of concrete and the effects of mineral and chemical admixtures on the properties of concrete. As well, tests on concrete specimens made with different Blaine values of BAB cement will be carried out to investigate the durability against different environmental effects.

ACKNOWLEDGEMENTS

The authors would like to deeply thank those individuals who provided the DSİ Genel Müdürlüğü with useful and helpful assistance and in particular the National Boron Institute (BOREN) and the Turkish Cement Manufacturers Association (TCMA).

ABSTRACT

Variety of consumption in wood products, new situations, variety of chemicals which are used for wood finishing, finishing process and necessity of wood preservation illustrate the necessity for choosing the best materials for wood and wood product finishing.

In this research, in order to study the effects of wood finishing materials on wood and plywood durability, nitrocellulose lacquers, acid catalyst lacquers and polyesters are applied on wood and plywood; next, the specimens are imposed to accelerate aging situation according to D3459 ASTM standard. Then, their physical and mechanical properties are measured.

The results have indicated that in bending strength and modulus of elasticity, polyesters are the best material; however, their efficiency are perceived only on plywood's specimens. On the other hand, there aren't many differences between paints in the case of massive wood. In glue-line shear strength, results have indicated that polyesters are the best materials after aging situation. In water absorption tests, acid catalyst lacquers are suitable finishes for water absorption; although, the rate of water absorption in polyesters are slower at first but this finishes couldn't endure aging and after accelerate aging the rate absorbed water increased. In Swelling Thickness, like water absorption, acid catalyst lacquers are the best water resistant paints; while, in long run, it could be useful after aging; but generally in short term preservation polyesters are the best of all.

1 INTRUDUCTION

In Regard to limited resources of wood, the necessity of wood products' preservation is clear. Wood surface treatment is a method that is applied for preservation of wood and wood substrates. In addition, woods and wood products' durability against decay, temperature, moisture, chemicals and etc, makes their appearance more attractive and improve their efficiency to some extent. 'T. Eldwson *et al* [2003] find that the method of painting had the most effects on water movement in wood'. 'W.C.Feist and R. C. Williams [2004] studied on strength of plywood and paints efficiency that imposed in outdoor places. The results showed that the efficiency of oil based and latex against decay was excellent. In addition, paints had better durability in comparison to film forming paints. But their resistance against decay was more than film forming paints after 16 years of aging in the same situations'.

Application of surface treatments in comparison to other methods is simpler and make it possible to use it in structures that have built before; furthermore, it can be used easier with less limitation in wood substrates for example plywood.

Temperature, moisture, their interactions and periodical changes are critical factors on mechanical properties of wood and wood substrates; besides, these can change the solid wood properties and influence on glues in wood substrates. Therefore, these agents not only affect wood, but also they influence on internal glues and defects occur because of glue failures. 'B.H. River [1994] studied on outdoor effects on wood and wood substrates. They compare their efficiency to specimens that subjected to aging in laboratory tests. Results covey that solid wood have the best properties in comparison to wood substrates; that is because of the effects on glues, certainly density, the amount of chemicals and wood spices are influential on the results'. 'C.G.Carll and W.C. Feist [1989] prepare wafer board panels with different finishing and imposed them to weathering. Results showed that weathering and subsidence of application properties are touch on their finishing'.

There are many researches on practical properties of wood and wood substrates in outdoor situations but there are a few studies on properties and aging on wood and wood substrates on indoor spaces. As far as a perfect finishing may increase the efficiency of wooden structures, so the prospect of this research is the efficiency comparison of polyester, acid catalyzed lacquers and nitrocellulose lacquers, three chemicals that used for wood finishing and aging on wood and plywood on indoors spaces. These comparisons are based on mechanical and physical properties of specimens.

2 MATERIALS AND METHODES

At the first stage, the specimens which are *Fagus Orientalis* wood and plywood cut into standard tests dimensions according to ASTM D1037 with the exception of specimens that are used for water absorption and thickness swelling. In these specimens because of the limitation in the size of the logs the ISO standard are applied. After preparation of specimens all of them except those are used as untreated specimens paint with sealers; after that each group of them separately are painted with polyester, acid catalyzed lacquers and nitrocellulose lacquers.

Before the main aging stage, all specimens put in laboratory situations 23±2°C and 65±3% relative humidity (RH). Then, accelerate aging are used for this research according to ASTM D3459 standard. Half of the specimens are put in accelerate aging situation and others are put aside as untreated specimens. In accelerate aging, at first, the specimens are placed in oven 50±2°C while the air circulated around them to prevent overheating. After 48 hours the specimens are put in 50 ±2°C and 97±2% RH; germinator are used for this purpose. After 48 hours in germinator the specimens are put in 23±2°C and 65±3% relative humidity (RH). We repeat these periods five times and after that physical and mechanical properties of all specimens are measured, according to ASTM D1037. INSTRUN® machine are applied for measurement of these properties. The data analyzed by statistical

methods. In addition, the data are compared separately reaching the rate of changes in mechanical and physical properties of specimens.

3 RESULTS AND DISCUSSION

Statistical analyses and comparison of data showed these results which are mentioned here:

3.1 Bending Strength and Modulus of Elasticity in Grains Direction

In plywood specimens the effect of aging and finishing on modulus of elasticity (MOE) and bending strength (BS) in grains direction showed significant different of 1% in statistical analyses. Interaction of two factors on MOE is not significant and bending strength was significant in 1%. In solid wood the effect of aging, finishing and their interaction effect on MOE and bending strength are not significant in exception of aging on MOE that are significant in 5%. The rates of changes are showed in [Table1 and Table2] . The numbers in [Table 1] convey the differences between physical and mechanical properties of the specimens before and after accelerate aging. We can see that all the specimens lose their efficiency to some extent when they encounter to the aging situation. But these rates show a dramatic change in plywood, especially in the physical properties, (water absorption, and thickness swelling).

Table 1. The rate of decrease in physical and mechanical properties after accelerate aging in plywood and wood in all specimens.

tests	*plywood [%]*	*wood [%]*
MOE Parallel to grains direction	-6.9	-3.7
MOE vertical to grains direction	-7.5	-2.8
BS Parallel to grains direction	-9.9	-8.2
BS Vertical to grains direction	-7.4	-2.8
Glue-line shear	-24.7	-
Water absorption 2hours	-37.3	-25
Water absorption 24hours	-15.5	-21.5
Swelling in thickness 2hours	-33.9	-2.5
Swelling in thickness 24hours	-25.2	-11.7

We could find from these results that aging in bending strength were effective on plywood rather solid wood and it approximately hasn't effect on MOE and bending strength. For example, [Table1] show 6.9 percent decrease in MOE parallel to grains in comparison to 3.7 percent decrease in wood. We can find their reasons in the structure of these materials. In plywood urea formaldehydes as glue are sensitive in periodical changes of temperature and moisture. Temperature and moisture cause fail in performance of glue that it eventually decrease the mechanical properties in plywood but in solid wood temperature and moisture periodical changes can't influence on wood properties because of its solid and massive structure; however, it may cause some cracks that it happen in plywood too, but, it's less than we observed in solid wood.

In the case of paints polyesters show the best resistance in accelerate aging situation [Table2]. Furthermore, it increases MOE and bending strength of specimens. That is because of the solid structure of polyesters that enhanced the mechanical properties; in addition, it preserved wood materials from periodical changes of temperature and moisture. Also, it's found in comparison of nitrocellulose lacquers and acid catalyst lacquers (A.C. lacquers) to untreated specimens that these paints have positive effects on preservation of specimens in accelerate aging situation, but they don't strengthen the mechanical properties of specimens because of the more flexible structure of these film layers that they have.

In the case of solid wood polyesters are the best materials for surface preservation against aging and then nitrocellulose lacquers and at last A.C. lacquer; but this difference generally is not significant in statistical analyses in wood specimens. 'According to River [1994] decrease in MOE and bending strength in solid wood specimens was less than the same properties in plywood specimens'. Therefore, in this case the best material for aging preservation is polyester; however, its efficiency on plywood and in the case of solid wood doesn't show many differences between paints in statistical analyses.

Table 2. Comparison of polyesters [A], A. C. Lacquers [B] and nitrocellulose lacquers [C] to untreated specimens in plywood and wood in all specimens before and after aging.

tests	*plywood*			*wood*		
	A	*B*	*C*	*A*	*B*	*C*
		[%]			*[%]*	
MOE Parallel to grains direction	+8.9	+2.4	+5.7	+2.3	+2.8	+1.6
MOE vertical to grains direction	+6.68	+7.26	+4.68	+1.8	+6.8	+4
BS Parallel to grains direction	+11.5	+3.01	+8.41	+0.5	+0.6	+0.2
BS Vertical to grains direction	+7.5	+1.9	+2.1	+1	+0.01	+0.3
Glue-line shear	+34.7	16.1	+12.1	-	-	-
Water absorption 2hours	+81.4	+77.7	+74.9	+57.8	+78.6	+77.7
Water absorption 24hours	+62.9	+44.9	+43.3	+57.2	+53.3	+54.1
Swelling in thickness 2hours	+61.3	+68.6	+43	+13.1	+49.5	+42.6
Swelling in thickness 24hours	+52.2	+27.7	+25.5	+27	+44.9	+33.2

3.2 Glue Line Shear Strength

Statistical analyses results show a significant difference 5% after aging in this property and it isn't significant about finishing and finishing - aging interaction. However, [Table1 and Table2] show the efficiency of paints in accelerate aging situation; but, they can't improve the mechanical properties in specimens that aren't imposed in accelerate aging situation. Aging affect the glue line and decrease this property. This test is measurable only in plywood.

3.3 Water Absorption

It can be inferred from results that aging is an initial factor in water absorption and it affect on finishing performance. In accordance with statistical analyses and the amount of water absorption that are showed in [Table 1 and Table 2] a large amount of water absorption are observed in solid wood. We can come to conclusion that the amount of water absorption in specimens are because of the water that absorbed by wood material itself; of course, the amount of absorbed water in plywood is more than solid wood and it might be because of the remained water between wood layers and broader surface that face to water. A. C. lacquers specimens can be the best finishing in water absorption. In spite of that the amount of water absorption in polyester specimens is rather than other paints at first. But these paints can't tolerate accelerate aging situation that lead to absorption of more water that is because of the fine cracks occur on the surface of the paint's layer. So, water can penetrate easily under paint but the efficiency of these paints is like nitrocellulose lacquers after aging. In the case of A.C. lacquers thanks to their flexible structure, the paint's layer can protect the wood and plywood better; therefore, it's an ideal paint against water absorption in long run.

3.4 Thickness Swelling

In this case results indicate that the most important factor in thickness swelling in plywood is the separation of wood layers in plywood. Statistical analyses show that there aren't significant differences between paints and specimens that are imposed to accelerate aging situation and those that aren't. In regard to [Table 1 and Table 2], thickness swelling in polyesters are not so high because of theirs solid molecule structure. Solid structure hold wood layers tightly in theirs solid structure; but

fine crakes appear after aging. When these fine cracks develop the solid structure may break up and layers separate because of more water absorption and it causes more thickness swelling. But in nitrocellulose lacquers their flexible layer are more stable in periodical change of moisture and temperature; therefore, in long term preservation can be the best materials; however, polyesters are the best one in short term periods of preservation. Nitrocellulose lacquers in comparisons to others are in the lower level. More water absorption and thickness swelling of these specimens are because of their chemical properties. A complete polymerization that there are in polyesters and A.C. lacquers don't happen in these paints; therefore, water can penetrate easier under the paints layers.

4 CONCLUSIONS

The results have showed that in bending strength and modulus of elasticity, polyesters are the best materials, but, these paints are effective only on plywood and there aren't many differences between wood finishing materials in the case of massive wood .it is because of that aging effect on glues more than wood itself. Therefore, when plywood imposed to aging situation, the paints can show their efficiency better.

In glue-line shear strength, results have indicated that polyesters are the best materials after aging situation. In water absorption tests, acid catalyst lacquers are suitable finishes for water absorption; however polyesters absorb less water at first but this finishes can't endure aging and after accelerate aging situation the amount of absorbed water increase. We can find its reason in different chemical properties that paints have.

In Swelling Thickness, like water absorption, acid catalyst lacquers are the best water resistant paints; then in long term, it can be useful after aging; however, in short term preservation polyesters are the best of all.

Tsuyoshi Yoshimura [2]
Yuji Imamura [3]

T 12

ABSTRACT

In the study, tetraethoxysilane and methyltriethoxysilane were tested as modifying Si-compounds to limit boron leachability from modified wood and to increase biological durability of the wood against fungi and termites. Both silane compounds were used in silane state in where acidified ethanol was added and stirred at ambient temperature for 30 min. There were two different processes for preservative treatments: double and single treatments. In double treatments, specimens from sugi wood were first treated with boric acid at 1% concentration and the specimens were then treated with the silanes. In single treatments, boric acid was mixed with the silane compounds in silane state yielding 1% boric acid concentration. After treatments, the wood specimens were subjected to laboratory leaching tests and leachates were analyzed for boron content by using Induced Coupled Plasma Spectrometry (ICP). ICP analyses showed that silane treatments in the study were able to limit boron leaching from treated wood by about 40% in all cases for each silane compound. The specimens were subjected to laboratory termite and decay resistance tests using the subterrenean termites, *Coptotermes formosanus*, and the wood decaying fungi, *Fomitopsis palustris* and *Trametes versicolor*. Termite and fungal decay resistance tests revealed that resistance of modified wood with the silane compounds and boron increased when compared to untreated and boron-only treated wood specimens. More detailed studies are in progress to obtain a better understanding of the mechanisms of interaction between the silicon compounds, boron element and wood components.

1 INTRODUCTION

Various chemical compounds have been used for the modification of wood to improve its several characteristics [Donath *et al*. 2004; Rowell 1983; Militz *et al*. 1997; Norimoto 2001]. Many types of silicon compounds have been applied for this purpose. Silanes are long known as modification agents in a number of applications and they are used for hydrophobication of ceramics, scratch resistant surfaces, soil proofing and anti-graffiti coatings or as adhesion promoters between organic and inorganic materials [Donath *et al*. 2004; Hill *et al*. 2004; Mai *et al*. 2003]. The silanol groups of silanes can react with hydroxyl groups of cell wall polymers forming a covalent bond between the silicon compound and cell wall polymers; however, Si–O–C-bonds are weak and susceptible to hydrolysis. Alkylalkoxysilanes bear at least one alkyl group which remains after the sol–gel process because, in contrast to Si–O-bonds, the Si–C-bonds are stable against hydrolysis [Brinker and Scherer 1990; Sebe and Brook 2001; Donath *et al*. 2004].

Besides improved wood properties, modification may have potential for limiting preservative release from treated wood and increasing biological resistance against wood degrading fungi and insects. Kartal *et al*. [2004] found that acryl-silicon type resin emulsion and boron-treated wood specimens resulted in about 54% boron release after a 10-day leaching process; however, nearly all boron was leached out from boron-only treated specimens. Similar results were obtained when wood specimens were treated with both boron containing quaternary ammonia compound (DBF) and the same emulsion in surface treatments Kartal *et al*. [2004]. A study by Lin and Chen [2005] has showed that a series of cleavable water-soluble silicon surfactants prepared by the reaction of a hydroxyl-terminated polyester and an organopolysiloxane bear siloxane as the functional group of water repellency effect.

Since several silicon compounds may have ability to increase water repellency and reaction with cell wall components, such compounds can be used for limiting boron release from boron-treated wood. In this study, tetraethoxysilane and methyltriethoxysilane compounds as modifying Si-compounds were tested to limit boron leachability from chemically modified wood and to increase biological durability of the wood against wood degrading fungi and termites.

2 MATERIALS AND METHODS

Wood specimens, 20 (radial) by 20 (tangential) by 10 (longitudinal) mm, were cut from sapwood portions of sugi wood (*Cryptomeria japonica* D. Don). Before treatment, all wood specimens were conditioned at 20°C and 65% relative humidity (RH) for 2 weeks. The specimens were free of knots and a visible concentration of resins, and showed no visible evidence of infection by mold, stain, or wood-degrading fungi.

As modifying agents, tetraethoxysilane (Si-I) and methyltriethoxysilane (Si-II) were used in silane state where acidified ethanol (1 mol) was added to the silanes and stirred at ambient temperature for 30 min as described by Donath *et al*. [2004]. As catalyst, 2.1 and 0.9 mg/l HCl (37%) was added to tetraethoxysilane and methyltriethoxysilane compounds, respectively [Donath *et al*. 2004].

There were two different processes for preservative treatments: double treatments and single treatments. In double treatments, wood specimens were first treated with boric acid (BA) at 1% concentration. The specimens were then reconditioned at 20°C and 65% RH for one day and treated with the silane compounds in silane state. In single treatments, BA was mixed with the silane compounds in silane state yielding 1% boric acid concentration.

In both treatments, treatment cycle consisted of a 40-minute vacuum (-88 kPa absolute pressure) in a treatment desiccator. After all treatments, the specimens were blotted dry and reweighed to determine

the uptake chemical retention. All treated specimens were then reconditioned at 20°C and 65% RH for one day and then dried at 105°C for one day before leaching process.

The leaching process was conducted according to Japanese Industrial Standard (JIS) K 1571 [2004] The process involved immersing wood specimens in distilled water, stirring with a magnetic stirrer (400-450 rpm) at 27°C for 8h followed by drying at 60°C for 16 h. This cycle was repeated 10 times. After each leaching cycle, the water was renewed with fresh distilled water to a ratio of 10 volumes of water to 1 volume of wood. The sample preparation for boron analyses was similar to the American Wood Preservers' Association (AWPA) A2-98 standard method [AWPA 1999]. The specimens were ground to pass through a 40-mesh screen in the Wiley Mill, oven-dried, and 1.5 g of ground wood was weighed to the nearest 0.001 g into a 250 ml flask. For each treatment group, two specimens were ground and analyzed. One hundred ml of deionized water was added to the flask containing the ground wood. The flask was placed in a water bath at 90-95°C for 60 min with agitation every 15 minutes. After cooling, the contents in the flask were filtered through Whatman #4 filter paper, rinsed 3 times with 20 ml of hot deionized water, and diluted to 200 ml in a volumetric flask. Leachates sampled from the leaching cycles for 10 days and extracts from the treated wood were analyzed with an ICP Sequential Plasma Spectrometry (ICP-S 1000III Shimadzu Co Ltd, Japan). The percentage reduction of boron in the specimens was calculated based on the initial amount of boron in the specimens.

Untreated and treated specimens were exposed to the subterranean termites, *Coptotermes formosanus* Shiraki, according to the JIS K 1571 standard method [(2004]. An acrylic cylinder (80 mm in diameter, 60 mm in height) whose lower end was sealed with a 5 mm thick hard plaster (GC New Plastone, Dental Stone, G-C Dental Industrial Corp., Tokyo, Japan) was used as a container. A test specimen was placed at the centre of the plaster bottom of the test container. A total of 150 worker termites collected from a laboratory colony of RISH, Kyoto University were introduced into each test container together with 15 termite soldiers. Five wood specimens per treatment were assayed against the termites. The assembled containers were set on damp cotton pads to supply water to the specimens and kept at 28°C and >85% RH in darkness for three weeks. The mass losses of the specimens due to termite attack were calculated based on the differences in the initial and final oven-dry (60°C, 3 days) weights of the specimens after cleaning off the debris from the termite attack.

Decay resistance test was conducted according to Japanese Industrial Standards [JIS K 1571 2004] using the brown-rot fungus, *Fomitopsis palustris* (Berkeley et Curtis) Murrill (FFPRI 0507) and the white-rot fungus, *Trametes versicolor* (L. ex Fr.) Quel. (FFPRI 1030). After the oven-dried weights were determined, the specimens were sterilized with gaseous ethylene oxide. Three wood specimens per treatment were placed in a glass jar on the surface of 250 g quartz sand wetted with 80 ml nutrient solution and inoculated with liquid fungal cultures. Liquid fungal cultures were prepared inoculating 1000 ml liquid medium which contained 40 g glucose, 3 g peptone, 15 g malt extract and 1000 ml distilled water. The medium was shaken at 26°C for 10 days at 100 rpm. The nutrient solution used for wetting the quartz sand contained 40 g glucose, 3 g peptone, 15 g malt extract and 1000 ml distilled water for the white-rot fungus and 20 g glucose, 1.5 g peptone, 7.5 g malt extract, and 1000 ml distilled water for the brown-rot fungus. The test jars were then incubated at 27°C for 12 weeks. Nine replicates were tested for each decay fungus. The extent of the fungal attack was expressed as the percentage of mass loss.

3 RESULTS AND DISCUSSION

Figure 1 shows a scheme for the sol-gel deposition of alkoxysilane on the wood surface, causing covalent bonds with the wood surface and resulting in hydrophobication. Sebe *et al*. [2004] has stated that silicon-based monomers undergo selective bond cleavage and recombination to form macromolecular layers based on Si-O-Si and Si-O-C linkages. Covalent grafting of silicon polymers is considered as another potential reaction of wood hydrophobization. Saka *et al*. [2001] have suggested that silane compounds react with the cell wall via the sol-gel process to achieve a deposition of the

silicon in the wood. They also observed that the silicon compounds in the lumina of the wood did not make any contribution to decreased water absorption [Saka *et al*. 1992]. Sol-gel polycondensation networks of alkoxysilanes deposited within the wood cell wall enhance the water resistance properties of wood [Tshabalala *et al*. 2003].

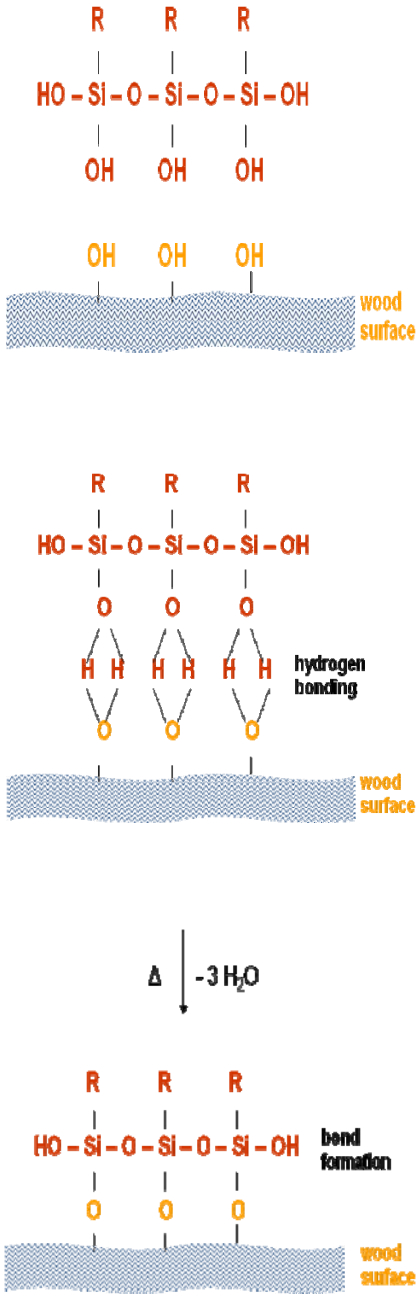

Figure 1. Scheme for deposition of alkoxysilane on wood and hydrophobication - covalent bond formation in silanol groups of alkoxysilane, and hydrophobication on wood surface.

Figure 2 shows the amount of boron released from the specimens during the 10-day leaching course as ppm. In BA-only treated specimens, totally 212 ppm boron release was determined and only 189 ppm boron was released on the first day of leaching. Si-I and Si-II treated specimens showed less boron release during the course.

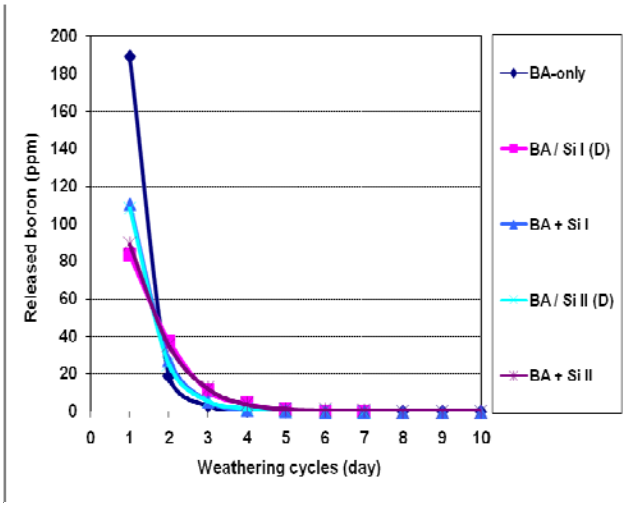

Figure 2. Released boron from treated specimens.

Figure 3 shows the percentage boron release from the specimens at the end of the leaching course. Nearly all boron was leached out from BA-only treated wood specimens; however, about 40% of total boron remained in the specimens treated with either Si-I or Si-II compounds. It should be noted that original BA retention was in the specimens nearly 7 kg/m^3 before leaching. Less boron leachability in Si-I nd Si-II treated specimens likely resulted from a reduction in the pore size and spaces within the cell wall, which are a pathway for the adsorption of water. Similar results were obtained by Donath *et al*. [2004]. They treated wood specimens with various types of alkoxlysilanes and has suggested that the chemical modification of wood requires the reaction of chemicals with cell wall components to achieve mechanical fixation of the compounds in the wood. In our study, most of the boron located in the wood lumina was leached out from the treated specimens, since there was no reaction between either boron or silicon precipitated in the lumina. It is assumed that some parts of boron located in the cell wall together with the silicon emulsion remained in the wood after the leaching process.

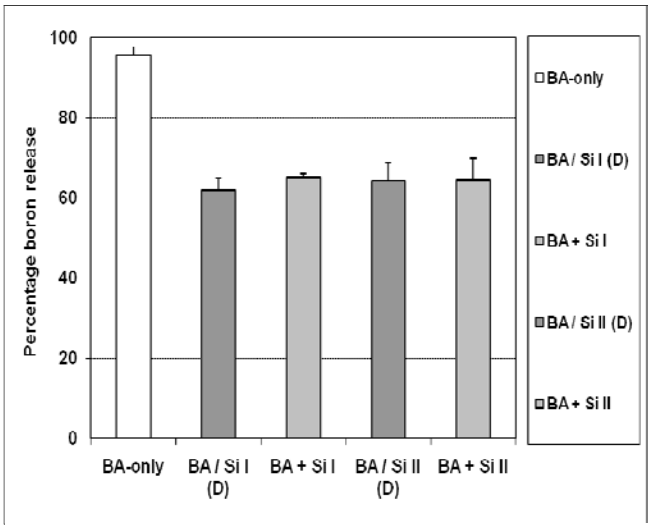

Figure 3. Percentage boron released from treated specimens.

Figure 4 shows mass losses in the specimens occurred after a 3-week exposure to the subterranean termites, *C. formosanus*. All unleached specimens showed perfect protection against the termites; however, mass losses in control specimens and BA only treated and leached specimens were nearly 30%. The more interesting results were obtained in Si-I and Si-II treated specimens. In those specimens, mass losses were considerably lower than BA-only and untreated control specimens. As

mentioned before, about 40% of total boron remained in those specimens suggesting that remaining parts of boron along with the silicon compound increased the resistance. In our study, it was found that nearly 2.5 kg/m^3 BA-retention in the specimens was achieved after leaching. Commercial retentions to provide protection against termites are usually in excess of about 4.5 kg/m^3 boric acid equivalent (BAE). However in the UK, treatments require 1.8 kg/m^3 BAE minimal cross-sectional retention because termite risks are considerably lower. Lumber receiving commercial treatment with borates in the United States is treated with DOT (disodium octoborate tethrahydrate) and receives a borate retention of 2.7 kg/m^3 BAE to control decay, beetles, and native termites or 4.5 kg/m^3 BAE to protect against Formosan subterranean termites [Lloyd 1997].

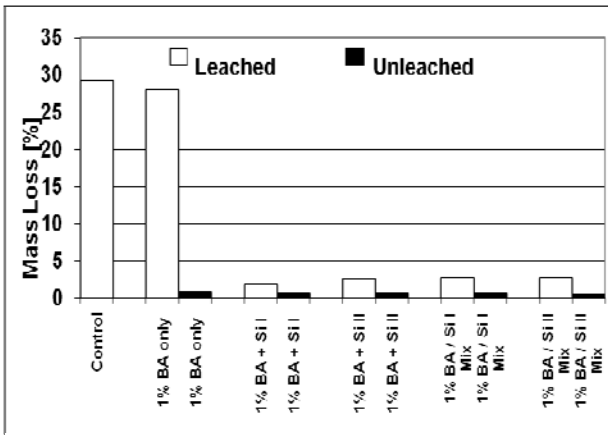

Figure 4. Mass losses in the specimens exposed to termite resistance tests.

Mass losses in the specimens exposed to 12-week fungal resistance tests followed by a 10-day leaching process are given in Fig. 5. Mass losses in untreated control specimens for both fungi, *F. palustris* and *T. versicolor* exceeded 30%. BA-only treated specimens also showed similar mass losses due to high boron release from the specimens during the leaching process. However, unleached specimens of this treatment group showed no mass losses. Mass losses in Si-I and Si-II treatments were lower than 5% suggesting that remaining boron in the specimens after leaching was able to protect wood against the fungi tested.

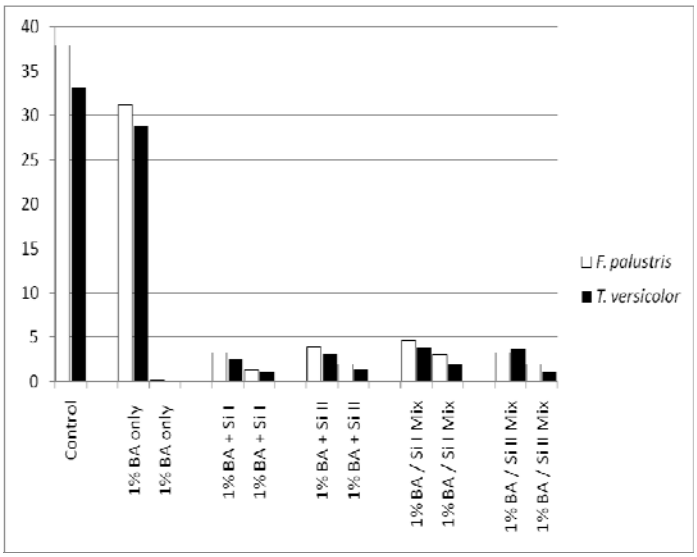

Figure 5. Mass losses in the specimens exposed to decay resistance tests.

European standards usually require 0.76, 0.59, 0.32, and 0.30 kg/m^3 DOT retention levels for protection against *Trametes versicolor*, *Gloeophyllum trabeum*, *Coniophora puteana*, and *Poria placenta*, respectively [Lloyd 1997]. Na-borate retention levels of 0.8-1.1 kg/m^3 were needed to protect wood against *Neolentinus lepideus*, *C. puteana* and *P. placenta*, but more Na-borate retention levels were needed against *T. versicolor* and *G. trabeum*, respectively [Abbot *et al*. 2000]. Tsunoda [2001] found that the toxic threshold values for sugi sapwood specimens treated with BA were 0.8 kg/m^3, 0.9-1.8 kg/m^3, and 0.9-1.8 kg/m^3 BAE against *T. versicolor*, *F. palustris*, and the subterranean termites, *C. formosanus*, respectively. A study by Akbulut *et al*. [2004] showed that 0.1% BAE borax treatment in the MDF specimens decreased mass losses to below 3% against *F. palustris* and *T. versicolor*.

4 CONCLUSIONS

The effects of two silane compounds, tetraethoxysilane and methyltriethoxysilane on both boron leaching and decay and termite resistance of wood specimens under laboratory conditions were evaluated. The silane treatments helped wood retain about 2.5 kg/m^3 boric acid retention in the specimens after the leaching process. Several previous studies showed that termite resistance usually requires retention levels of BAE of more than 1 kg/m^3 in the wood; however, less than 1 kg/m^3 retention is needed to protect wood against wood decaying fungi. In our study, the specimens treated with BA and the silane compounds showed resistance against the fungi and the subterranean termites, *C. formosanus* after the leaching process.

The Old, Wooden Window
a Balance between Romantism and Performance

Ana-Maria Dabija [1]

T 12

ABSTRACT

As the knowledge and technology increases, it is interesting to observe how the expression of the building components becomes… poorer. The most important measure that is being used to compare buildings as a whole or parts of buildings is in terms of performance, either thermal, energy, acoustic, durability and so on Mies van der Rohe's *"Less is more"* became a universal statement as in recent years the preoccupation for the decoration of the building components almost vanished (and unfortunately, where it did not, the result is rather catastrophic). While discussing the glazed part of the envelope we observe how more and more new, performant windows take the place of old, "worn out" wooden ones, in existing buildings. Traditional windows, old bow-windows, shutters and blinds are replaced with modern windows with special glazing, with performant hardware, with ever-lasting self-maintaining finishing. In less than one century a time-verified window system left the market and will eventually vanish even from the facades of the old buildings. The paper aims to present these types of windows – in principles and performances – as well as some exquisite sculptures that were carried out on the wooden components of the old window.

[1] Ion Mincu University of Architecture and Urbanism, Bucharest, Romania, Phone: +40 (0)752 230 646, Fax: +40 21 312 39 54, am.dabija@iaim.ro

1 INTRODUCTION

During the last twenty years we have assisted – helplessly – at the declining of the traditional windows: everywhere the wooden windows are replaced with new, contemporary, PVC or metallic windows, that use performant insulated glass units. The theory goes that these high quality windows ensure better energetic performances, better economic performances .

The wooden window, on hinges, is the most commonly used type of windows and has carried us through the last centuries, mainly in the housing programme but also in other types of buildings: schools, offices, theatres etc.

In a country like Romania, with a very rough climate*, the windows had to be double. Even old, peasants' houses [see Figure 1] have two lines of sashes mounted on the same frame, in order to protect better against weathering.

Figure 1. XVIII Century house, Peasants' Museum, Bucharest.

2 CHARACTERISTICS OF WOODEN WINDOWS

The wood is a "warm" material and has the natural quality of "breathing". Therefore the thermal performances of the wooden elements have only recently been achieved by PVC profiles with at least 4 chambers.

Wood also has a capacity of absorbing a certain amount of vapours from the atmosphere, thus contributing to a natural balance of the humidity in the interior environment.

However, beyond that critical amount, humidity deforms and deteriorates wood. The deformations are different according to the type of wood.

Common wood species that are used in Romania are fir and oak. For the windows of the more expensive buildings, oak profiles were used.

The mechanical resistance of the window is different, according to the mechnical resistance of the type of wood. Deformations at the joining of the wooden parts, especially of the sashes, are caused also by the shrinking of the elements.

* excessive continental temperate climate, with very high summer temperatures (as high as +45 C^0 in Bucharest in 2007) and winters with very low temperatures (going down to -20 C^0 in 2004)

The sealing between the frame and the sash is made by the overlapping of the grooves, thus resulting a reduction of the air and water tightness.

This is not altogether bad, in the case of wooden windows that are in a good state, as the imperfect overlapping of the elements allows a (hopefully) feeble air movement between the two environments: the interior and the exterior of the building. If the gap between the elements increases, however, steps should be taken in order to keep it in controlled parameters [Dabija, 2002]. Wood is flammable and combustible.

3 COMMON TYPES OF WOODEN WINDOWS

In the less heated spaces (cellars, staircases that lead to appartments etc.) – or unheated altogether – of the "civilian" buildings (dwellings, etc), simple windows were used (with a single sash).

In some situations of double windows the second sash was taken off the frame, considering that the space needs not to be comfortably warm. In the heated spaces of the buildings double windows are used (two sashes that accomplish a window).

Currently, in the interior warm environment we deal with two main types of wooden windows, that practically cover the market; both of them on hinges applied on the vertical elements of the window: customary opening windows and interior opening windows.

In Romania, the double window in which one sash opens towards the interior and one towards the exterior is called "customary opening window" (see Figure 1and Figure 2).

It was the usual system of opening windows; therefore the name of the type of opening is "customary".

Figure 2. "Customary" opening window – University of Bucharest, arch. Al. Orascu, 1857-1869.

The interior opening system is accomplished by two sashes on a common frame or on two independent frames that open towards the interior (Figure 3).

While the *declared* thermal performances of these types of windows are similar (as there is a mathematical formula by which the performance is established), the effective protection against dust, cold air and rain penetration is different [Dabija, 2004] from one system to another.

Figure 3: "Interior" opening window – Bucharest, early XX-th Century.

There are several levels of discussion about windows:

1. the characteristics of the two main types (advantages, disadvantages)
2. the supplementary devices that can be adapted for these types of windows
3. the decorative approach, according to the geometric features of the types of windows

3.1 The Characteristics of the Two Main Types (Advantages, Dissadvantages) of Windows

One common feature is the depth of the profile of the massive wooden sash: 42mm. Laminated wood profiles of today, mainly built according to norms [DIN 68121], are over 20mm deeper (currently 68mm). It is true that these profiles bear the load of insulated glass (I.G.) units. Also in terms of widthness, the old massive wooden sashes were slimmer than the ones used today (mainly due to the same reason, the load of the insulated glass unit).

3.1.1 Features of the "customary" opening windows

Without considering the material that the windows are made from (metal, plastic, wood), the main advantage of the "customary" opening windows is that it acts like a storm window: when the wind blows on a facade, the exterior sash is being pressed against the frame, thus increasing the air and water tightness of the window assembly. Rain water, pushed by the wind on the window, will not penetrate between the sash and the frame. This is the reason for which the "customary" opening windows are not provided with larmiers on the inferior traverse. However, in the case of fanlights the principle does not apply: water can penetrate on the traverse of the window and from there inside, at the top of the lower window. In this case a larmier is attached, either on the inferior traverse of the fanlight sash or on the intermediary traverse of the window (see Figure 4).

Among the defficiencies of the customary opening windows are the problems of maintenance (the exterior opening sash is difficult to clean; if left open for longer periods, the hardware can be more easily rot as it is more exposed to weathering).

Also, the position of these windows should be well thought of, as there is a danger for the pedestrians to be hit by an opening window, if the window is placed on the ground floor of a building at the street front.

More than the advantages, the dissadvantages (in maintenance, mainly) led to the abandon of these types of windows. However, in countries with rough, windy climates (near the sea for instance or in the Northern countries) the traditional way of building includes the "customary" opening windows.

Figure 4. Customary opening window, with fanlight and larmier
School of Architecture, Bucharest arch. Grigore Cerchez, 1912 – 1927.

3.1.2 Features of the "interior" Opening Windows
In the case of the "interior" opening windows, the wind pressure (applied on a façade) pushes the sash away from the frame. The measures to avoid water penetration between the sash and the frame are the provision of larmiers on the horizontal elements of the window and the geometry of the sash (with grooves that allow the water to flow on "channels" to the base of the element and lead it out through special perforations).

No special maintenance measures have to be taken for the "interior" opening windows.One of the geometrical characteristics of these double windows is that, due to the necessity of opening both sashes at an angle of 90^0, the exterior frame is broader than the interior one (Figure 5) and also broader than the one of the "customary" opening windows (where both frames – interior and exterior – were identical). In order to give the appearance of a slimmer window, the masonry can partly cover and hide the broad frame.

Figure 5. Interior opening window – School of Architecture arch.
Grigore Cerchez, 1912 – 1927.

3.2 The Supplementary Devices that can be Adapted for these Types of Windows

Most wooden windows are provided with blinds and shutters. In some situations they may fulfill a triple role [Dabija, 2005]: sun protection, aditional thermal insulation and protecton against the intruders.In the case of "customary" opening window, textile rolling blinds or venetians are provided between the sashes (the distance between the sashes is about 9 cm, so there is plenty of space).
These systems are not as efficient as if they were provided on the exterior, but it is the only way to achieve some protection and open the window as well. At the end of the ninteenth and the beginning of the twentieth Century both types of wooden windows were set on buildings with two or three

storeys: on the ground floor the double windows with interior opening that would protect pedestrians from being slammed by a window pane – and which, in the case of dwellings, were provided with shutters for safety reasons as well as for summer sun protection and winter thermal protection – on the higher levels, "customary" opening windows, excelent for protection against weathering (see Figure 6).

Figure 6. Interior opening and customary opening windows
School of Architecture, Bucharest, arch. Grigore Cerchez, 1912 – 1927.

In the case of the interior opening windows, the supplementary devices can be either rolling blinds or shutters, as the protection is operating on the exterior of the window and allows the window to open independently for ventilation. In most of the situations they are provided on the exterior of the window, as this position ensures the most efficient sun protection as well as the protection agains intruders. In order to keep them in the open position, metalic (decorated, in many situations) elements are fixed onto the façade wall. In old houses the groundfloor windows are protected with traditional shutters on sashes. They are sometimes lively painted (Figure 7).

Figure 7. Exterior shutters, discontinuous or continuous; Peasants' Museum, Bucharest.

3.3 The Decorative Approach, according to the Geometric Features of the Types of Windows

Another characteristic that has not been mentioned, as it is obvious, is that wood can be easily carved. It is an important feature, as it allows a vaste variety of shapes and decorations to be worked out, thus ensuring specificity and personality for each window.

In the Art Nouveau period, all over Europe curves were emphasized. Gaudis' windows in Barcelona for instance are world famous (Figure 8). Curved windows have been used throughout the Art Nouveau period in all the countries touched by this architectural style.

Figure 8. Door and windows at Gaudi's Casa Bathllo, Barcelona.

Not only the geometry of the window frame is more easily shaped in wood, but – and this is specific to the wooden windows of the end of the nineteenth century – the perfect subdivision of the vertical or horizontal wooden components was done by means of decoration, if the dimension of the profile requested it.

In the case of windows with fanlight, for instance, the intermediary traverse is very broad. The field is usually subdivided, like in the example given in figure 9, with decorations taken from the means of expression of the classic architecture.

Figure 9. "Customary" opening windows, with decorations on the intermediary traverse.

In the case of windows with more than one leaf, the performance request is to ensure the sealing between the frame and the sash by overlapping of the elements. Therefore, the mullion becomes broader, so that both sashes can be pressed onto it. The vertical field is not let flat, but decorations are applied, in the form of columns with capitels and consoles or cable mouldings. The image is being corrected and the window seems slimmer (Figure 10).

Figure 10. "Customary" opening windows, with decorations on the intermediary mullions.

In (very) rare cases of buildings the decorations on the frames and the sashes are also painted, thus integrating the window more organically into the façade, as presented in Figure 11.

Figure 11. Windows at the Central School in Bucharest, arch. Ion Mincu 1890.

CONCLUSIONS

The contemporary era is associated with an intense building activity. New needs appear and higher requests are formulated for the building components. Higher technical performances lead to changes in the concepts of buildings altogether. *Speed of execution* is a key word. *Technological performance* is another one. The time in which a building is finished decreases as the performances of the components increases. Industrializaton also means simplicity: profiles are more or less the same and windows have a more or less anonymus aspect. Due to the difficulties of maintenance, the "customary" opening windows are also almost lost, even if their performances are better than the ones of any other type.

While the principles for opening are kept and, of course, respected, the refined concepts in how to individualize buildings by their elements, how to divide a surface in order to obtain the maximum aestetical effect, is lost.

Contemporary demands of energy savings of the tennants or owners of buildings have led to the replacement of the old, almost centenary windows, sometimes altering the holistic image of the building (see figure 12.a). The simple approach is the replacement of an old, wooden window with new ones, provided with gaskets and carrying IG units. The fair approach would be to analyze the quality of the buildings, of the windows and instead of replacing, to **add** a performant window, **inside** the building. This way the improvements are made and the cultural, historical and professional heritage are also kept (Figure 12.b).

a. aggressive intervention (replacement)

b. discrete intervention (adding an interior window)

Figure 12. Interventions on existing wooden windows.

The romantic old wooden windows, witnesses of another epoch, are sadly and quietly dissapearing, their place being taken by more modern – but not always necessary better performing – ones.

Hurricane Katrina: An Overview of Damage to Timber Structures

Anthony J. Lamanna [1]
Brian Metrovich [2]
Jeremy Martin [3]

T 12

ABSTRACT

On August 29, 2005, hurricane Katrina made its second landfall as a Category 3 storm in South-Eastern Louisiana. Levees separating Lake Pontchartrain and several canals from New Orleans were breached a few days after the storm had passed, subsequently flooding 80% of the city and many areas of neighboring parishes for weeks. The storm is estimated to have caused over $81.2 billion (in 2005 U.S. dollars) in damage. Whether damage to a structure was caused by wind or flood waters has been a subject of great importance to homeowners with insurance for only wind or water.

Structures away from the immediate vicinity of levee breaches contained structural damage caused by floodwaters that was primarily due to the lack of connection between the timber structure and the foundation. In many instances the combination of rising and moving floodwaters swept structures off of their piers. The standing floodwaters from canals containing harmful chemicals and brackish water from Lake Pontchartrain caused corrosion problems in nails, screws, and other connectors.

Wind induced structural damage was observed primarily in the removal or loosening of roof decking from the underlying framing. Building claddings also suffered significant damage, especially where the stiffness of the cladding was significantly different than that of the underlying structure, such as brick cladding on a timber house.

1 INTRODUCTION

On August 29, 2005, Hurricane Katrina made its second landfall as a Category 3 storm in South-Eastern Louisiana. Levees and floodwalls along Lake Pontchartrain and the outfall and navigational canals breeched, causing the city to flood. Due to a variety of factors, including the approach of Hurricane Rita a few weeks later, parts of the city were not drained of water until a month later.

This paper is intended to provide an overview of the damage caused by Hurricane Katrina, and present some design advice and practices that can be learned. It is not intended to serve as a complete catalog of damage nor a complete design guideline for construction in hurricane prone regions, nor does it address the social and economical implications of the damage caused.

2 FLOOD DAMAGE

Flowing floodwaters in the vicinity of breeches caused a good deal of damage similar to that caused by the storm surge which preceeds a hurricane as it makes landfall. Building materials were also affected by long term sumbersion in the brackish water from Lake Pontchartrain.

2.1 Rapidly Moving Waters

The most readily apparent damage was in the immediate vicinity of the levee breeches. Timber frame structures which were inadequately tied to their foundations were often lifted off their foundations by water passing under the raised floors and/or pushed horizontally. A one story timber framed structure is shown in Fig. 1. There was no evidence of a mechanical connection between this structure and the foundation piers which used to support the floor framing, shown in Fig. 2. This particular structure showed a poor foundation layout, where the concrete masonry unit (CMU) piers were set on a very small concrete “spread footing.” In other instances, sill plates were firmly attached to the concrete foundation with anchor bolts; however, the wall studs framing into the bottom sill plates were only attached with toe nails, as seen in Fig. 3. These toe nails were unable to resist the horizontal forces imposed by the flowing waters.

Figure 1. One story timber frame structure pushed away from the concrete porch.

Figure 2. Foundation pier without evidence of mechanical connection.

Figure 3. Sill plate attached to knee wall with anchor bolt.

When a structure was adequately attached to the foundation, the rapidly flowing floodwaters often induced failure elsewhere in the structure. Entire sections of wall were destroyed by flowing water. These walls were standard load bearing portions of the timber frame structure. Walls which had brick cladding appeared to be more protected from lower velocity flowing water; however, in the immediate vicinity of a breech brick clad walls exhibited similar damage to walls clad with timber weatherboards or vinyl siding. Often, failures were clearly initiated in the vicinity of large door or windows,

indicating that unsecured or unprotected openings provided a weak point in the structure which allowed propagation of more significant damage. Some examples are shown in Figs 4 & 5.

Figure 4. Brick clad wall damaged in vicinity of a levee breech.

Figure 5. Wall clad with vinyl siding damaged in vicinity of a levee breech.

As a result of the damage caused by the floodwaters and the potential for portions of the city to flood, structures in New Orleans that were substantially damaged, substantially improved, or new construction must meet new elevation requirements. These structures must be elevated to either the Base Flood Elevation (BFE) or at least 3 feet above the higest exsiting adjacent grade elevation at the existing site. The Base Flood Elevation (BFE) represents the average floodwater elevation for a 100 year flood event. These new requirements adopted in the region assumes the U.S. Army Corps of Engineers is actively repairing and improving the flood control systems.

ASCE 24-05 Flood Resistant Design and Construction requires enclosures below the BFE to either have breakaway walls or have openings designed to allow equalization of hydrostatic pressure between the interior and exterior of the enclosure. The asthetics of raising structures is of concern to many residents. An example of a recently elevated house is shown in Fig. 6.

Figure 6. Structure recently elevated to above the BFE.

2.2 Long Term Submersion

There was a wide range of observed damage attributed to the long term submersion in the brackish waters of Lake Pontchartrain. Some homes remained partially under water for up to four weeks. While we focus on structural materials in this paper, it is worthy to note the severe mold issues that arose on drywall.

The paper layer remained wet for an extended period of time after the flood waters receeded, and grew mold in most instances. This mold was not seen on walls that were covered with plaster or cement board. This mold may be a significant health hazard.

The most easily observed type of damage was the rusting of metal fasteners, which can be seen above in Fig. 3. Other metal hardware, such as lintels in brick cladding over windows, exhibited some signs of rusting, which could lead to further water ingress if not repaired along with the rest of the structure.

The timber members became saturated in many cases. Timber structural members which were restrained or under load while saturated suffered damage to their grain structures. Many timbers became twisted or warped while in this saturated condition; many remained so upon eventual drying. Tounge and groove hardwood floors were the most visible example of this type of damage.

Some red brick walls which were submerged in the brackish waters showed a degradation in the mortar, which was apparent when the mortar was scraped with a knife blade. Calcium leaching has been shown to degrade the material properties of cementitious materials [Heukamp et al. 2005]. The high porosity of the red bricks and insulation board along the inside of red brick exterior walls likely trapped moisture, which extended the amount of time past flood subsidence that leaching could occur.

It is important to note that damage caused by long term exposure to brackish water, such as the corrosion, warping, and leeching described above, may not be readily apparent. Post disaster inspections of structures exposed to these elements should keep a special look out for these effects as they may otherwise go undetected until they fail in some future, perhaps less extreme condition.

3 WIND DAMAGE

On August 29th, 2005 Hurricane Katrina passed over New Orleans with maximum sustained winds estimated to be around 105 mph (170 km/h) [Knabb et al. 2005]. It is important to keep in mind while observing and analyzing damage from high winds that several factors affect the wind speeds near structures such as height above the ground, type of terrain surrounding the structure, dependence of measured wind speed on averaging time, and turbulence features such as flow separation and vortex shedding around a structure.

3.1 Lack of Uplift Load Path Continuity

The most spectacular form of this failure was the removal of entire sections of roof. Figure 7 shows the removal of a church roof from the supporting walls. Large uplift pressures on the overhangs helped contribute to the failure in this case; however, there was no evidence of tie downs between the roof rafters and the supporting walls.

Cases were also oberved where porches and carports, which were open to the wind, lifted up off of the support columns. If structurally attached to the primary structure, the porch or carport would cause damage to the primary structure when it collapsed. An example of a collapsed porch is shown in Fig. 8.

Figure 7. Removal of a church roof from the supporting walls.

Figure 8. Porch collapsed from uplift forces and lack of tie downs.

3.2 Poor Construction Practices

It is sometimes difficult to separate poor construction practices from poor design practices. The decision to construct a building with a gabled roof instead of a hipped roof in a high wind area would be an example of a poor design practice. The lack of adequate fasteners attaching the sheathing to the structure or fasteners driven through the sheathing and missing the underlying framing would be an example of poor construction practices. Often builders use pneumatic nailguns, which do not provide feedback to the user whether or not the nail entered a structural member. Figure 9 shows decking nails that missed the supporting rafter. Figure 10 shows poorly fastened sheathing that was blown off of a gabled end wall. It is important to realize that while some construction practices are poor, they may be typical and accepted for a particular region.

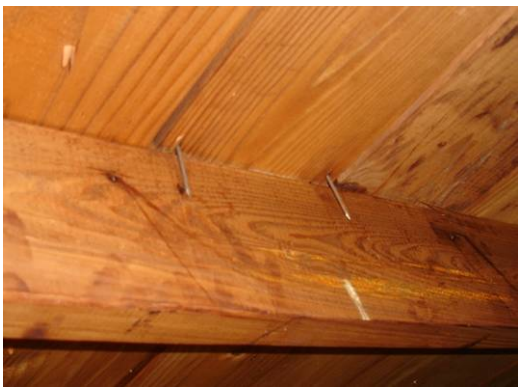

Figure 9. Decking nails that missed the supporting rafter.

Figure 10. Poorly fastened sheathing that was blown off of a gabled end wall.

Another poor construction practice that was observed throughout property inspections was the reduced number of fasteners in hurricane ties. The majority of ties are engineered to have a nail in each hole; a reduced number of fasteners means a reduced load capacity for the anchor. Many contractors do not install the full compliment of fasteners because they must be installed by hand and not with a pneumatic nailgun (it is very difficult to line up the nail with the hole in the connector).

Lack of oversight on small timber framed buildings during the construction process can lead to poor quality and many of the errors previously explained. Some local goverments have instituted inspection processes which can reduce the amount of errors and increase overall quality; for example, Jefferson

Parish in Southern Louisiana requires the design engineer to inspect and approve the construction before the interior gypsum board and other wall and floor coverings are installed.

4 UPLIFT AND LATERAL LOAD PATH DESIGN

Wind design has evolved significantly recent years. The design of timber structures for high winds can be easily completed utilizing manufactured connections and tie downs. Story offsets and geometric irregularities (such as large dormers or porch awnings, which are common in New Orleans) make wind analysis and design more difficult than a simple rectangular building with a gabled or hipped roof. An overview of typical uplift and lateral load paths is shown in Fig. 11.

Structural sheathing and structural sub-flooring plays an important role in resisting lateral wind forces through diaphragm action. The sheathing thickness, size and amount of fasteners must be designed so that the diaphragm can adequately resist the imposed loads. Openings in floor diaphrams need to be engineered so as not to interfere with the lateral resistance of these diaphragms.
The State of Louisiana will soon move to the 2006 versions of the International Building Code and International Residential Code. All new construction will be required to be designed to the high wind levels required in these codes which should help to mitigate some of the damage discussed in this paper. Although local permitting processes differ, most additions, repairs, and major remodelling will also be required to meet these new high wind requirements.

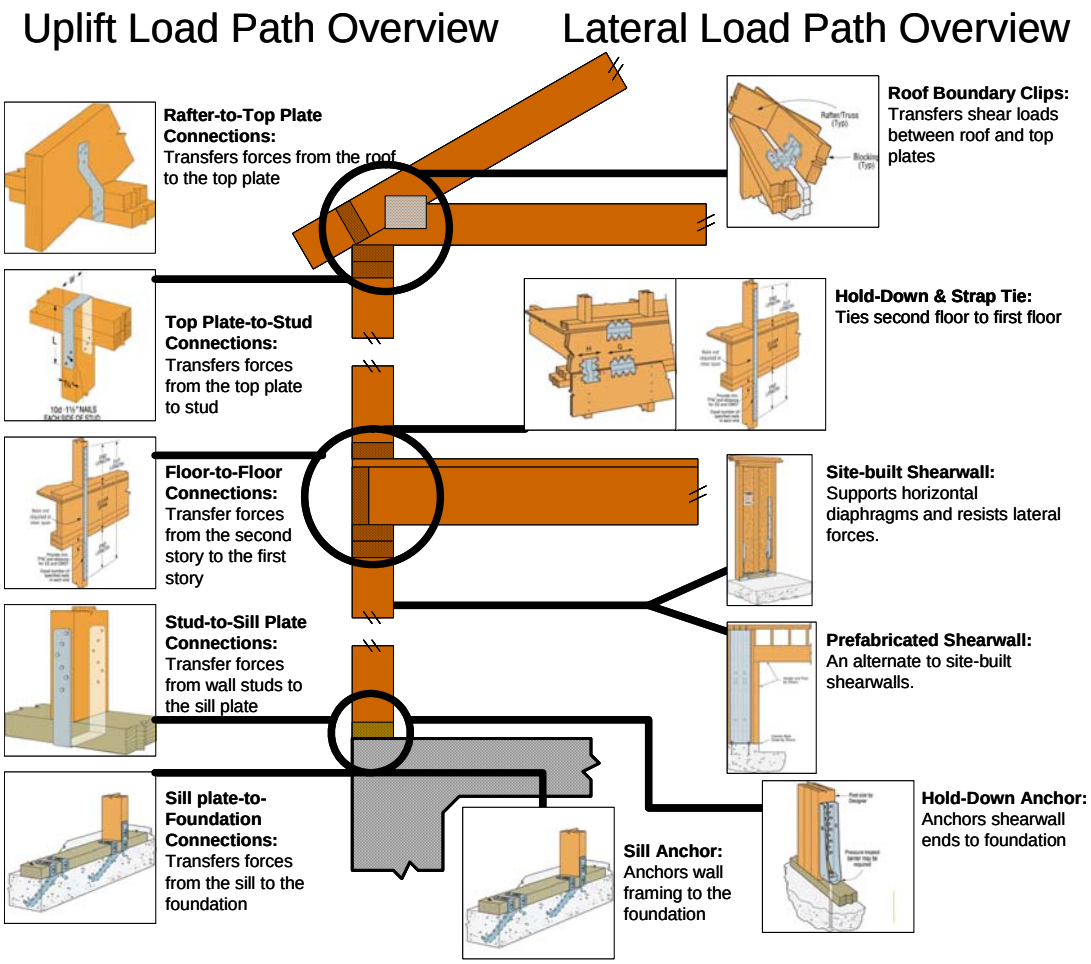

Figure 11. Overview of uplift and lateral load paths [Adapted from Simpson 2006].
With the recent passage of House Bill No. 558, owners in Louisiana can also expect to see discounts in their insurance premiums if they retrofit their buildings to resist high winds. While the details are

still being developed, there is a possibility of partial premium discounts for partial retrofit. This legislation is intended encourage owners to retrofit older buildings, which are typically exempt from the more current building codes which include design for high wind resistance. These measures should prove to be a significant incentive to improve existing structures as insurance premiums have more than tripled for some residents of New Orleans, while coverage has declined.

5 CONCLUSIONS

Large scale disasters like hurricane Katrina subject timber structures to a combination of destructive forces from both flood water and wind. Damage from these forces varies significantly and can be mitigated with different improvements to the structures, which can be addressed in local building codes. Building codes and construction requirements change over time. As we learn more about the forces imposed upon structures by natural and manmade disasters with magnitudes such as Hurricane Katrina, it is imperative to take these lessons and apply them to future designs and building practices. Accordingly, the State of Louisiana and its parishes have been adpoting and updating building codes and practices as a direct result of Hurricane Katrina, and have been taking steps to encourage owners to upgrade existing buildings which are exempt from the new codes.

Wood as a Structural Material

N.Papatya Seçkin [1]

T 12

ABSTRACT

Wood has high strength, is easily worked, is relatively abundant, and its grain structure is naturally attractive. By the way, wood is probably the single most widely used structural material, and some of the most beautiful structures have been constructed with wood.

There are as many different types of wood as there are species of trees. Each species has its own unique qualities. Some have very beautiful grain patterns. Some of extremely strong and stable, and others have natural resistance to rot and decay. Before selecting a species for a project application, designers must know the characteristics of the species of wood. They are contemplating using. Often the qualities of a particular species will vary from tree to tree and can even vary within an individual tree. How the wood is processed can complicate the selection of a type of wood even further. Damage incurred during felling, the saving method used to convert the timber into boards, the method used for seasoning, the introduction of preservatives, and laminating or gluing separate pieces together can all have a dramatic impact on the quality and characteristics of the final product.

In some societies, wood is revered and endowed by the people with mystical properties. Craftsmen in these societies consciously seek to express these qualities in the structures that they design and build.

The majority of structural wood used in the world comes from softwoods. Softwoods are typically preferred over hardwoods for structural purposes because they are generally lighter, more easily worked, less prone to structural defects, and available in greater quantity and in larger size ranges than hardwoods.

1 INTRODUCTION

Forests and the wood they produce, have played an important role in human activity since before recorded history. Indeed, one of the first major innovations of humankind was utilizing fire, fueled by wood, for cooking and heating. Since this ancient beginning, the uses of wood, and the value of the forest, have expanded dramatically, as the population of humans and their economies grew.

Wood has remained as an important substance throughtout history because of its recyclable, renewable and biodegradable unique and useful properties. Today, wood is used in tools, paper, buildings, bridges, guardrails, railroad ties, posts, poles, decks, fences, gazebos, play structures, mulches, furniture, packaging, and thousands of other products.

As known, wood as a structural material has high strength, is easily worked, is relatively abundant, and its grain structure is naturally attractive. It has probably been the single most widely used construction material in the world.

Architects and Landscape Architects often design projects that use wood as a structural material. The designer who wishes to utilize wood in a Project needs to understand its capabilities and limitations in order to maximize its potential.

Some of the most beautiful structures in the world have been constructed with wood and have been designed to last indefinitely. Conversely, some of the most homely and pitiful structures have also been constructed of wood.

The versatility of wood can be seen in the houses in Figs 1 and 2. The classic revival houses emphasizes the flexible nature of wood and the ease with which it can be worked into a multitude of shapes and forms. The modern house relies more on the inherent beauty of the grain and color of the wood and its utilitarian as a building material.

Figure 1. Classic revival home, Adalar-Istanbul.

Figure 2. Modern house, House Into –Finland [Seçkin, 2006].

2 UTILISATION OF WOOD

Wood is used in both solid wood (timber) and manufactured wood products (wood composites).Our subject in this paper is only to concentrate on the types of wood composites and applications. In following, first is described laminated timbers (such as glulam) and structural composite lumber. These materials are primarily used in load-bearing building applications in the form of beams; then wood composition boards such as plywood, flakeboard, particleboard and fiberboard. The wood composition boards can be classified according to density, raw material form and process type (Fig 3).

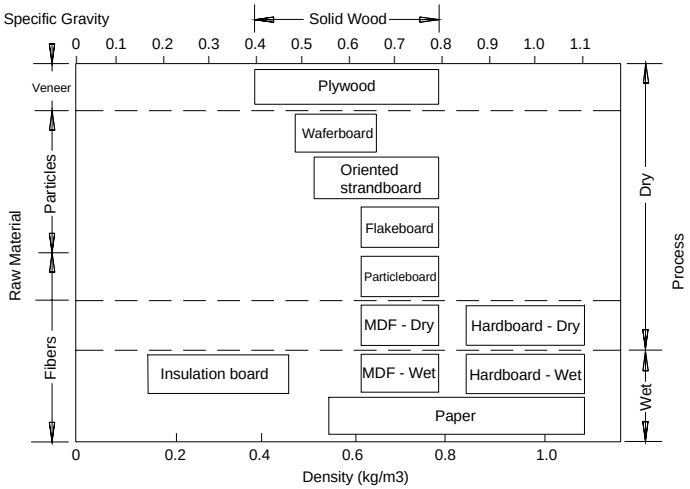

Figure 3. Classification of wood composite board materials by particle size, density and processing principle [Rowell, 2005].

2.1 Laminated Timbers

Structural glued laminated beams (Glulam) is a structural product that consists of two or more layers of lumber glued together with the grain all going parellel to the length. Typically the laminates are 25 to 50 mm in thickness.

The biggest advantage of using glulam is that large beams can be made using small trees. In addition, lower quality wood can be used, thinner lumber can be dried faster than large, thick beams, and a variety of curved shapes can be produced.

Common wood species used to make glulam are softwoods such as Douglas-fir, Southern pine, Hemlock-fir and spruce.

For example, The roof system of Disney ICE rink in Anaheim is a combination of southern yellow pine glulam girders and solid sawn Douglas-fir purlins spaced at 48" on center (Fig. 4). Curved supporting columns are steel encased in concrete. The arched glulam girders are 8-3/4" x 50-7/8" in section. The curved girders are spaced at 22 feet on center and span 116 feet.

Figure 4. Glulam and plywood roof system of Disney Ice, in California, create a modern sculptural quality and recall traditional [APA, 2002].

The roof sheathing is 1-1/8" tongue-and-groove AFA trademarked plywood. Bending the thick 1-1/8" plywood over the glulam beams by hand was very challenging because the arches were curved to a 75-foot radius and to span 48 inches between purlins (Fig. 5).

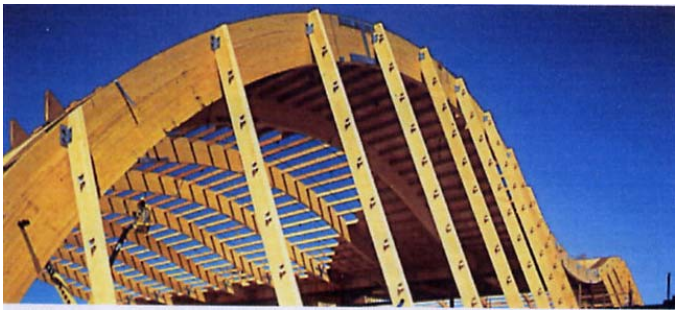

Figure 5. Glulam arches were curved to a 75-foot radius to form the ice center's roof system [APA, 2002].

Glulam can be used in almost any type of structure for architectural and structural purposes including domestic construction, recreational buildings, industrial structures requiring large column free spaces, and high quality architectural/structural uses in churches, shopping centres etc. Glulam is also used in joinery, benchtops, stairtreads, stringers, handrails, etc where both the structural properties and aesthetic appeal of the timber are required.

2.2 Plywood

Thin veneers can be glued together for plywood. Different thickness of plywood can be produced using multi-layers of veneers. The alternation of grain direction in adjacent plies provides plywood panels with dimensional stability across their width.

This material is used as a structural underlayment in floors and roofs and in furniture manufacturing. There are two basic types of plywood: construction and decorative. Construction-grade plywood has traditionally been produced using softwoods such as Douglas-fir, Southern pines, White fir, Larch and Western hemlock. Decorative plywood is usually produced using softwoods for the back and inner layers, with a hardwood layer on the outer surface.

The Sydney Opera House is an example for the use of plywood and laminated hardwood in a public building (Fig. 6).

Figure 6. The use of plywood and laminated hardwood at the Sydney Opera House [Toogood, 2006].

2.3 Structural Composite Lumber

Structural composite lumber (SCL) is manufactured by laminating strips of veneers or strands of wood glued parallel to the length. There are many types of SCL products: oriented strand lumber (OSL), parallel strand lumber (PSL) (Fig. 7), laminated veneer lumber (LVL) (Fig. 8), laminated strand lumber (LSL), and oriented strand board (OSB) (Fig. 9). Usually Douglas-fir, Southern pines, Western hemlock and Yellow-poplar are used, but other species are also used. The major adhesives used to produce SCL products are phenol-formaldehyde or isocyanates. All of these SCL products are used as replacements for solid wood.

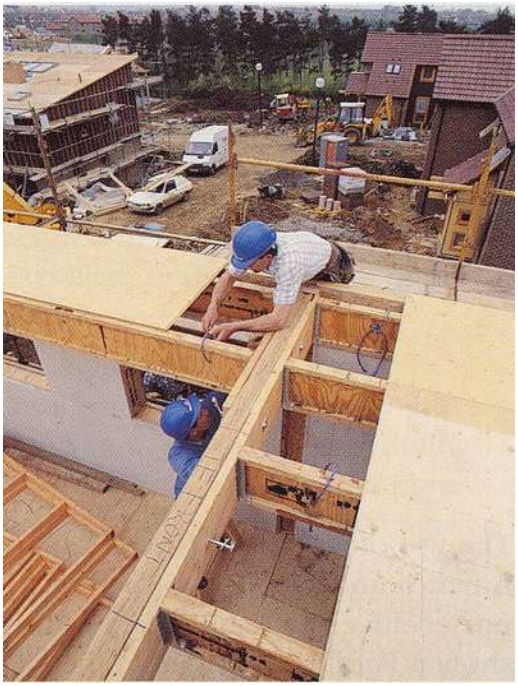

Figure 7. The use of PSL on wall, floor and roof panels of a building [Seçkin, 2006].

The store building in Australia is a 32m span fixed portal frame structure with 9 bays at 8.5m centres and one at 5m. The portal is 12m clear at the eaves and rises to 15m at the ridge (Fig. 8). Columns and rafters are fabricated from 63mm thick LVL forming a box section 900 x 426mm. The roof purlins and wall girts are 300 x 45mm LVL spaced at 1200 centres. The walls were trussed with 50 x 2mm steel straps and 90 x 45mm pine noggings.

Figure 8. The use of LVL at the store building in Australia [Ferguson, 2006].

Figure 9. Use of OSB in wall sheathing, roof sheathing, and floor sheathing [LP Building Products 2005].

2.4 Composite Beams

Composite structural beams can be produced by combining several elements such as sawn, or structural composite lumber flanges and plywood, hardboard, flakeboard and oriented strandboard, bonded together with exterior type adhesives. Especially, prefabricated I-beams are used by builders because they are lightweight, uniform, and easy to use (Fig. 10).

Figure 10. I-joist compatible glulam beams are supplied in depths of 9-1/2", 11-7/8", 14", and 16" [APA 2003].

2.5 Flakeboard

Large, thin wafers or smaller flakes can be produced by several methods and used to produce a composite board. Wafers are thicker than flakes. Wafers are almost as wide as they are long while flakes are much longer than they are wide. Wafer and flakeboard are made with a waterproof adhesive, such as phenol formaldehyde or an isocyanate.

2.6 Fiberboard

Fiberboards can be formed using a wet-forming or a dry-forming process. There are three types of fiberboard: low-density fiberboard (LDF), medium-density fiberboard (MDF) and high-density fiberboard (HDF, insulation board).

2.6.1 Low-Density Fiberboard (LDF)

Low-density fiberboards are usually produced by a dry process that uses a ground wood fiber. They are used for insulation and for light-weight cores for furniture.

2.6.2. Medium-Density Fiberboard (MDF)

Medium-density fiberboard is mainly used as a vore for furniture (Figure 11).

Figure 11. The use of MDF walls panels [Stahl and Benschneider 2007].

2.6.3. High-Density Fiberboard (HDF)

High-density fiberboard is produced both with and without wax and sizing agents. The wax is added to give the board water resistance. HDF is used as an overlay on workbenches and floors, and for siding. There are the different types of high-density fiberboards.

3 CONCLUSIONS

Wood is probably the most widely used structural material in the world. It is universally available, also a renewable resource. In addition, wood is easily worked and shaped with simple hand tools. A skilled carpenter can build marvelous structures with nothing more complicated than hammer, saw, square, and a few other common tools. Moreover, if properly protected from moisture and insects, wood can be considered a permanent material. There are numerous examples of structures around the world that are hundreds of years old and are still in perfect condition.

As mentioned before, there are two primary classifications of woods: Hardwoods and softwoods. Hardwoods are used most often for furniture, flooring, veneers, and other applications for which appearance of grain and durability are paramount. Softwoods are typically preferred over hardwoods for structural purposes because they are generally lighter, more easily worked, less prone to structural detects, and available in greater quantity and in larger size ranges than hardwoods.

Wood composites constitute a wide variety of materials, such as glulam and laminated veener timber used in beams, as well as board materials such as particleboard, fiberboard and oriented strand board. Waste-wood and smaller trees can be used in wood composites, strength is increased since defects are removed, and structural shape can be designed. The scale of the wood element, its orientation, and material density are important factors controlling performance.

Optimization of structural shape, in combination with variations in material and material compositions, has great potential for components in building systems. I-beams with different materials in the flange and in the web are simple examples already in existance, although the concept may be brought much further.

Preparation Method and Service Condition Effects on the Performance and Durability of Epoxy Adhesives Used in Structural Timber Repairs

João Custódio [1]
Helena Cruz [2]
James Broughton [3]

T 12

ABSTRACT

Rehabilitation/restoration systems involving structural adhesives represent an efficient method for the repair and/or reinforcement of both new and existing timber members. Epoxy adhesives have been used for many years in the repair and strengthening of timber structures, and are currently the most appropriate adhesive type for in-situ operations. Nevertheless, there is still a lack of knowledge about their durability and long-term performance derived from the absence of standards on this issue. This paper describes an experimental campaign developed to address these concerns, which included the development of a test procedure to assess long-term behaviour of bonded-in rod connections. The effect that the type of mixing, curing, and post-curing had on the epoxy adhesive's mechanical properties was also assessed.

From the results, it was seen that the mixing procedure influences the mechanical properties of the cured adhesive, and its effects varied with the different adhesives tested. Post-curing the adhesives was beneficial, but with different magnitudes for each adhesive. The data obtained using the new test procedure are, so far, encouraging, providing very different behaviours depending on the system employed.

1 INTRODUCTION

Adhesives have been used for many years in the aerospace and automotive industry. A great deal of research has been carried out on the behaviour of adhesively bonded joints of the types used by those industries. However, there is a lack of appropriate guidance for their use in the construction industry. As far as the various construction materials are concerned, the largest use of adhesives for structural applications is with timber, either in the form of pre-fabricated products, or for connections between members. Some applications for structural adhesives are well established (*e.g.* anchors and fixings, including dowels in concrete and timber; ground anchors; timber composites; timber-timber connections; steel plate bonding; pre-cast concrete segmental construction; fibre composites; etc), with the appropriate guidance readily available, while other applications are still being developed (*e.g.* like the repair and strengthening of timber structures).

Rehabilitation of buildings has an increasing economical and social importance in most countries, due to the historical value of the built heritage and to the need to maintain and improve the built environment of cities. Rehabilitation/restoration systems involving structural adhesives represent an efficient method for the repair and/or reinforcement of both new and existing timber members. Epoxy adhesives have been used for many years in the repair and strengthening of timber structures, and are currently the most appropriate adhesive type for in-situ operations. They can be used on their one or in conjunction with steel plates, rods or fibre reinforced polymer (FRP) composite materials for the consolidation or reinforcement of wood structures. Structural epoxy adhesives are generally used in service conditions equivalent to service classes 1 and 2 (EN 1995-1:2004). However, because they exhibit excellent initial joint strength when tested in standard climate conditions, there has not been a major concern about its service durability. The lack of knowledge about the way in which high service temperature affects their performance lead the authors to develop research studies to address those concerns. The results from those studies clearly showed that the performance of an adhesive is severely influenced by service temperature, and its immediate effects may be critical for structural safety [Cruz et al. 2005; Cruz & Custódio 2006; Custódio et al. 2007]. In addition, reliable and realistic accelerated ageing tests do not yet exist, and the application of the existing European or national test and performance standards to epoxy bonded products are much too penalising, since they merely impose severe conditions that are not verified in service because they were developed originally for other adhesives, namely for phenolic and aminoplastic adhesives. The lack of standards in this field impedes the objective evaluation of the reliability of a glued connection, causing engineers to avoid this type of solution and sometimes to commit errors with potential disastrous results [U. S. National Transportation Safety Board 2007; Hansson & Larsen 2005].

The European Committee for Standardization (CEN) has already identified the need for development of standards for the evaluation of bond durability and long-term performance of epoxy adhesives, but so far, no standards have been produced. To address these concerns a test programme was developed to assess the effect that the preparation method, application environment and service conditions, have on the performance and durability of epoxy adhesives. In addition, using the findings from the above, a test procedure to assess and to predict the long-term behaviour of bonded-in rod connections was developed.

2 EXPERIMENTAL PROGRAM

The study undertaken at LNEC and JTRC is divided in two main experimental campaigns. The first deals with the influence of the preparation method on the short-term properties of the epoxy adhesives. The second part focus on the long-term effects of service environment on the timber bonded joints durability. Since this study involves long-term tests, the experimental campaign is still ongoing so that this paper presents the results obtained until this moment, more results will be available at the time of the conference presentation.

2.1 Preparation Method Effect on the Performance of Epoxy Adhesives

The viscoelastic properties of the adhesives were determined through dynamic mechanical analysis (DMA) in the 3 point bending deformation mode. The DMA multi-frequency stress/strain mode was used, because it allows the assessment of the temperature dependence of the stiffness, loss modulus, and tan δ, while the oscillation amplitude (15 μm) is held constant, using a frequency of 1 Hz, a temperature ramp rate of 2°C/min, and a temperature range of 10-140ºC. Three replicates were used for each test. The test specimens had a rectangular prism shape measuring 60 mm in length, 10 mm in width and 4 mm in thickness. The width and thickness varied along the specimen length by less than 2 % of the mean value. The tests involve 4 different two-component structural epoxy adhesives, 2 mixing procedures, and several different conditioning and ageing (artificial accelerated weathering, AAW, and natural weathering, NW) processes. Figure 1 summarizes the test campaign.

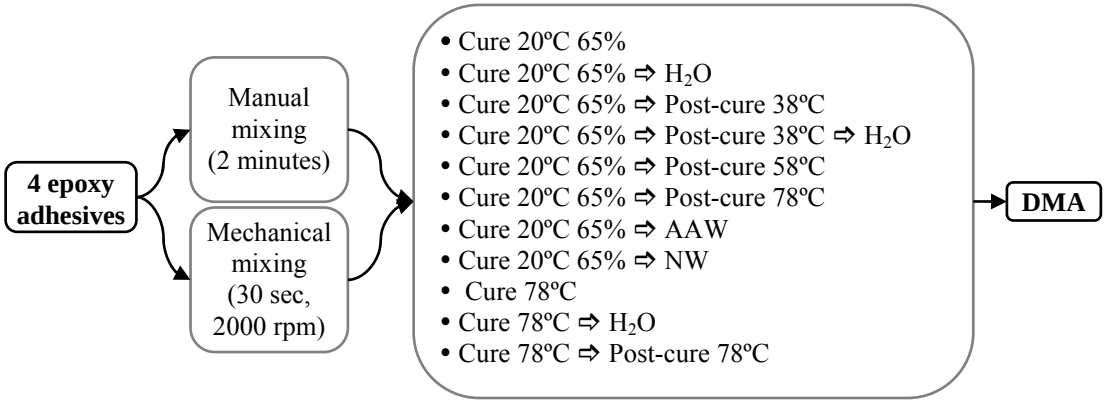

Figure 1. Description of the DMA test campaign.

2.2 Service Conditions Effect on the Durability of Epoxy Adhesives

The method developed to assess and predict the long-term durability of a bonded timber joint, consists of submitting test specimens to natural and artificial accelerated weathering, and to evaluate periodically any creep deformation and residual bond strength. These tests were performed in loading rigs specifically developed and designed for this purpose (Figure 2). The loading rigs were created with the objective of testing several replicates at the same time, with the minimum possible amount of materials (adherents and adhesives), the space occupied by the set up was to be as small as possible, and it was necessary to be able to take measurements during the ageing of the specimens with minimum disruption. The bonded joints are being aged in laboratory-controlled environments and out-door conditions (both in the United Kingdom and Portugal). The latter will simulate the real conditions that this type or repair system is exposed to in service, and will allow the comparison of the results obtained in this way to the ones obtained from laboratory test procedures. The load applied to the specimens is equivalent to approximately three times what they experience in service, which corresponds to about 20% of its ultimate failure load.

Daily weather information (temperature and relative humidity) registered in Lisbon and London in the last seven years, and the weather data registered in two roof covers (one in Lisbon and one in Oxford) since October 2005 was collected, compiled and analyzed. This allowed the determination of the expected service conditions to which a joint in this type of repair technique is likely to be exposed in both countries, as well as to the definition of the artificial weathering conditions to which joints will be exposed (Table 1).

Table 2 illustrates briefly the planning of the on-going long-term durability tests in both countries. Several different combinations of adherend/adhesive/weathering/load/rods were tested in order to verify their influence on the durability of the bonded joints.

3 RESULTS AND DISCUSSION

3.1 Preparation Method Effect on the Performance of Epoxy Adhesives

Considering the effect of type of mixing in the glass transition temperature, Tg, of the adhesives (Table 3), we observe that for two of the adhesives (A, C) there is not a substantial difference between the Tg of the hand- and machine-mixed specimens (average Tg increase of 0.3ºC for A and 0.1ºC for C). Nevertheless, for adhesive B it seems that the machine mixed specimens had a slightly lower Tg (average Tg decrease of 2.3ºC).

Regarding the post-curing effects on the Tg, it can be concluded that there is always an increase in its value, and that the magnitude of the Tg increment is different for each adhesive. The post-curing was more effective for adhesive C (average increase of 7, 21, and 29ºC) and A (average increase of 5, 11, and 8ºC), and the least influenced was adhesive B (average increase of 2, 1, and 3ºC).

Table 3. Glass transition temperatures obtained for hand- (HM) and machine-mixed (MM) specimens.

Glass transition temperature (ºC)		*No post-cure*		*Post-cure 38ºC*		*Post-cure 58ºC*		*Post-cure 78ºC*	
		Avg.	*S. D.*	*Avg.*	*S. D.*	*Avg.*	*S. D.*	*Avg.*	*S. D.*
Adhesive A	HM	56.7	0.27	61.6	0.04	67.5	0.46	64.6	0.30
	MM	57.2	0.40	61.8	0.34	67.5	0.60	65.3	0.41
Adhesive B	HM	46.6	0.72	47.9	0.29	48.8	0.54	49.7	0.38
	MM	44.7	0.13	46.7	0.87	45.2	1.69	47.0	0.44
Adhesive C	HM	58.9	0.25	66.0	0.20	79.6	0.41	87.2	0.37
	MM	58.2	0.23	65.4	0.41	80.2	0.05	88.3	0.23

NOTES: Avg. = average of three replicates; S. D. = standard deviation associated.

Due to the large amount of experimental data concerning the DMA tests, the authors opted by not presenting the actual stiffness values obtained, but instead showing the variations obtained in the stiffness for each adhesive. Thus, Table 4 presents the stiffness variation with temperature obtained with the different curing conditions. The 100% value corresponds always to the stiffness of the hand-mixed adhesive at 20ºC. All the other percentages were calculated in respect to that stiffness value.

Table 4. Stiffness variation obtained for hand- (HM) and machine-mixed (MM) specimens.

Stiffness variation (%)		*No post-cure*		*Post-cure 38ºC*		*Post-cure 58ºC*		*Post-cure 78ºC*	
		HM	*MM*	*HM*	*MM*	*HM*	*MM*	*HM*	*MM*
Adhesive A	20ºC	**100**	99	94	99	89	97	92	105
	30ºC	93	94	88	92	83	90	85	98
	40ºC	81	83	77	82	73	78	69	83
	50ºC	25	29	44	49	46	49	36	44
	60ºC	3	3	7	8	20	21	13	16
Adhesive B	20ºC	**100**	107	107	96	109	106	107	110
	30ºC	85	82	91	63	95	87	94	92
	40ºC	28	16	36	17	44	22	48	27
	50ºC	2	1	2	2	3	2	4	2
	60ºC	1	1	1	1	1	1	1	1
Adhesive C	20ºC	**100**	88	99	87	100	90	103	77
	30ºC	95	84	95	84	97	87	100	75
	40ºC	88	79	90	79	92	82	96	72
	50ºC	61	49	82	71	83	75	88	67
	60ºC	6	4	34	27	74	67	77	60

The effect of type of mixing is quite different for each adhesive. Only adhesive A seems to benefit with the machine mixing procedure, but this does not mean that the other adhesives could not also benefit from it, this only means that the mixing conditions used (30 seconds at 2000 r. p. m.) are more favourable for adhesive A. For adhesives A and C the stiffness difference magnitude for the two mixing processes seems to stay constant up to a temperature of 40ºC and then decreases gradually until 60ºC. Adhesive B, which has the lowest Tg, showed the opposite behaviour.

Post-curing had also resulted in very different influence in the mechanical properties of each adhesive, as was the case for the glass transition temperature. For adhesive A the post-curing resulted in a stiffness increase only above 40ºC, the best result was obtained with a post-curing temperature of 58ºC. Adhesives B and C benefit from it, from ambient temperature, the best result was obtained with a post-curing temperature of 78ºC (except for MM adhesive C that was 58ºC). It can be concluded that post-curing is beneficial and, for some adhesives, even advisable.

3.2 Service Conditions Effect on the Durability of Epoxy Adhesives

The results presented here refer to the bonded timber specimens subjected to natural and artificial accelerated weathering having 6 and 3 months of ageing, respectively. Table 5 exhibits the temperature and relative humidity to which the test specimens were subjected to during the weathering. It can be seen that the conditions experienced in Portugal were, as expected, far more severe than the ones registered in the UK. Also, the artificial accelerated cycle had temperatures closer to those of Portugal and the relative humidity somewhere in between, at least for this period. Table 6 presents the results obtained for the durability tests undertaken in Portugal (PT) and in the United Kingdom (UK).

Table 5. Temperature and Relative Humidity registered during the weathering.

	Temperature (ºC)			*Relative Humidity (%)*		
	Maximum	*Minimum*	*Average*	*Maximum*	*Minimum*	*Average*
PT Shed	46	8	**22**	87	15	**58**
UK Shed	31	5	**16**	89	26	**70**
A.A.W	50	9	**22**	94	11	**64**

Table 6. Creep results for the specimens using zinc plated threaded steel rod and loaded.

Weathering	*Adhesive*	*Country*	*Timber*	*Creep (mm)*			
				No load	*0 months*	*3 months*	*6 months*
None	A	UK	Pine	0.00	0.02	0.00	0.03
			Oak	0.00	0.03	0.04	0.04
	B	UK	Pine	0.00	0.07	0.16	0.19
			Oak	0.00	0.09	0.30	0.33
Natural	A	UK	Pine	0.00	0.03	0.20	0.05
			Oak	0.00	0.04	0.16	0.06
		PT	Pine	0.00	0.16	0.44	0.44
			Oak	0.00	0.19	0.44	0.45
	B	UK	Pine	0.00	0.06	0.39	0.46
			Oak	0.00	0.10	0.42	0.57
		PT	Pine	0.00	0.22	1.81	2.34
			Oak	0.00	0.33	1.56	2.02
Artificial Accelerated	A	UK	Pine	0.00	0.02	0.45	–
	B	UK	Pine	0.00	0.04	Failed*	–

NOTES: Creep 3 months * = specimens failed after 1 week of AAW.

Comparing the creep behaviour of specimens kept in a controlled environment with that of the naturally and artificially aged specimens, we observe that the former was always lower. As expected adhesive B always showed more creep than adhesive A. Globally, the specimens aged in PT had a more pronounced increase in the creep value, which is consistent with the more severe weathering conditions in Lisbon. In addition, for adhesive A the creep seems to be slowing down, while for adhesive B it continues to rise. Considering the creep values for adhesive A specimens aged in PT and the ones from the specimens aged artificially, we observe that 3 months in AAW correspond to 6 months of NW. However, the creep values in the UK after 6 months are still below the ones verified in AAW. Adhesive B specimens subjected to AAW failed immediately after the first half of the weathering cycle, and several NW specimens failed during the first 3 months in PT. Considering the pronounced creep of the adhesive B specimens aged in PT, it seems likely that all of them will fail before or during the next summer. In the UK, no adhesive B specimens have failed so far.

On Table 7 we can observe the pull-off strengths obtained and the number of specimens that failed during ageing. Comparing the pull-off strengths of the specimens aged naturally with those of the artificially aged specimens, we observe that with adhesive A the loss of strength was of 9% for pine and 11% for oak aged naturally in the UK during 6 months, and 11% for pine aged artificially during 3 months. Interestingly, for adhesive A aged naturally in Portugal during 6 months, the pull-off strength actually increased, possibly as result of an additional post-curing of the adhesive. Regarding the failure type, there seems to be a decrease in cohesive wood failure and an increase in cohesive adhesive failure with the weathering.

The results for adhesive B are quite different. The loss of strength was of 24% for pine and 10% for oak aged naturally in the UK during 6 months. For the specimens that did not suffer premature failure in PT, the pull-off strength was maintained for oak and seemed to increase for pine, but these may be influenced by the fact that only the strongest specimens in the group survived long enough to be tested. Regarding the failure type, there seems to be a decrease in cohesive woof failure and an increase in cohesive adhesive failure with the weathering.

Table 7. Pull-off tests results.

Weathering	*Adhesive*	*Country*	*Timber*	*Pull-off strength (MPa)*		
				0 months	*3 months*	*6 months*
Natural Weathering	A	UK	Pine	19.2 (4.0)	None failed	17.5 (2.9)
			Oak	18.7 (2.3)	None failed	16.7 (1.5)
		PT	Pine	16.9 (3.4)	None failed	18.2 (3.2)
			Oak	17.1 (1.3)	None failed	17.4 (1.4)
	B	UK	Pine	22.8 (3.8)	None failed	17.4 (2.6)
			Oak	21.1 (2.6)	None failed	18.9 (1.5)
		PT	Pine	17.6 (3.5)	Failed 32/50	19.6 (3.0)
			Oak	18.3 (0.9)	Failed 8/50	18.4 (2.7)
Artificial Accelerated	A	UK	Pine	19.2 (4.0)	17.1 (2.6)	–
	B	UK	Pine	22.8 (3.8)	Failed 40/40*	–

NOTES: Pull-off strength with standard deviation in parentheses; *specimens failed after 1 week of AAW.

4 CONCLUSIONS

One behaviour common to all three adhesives tested was the pronounced decrease in their strength with the increase in temperature. If one considers the service temperatures that this adhesives will have to withstand in service (usually up to 50ºC), the results indicate that a very careful selection of the adhesive is necessary. A great number of commercial product data sheets do not give this kind of detailed information about their mechanical properties changes with temperature. If this is the case then it is necessary to obtain that information from the manufacturer or to determine them experimentally. With the data obtained so far, it seems that the main factor influencing the durability

of an epoxy-bonded repair was the temperature induced creep behaviour. With that said, it could be tempting to state that the DMA technique could be used alone to predict the durability of these repair systems. However, the data analysed so far refers only to 3 months of artificial accelerated and 6 months of natural weathering. Furthermore, we must always consider the bonded system as a whole, and the intherphase between the adherend and adhesive plays also an important role in the system durability. We saw that the failure behaviour at the wood-adhesive interphase was different for each adhesive and timber tested, which means that when considering different combinations of adhesives and timbers the results could also be different.

The type of mixing, curing, and post-curing affected the mechanical properties of all the epoxy adhesives investigated, and consequently their durability. The mixing procedure influences the mechanical properties of the cured adhesive, and its effects varied with the different adhesives tested. Since they can be either beneficial or detrimental, the optimum mixing procedure needs to be determined for each adhesive. Post-curing the adhesives was always beneficial, but to different extents for each adhesive, again an optimum post-curing regime should be determined separately. The data obtained using the new test procedure is, so far, encouraging, providing very different results depending on the system employed.

Reduction of Water Absorption and Swelling of Fiberboard

Javad Torkaman [1]

T 12

ABSTRACT

In order to reduce water absorption and swelling of fiberboard, waterproof paraffin and beet molasses with ratio 5,10,15,20 and 25 percentage of solution as sizing agent were used. The fiberboards were made with both materials and were compared with control boards. The results showed 42 and 49 % reduction in water absorption and swelling by using15% waterproof paraffin respectively. The values that obtained for 20 % beet molasses were 3 and 15.5% reduction in water absorption and swelling respectively. At 15 % waterproof paraffin and 20% beet molasses thickness swelling were reduced 49.78 and 15.53% respectively. Also the fiberboards were tested at 30 ,66 ,80, 98% RH and 100%(liquid water) after 30 days. In all relative humidities tests, except 100% the maximum water absorption was 2.4 % without increase in swelling.

1 INTRODUCTION

Sizing is a processing which by adding Suitable chemical materials to pulp can control water absoption and swelling thickness in fiberboard or paper. The aim of sizing is cover the fiber surface by materials which reduction surface energy of fiber caused them hydrophobic [Suchsland 1986].

The hydrophilic characteristic of fiber can be explained by sorption behavior of the chemical wood components such as cellulose ,lignin and their proportions in the chemical composition of the wood as well as their different thermal constancy[Kollman and Schnider 1963].

The usual size in fiberboard is paraffin size which is solid and doesn't solve in water and chemically is neutral. Therefore must be emulsion and we need to use positive alum[$AL_2(SO_4)_3$] to settle over the negetive fibers.Whereas our waterproof paraffin is Ionic compounds and dosenot need alum.The cost of Ionic paraffin is a little more than solid paraffin but the beet molasses is low-priced and available.The other materials which were tested for dimentional stability of fiberboards except paraffin are polyethylene glycol, formaldehyde, acetic anhydride.The treatment of fiberboard with formaldehyde at low temperature was increased dimentional stability of cell walls[Minato 1995].

Aspen fiber was reacted with either ketene gas or liquid acetic anhydride to product acetylated fiber. Board made from ketene-reacted fiber were not as dimentionally stable as boards made from acetic-anhydride-reacted fiber[Rowell 1989,1991].

The possibilities of intraction between wood *pinus sylvestris* (60%RH) and Polyethylene glycol (PEG 1500) have been investigated.The Dynamical Mechanical Techniques (DMTA) measurements shows interaction on the molecular level between wood and PEG 1500 [Wallstrom 1995].

The purpose of this research are dimensional stability and thickness swelling decrease of fiberboard according to cost and capable to use in industry scale.

2 EXPERIMENTAL

Sampling was done before add any additives to fibers.The fibers were spryed only with five levels of solution of waterproof paraffin and beet molasses 5,10,15,20 and 25 percentage. The fibers which were used for control boards didn't used this additives.The fiber was hand-formed into 100by 22 mm randomly oriented mats.then they were pressed to a maximum thickness of 3 mm at time and temperature press of factory condition.The swelling percentage and reduction of water absorption were calculated according to primary and seccondry weight and thickness of samples after 24 hours immersion at 20 ºC.The Anti-Swelling Efficiency and Water Repellency Efectiveness values of the treatment and control samples are determind on basis of oven dried measurement. Anti-Swelling Efficiency (ASE) and Water absorption (WRE) were calculated as:

$$S(\%)=\left(\frac{V_2}{V_1}-1\right)\times 100$$

S=Volumetric Swelling

V_2= the volume of the swollen samples

V_1= the volume of the oven dried samples

$$ASE(\%)=\left(1-\frac{S_2}{S_1}\right)\times 100$$

S_1=Average Swelling of untreated samples(control)

S_2=Average Swelling of treated samples

$T(\%)=({}^{Ww}/_{Wo} -1) \times 100$

T= Rate of the water absorption Specimen
W_W = Weight of wet samples
W_O=Weight of oven drying samples

$WRE\ (\%)=(1-{}^{T2}/_{T1})\times 100$

T_1= Rate of the water absorption of control specimen
T_2=Rate of the water absorption of test specimen

Same of other wood products fiberboard is absorbent and repellent air humidity.Therefore fiberboard specimens(50by50 mm) were placed in a humidity dessicator at 30,66,80, 98% RH and 100% (liquid water) and 20 ºC separately water absorption and thickness swelling were determined after 30 days.

3 RESULTS AND DISCUSSION

The water absorption and thickness swelling of treatment boards were campared with control boards obtained 77.2 and 46.5 % respectively. The results of treatment specimens were showed in Table1 and 2.

Table 1. Results of measuring of water absorption and swelling percentage of fiberboards which were treated with water proof paraffin.

Measurement factor	*Water proof paraffin* [%]				
	5	10	15	20	25
Water absorption [%]	71.6	54	44.6	70.6	79.4
Swelling percentage [%]	26.3	25.5	23.4	36.2	41

As can be seen from table1.Decrease and increase in waterproof paraffin from point of 15% increasing water absorption and swelling percentage of fiberboards while in comparison with control boards. Water absorption and swelling percentage were showed 42 and 49 % decrease respectively.

Table 2. Water absorption and Swelling percentage of fiberboards made at various amounts of beet molasses.

Measurement factor	*Beet molasses* [%]				
	5	10	15	20	25
Water absorption [%]	91.4	82.4	84.7	76.94	79.5
Swelling percentage [%]	41.02	40.12	43.12	39.28	41.97

According to table 2.The use of 20 % beet molasses decreased maximum 3 and 15.5% in water absorption and swelling percentage respectively. These are lower than values were obtained in use of 15% water proof paraffin. Both materials improve water absorption and swelling in low values but these materials can also play a major role in adhesion and in high values damage fiber bonds. Consequent the water absorption and swelling increase in fiberboard.

Table 3. The Anti-swelling and Anti-water absorption efficiency of fiberboards were treated with paraffin and beet molasses.

Size type	*Amount* [%]	*Anti-swelling efficency (ASE)* [%]	*Anti-water absorption(WSE)* [%]
Paraffin (Water proof)	5	43.44	7.25
	10	45.16	30
	15	49.78	42.2
	20	22.15	8.55
	25	11.83	-2.85
Beet molasses	5	11.78	-18.39
	10	13.72	-6.73
	15	7.26	-9.71
	20	15.53	0.34
	25	9.74	-2.98

Attention to Table3. Maximum Anti-Swelling and Anti-Water absorption efficiency were obtained at 15 percentage of waterproof paraffin and 20 percentage of beet molasses.The data show that the effect of waterproof paraffin in Anti-Swelling and Anti-Water absorption is more than beet molasses.By using 15% waterproof paraffin the amount of decrease in thickness swelling and water absorption of fiberboards are 49.75 and 42.2 percentage respectively.

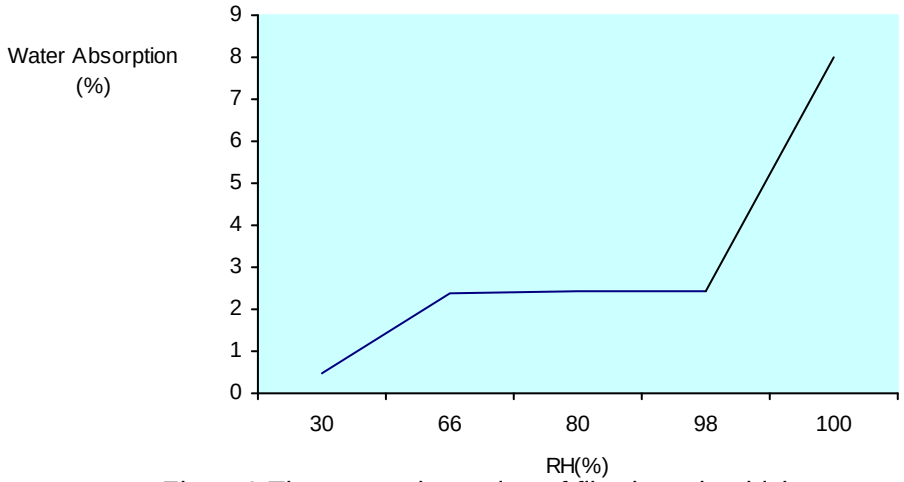

Figure1.The water absorption of fiberboards which were treated with paraffin in various relative humidity(RH)

In range of 30-100% relative humidity(RH) water absorption of fiberboards have been showed in figure1.The fiberboards which were treated with waterproof paraffin have lowest absorption (2%) in expose to below 100% relative humidity that doesn't show sensible swelling in this amount. Anti-swelling efficiency and Anti-water absorption were obtained 49.78% and 42.2% respectively.This material was tested in Iranian fiberboard factory processing and suitable results were obtained.

Generally the research showed that between two materials waterproof paraffin and beet molasses as size for decreasing of water absorption and swelling we can repleace 15 % waterproof paraffin solution instead of total additives materials in manufacturing fiberboards was given the better results. And also this material is economical and available.

ACKNOWLEDGMENTS

The author wish to thank to Prof, Dr.GH, Ebrahimi (University of Tehran; Iran)for his collaboration and assistance to this work and Mr.Bahremand and Mrs Naseri staff of Iranian fiberboard company for their invaluable advice and their supplying of materials.

ABSTRACT

The attenuated total reflectance (ATR) fourier transform infrared (FTIR) radiation experimental technique represents a powerful measurement tool on various materials. The ATR technique may be applied on both solid state materials, liquids and gases with none or only minor sample preparations, also including materials which are non-transparent to IR radiation. This facilitation is made possible by pressing the sample directly onto various crystals, e.g. diamond, with high refractive indices, in a special reflectance setup. Thus ATR saves time and enables the study of materials in a pristine condition, i.e. the comprehensive sample preparation by pressing thin KBr pellets in traditional FTIR transmittance spectroscopy is avoided.

Ageing processes in building materials, both ageing by natural and accelerated climate exposure, decomposition and formation of chemical bonds and products, may be studied in an ATR-FTIR analysis. In this work the ATR-FTIR technique is attempted utilized to detect wood rot decay and mould fungi growth on building material substrates. An experimental challenge and aim is to be able to detect the wood rot decay and mould fungi growth at early stages when it is barely visible to the naked eye. Another goal is to be able to distinguish between various species of fungi and wood rot.

1 INTRODUCTION

Wood rot decay and mould fungi growth on materials represent a problem. In addition to the building damages, e.g. wood rot decay, often due to unwanted water ingress, one of the large risks is related to mould fungi growth.

Trapped water or moisture, e.g. between water tight barriers, which has no possible way to dry or drain out, may lead to mould fungi growth under certain conditions. Unfortunately, these conditions are often fulfilled. The mould fungi initiation and growth are dependent upon the following factors:

- Availability of fungal spores, which are almost always present, except under sterile conditions.
- Nourishment, e.g. wood.
- Moisture.
- Temperature.
- Oxygen.
- Time.

There exists many different species of mould fungi, each of them with various requirements to the above initiation and growth factors. For example, a specific fungi specie may be latent with no growth below a certain temperature and might be exterminated above a certain temperature, where the temperature range will vary for each specie.

The exact relationship between mould fungi growth, with release of airborne fungi, and health problems is not yet fully understood. Nevertheless, that there is a health risk is not questioned, and many people have got ill due to moisture entrapment and the subsequent fungi growth. Occasionally, it has been necessary to evacuate buildings infected with mould fungi.

In this work we are trying to utilize the attenuated total reflectance (ATR) fourier transform infrared (FTIR) radiation experimental technique in order to detect wood rot decay and mould fungi growth on building material substrates. The ATR-FTIR technique makes it possible to study materials which are non-transparent to IR radiation in a pristine condition. That is, the extensive, time-consuming and often cumbersome sample preparation by pressing thin KBr pellets as in traditional FTIR transmittance spectroscopy, which might even change the sample material in question, is avoided. The ATR technique is based on a special reflectance setup where the sample is pressed directly onto various crystals with high refractive indices, e.g. diamond.

Of special interest, and an experimental challenge, is to be able to detect the wood rot decay and fungi growth at early stages when it is barely visible to the naked eye. Ultimately, one might think of future hand-held instruments scanning over a larger area and being able to detect wood rot decay or mould fungi growth before it is visible. Experimentally, the task is challenging, both to differentiate the biological growth and decay impact on the attacked material from the substrate material itself, as well as to being able to distinguish between various species of fungi and wood rot. Populistic, one may say that you are becoming what you are eating, i.e. with respect to FTIR spectra differentiation between the wood rot and mould fungi products versus the substrate material.

Several works are carried out applying infrared spectroscopy in various studies of microorganisms, e.g. by Fischer et al. [2006], Irudayaraj et al. [2002], Kos et al. [2002], Mohebby [2005], Naumann et al. [2005], Ngo-Thi et al. [2003], Orsini et al. [2000], Pandey and Pitman [2003, 2004] and Wenning et al. [2002]. Kos et al. [2002], Mohebby [2005] and Orsini et al. [2000] performed their works by employing the ATR-FTIR spectroscopical technique, which they describe as promising and with many advantages in these types of investigations.

2 EXPERIMENTAL

2.1 Sample Materials

The small sample materials for the FTIR measurements have been collected from the larger field samples depicted in Figure 1, with the following sample categories (no further details are given here):

- **Mould fungi on GU plaster board (GU = exterior grade gypsum board)**
  - Unexposed GU plaster board
  - Exposed GU plaster board with mould fungi scraped off, i.e. measured on plaster board
  - Mould fungi on GU plaster board
  - Mould fungi scraped off from GU plaster board, i.e. measured on a small mould fungi powder pellet
- **Mould fungi on wood**
  - Unexposed wood (30 mm below surface), the wood piece is in reality an exposed sample, but the measured sample is taken 30 mm below the outer surface of the wood piece, where there are no signs of mould fungi
  - Exposed wood (2 mm below surface), some mould fungi may be present 2 mm below the outer surface
  - Mould fungi on wood
  - Mould fungi scraped off from wood, i.e. measured on a small mould fungi powder pellet
- **Wood with wood rot decay**
  - Unexposed wood (30 mm below surface), the wood piece is in reality an exposed sample, but the measured sample is taken 30 mm below the outer surface of the wood piece, where there are no signs of wood rot decay
  - Exposed wood (2 mm below surface), some wood rot decay may be present 2 mm below the outer surface
  - Wood surface damaged by wood rot, measured sample close to wood rot on wood, i.e. adjacent to (but not onto) wood surface heavily infected with wood rot
  - Wood rot on wood, area on wood piece heavily infected with wood rot
  - Wood rot scraped off from wood, i.e. measured on a small wood rot powder pellet
- **Reference materials (for check/comparison of FTIR absorbance peaks)**
  - Water, distilled
  - Gypsum, non-dried
  - Gypsum, dried

Figure 1. Photos of the large field samples from where smaller samples have been collected for the FTIR measurements. Mould fungi on GU plaster board (left photo) and mould fungi on wood and wood rot (right photo). GU = exterior grade gypsum board (”outdoor use”).

2.2 FTIR Measurements

The FTIR material characterization was carried out with a Thermo Nicolet 8700 FTIR spectrometer with a Smart Orbit accessory, i.e. a horizontal attenuated total reflectance (HATR) accessory (single reflection) with a diamond crystal, in the wavelength range 4000 cm^{-1} (2.5 μm) to 400 cm^{-1} (25 μm) in an atmosphere with minimalized CO_2 and H_2O content through purging by a Parker Balston 74-5041 FTIR Purge Gas Generator. Each FTIR spectrum presented is based on a recording of 32 scans at a resolution of 4 cm^{-1}. In order to ensure satisfactory contact between the HATR diamond crystal and the sample, a minimum of three or more FTIR spectra were recorded at various locations on the sample.

The FTIR spectra given in this work have not been ATR corrected, neither with respect to penetration depths nor absorbance band shifts, which both are dependent on the refractive indices of the sample and the ATR crystal (diamond in this case) and the angle of incident radiation. The penetration depth is in addition also dependent on the radiation wavelength.

The FTIR measurements were performed on several samples within each sample category as described above (ch.2.1), of which only one single representative spectrum for each sample category is shown in the following (ch.3).

3 RESULTS AND DISCUSSION

FTIR absorbance spectra versus wave number for the various mould fungi and wood rot samples are presented in Figs.2-6. Mould fungi samples at various exposure degrees on GU plaster board are shown in Figure 2. Mould fungi samples at different exposure levels on wood are given in Figure 3. Wood rot samples at various decay levels are shown in Figure 4.

As the absorption of electromagnetic radiation, e.g. IR radiation, follows the Beer-Lambert law, i.e. the radiation is decreasing exponentially with the penetration depth in the actual material, it is often helpful to plot the spectra on a logarithmic absorbance scale vs. wavelength. Hence, a representative spectrum is chosen from each of the samples and plotted on a logarithmic absorbance scale for quantitative studies. Mathematically and physically it follows that a doubling of the logarithmic absorbance, also called optical density, is interpreted as a doubling of material thickness or a doubling of concentration of absorption active agents.

The mould fungi growth and wood rot decay makes the sample material undergo chemical changes and may then as a result of the chemical reactions change the actual thickness of the sample. In this work the experiments are conducted by applying the ATR equipment with the FTIR spectrometer. Hence, the IR radiation is only penetrating into a thin surface layer of the actual sample. With respect to the experiments carried out in this work, the material thickness will then be regarded as approximately constant, i.e. the change in the IR absorbance is explained by an increase or decrease of absorption active species within the sample material undergoing the chemical transformation.

Figure 5 gives the FTIR absorbance versus wave number between 4000-400 cm^{-1} for mould fungi on GU plaster board, mould fungi on a wood sample and wood rot at selected exposure levels (from Figs.2-4). In addition, the water spectrum is also plotted as a comparison.

Figure 6 shows the FTIR absorbance versus wave number between 1800-1400 cm^{-1} for mould fungi on GU plaster board, mould fungi on a wood sample and wood rot at selected exposure levels (from Figs.2-5). In addition, the water, non-dried gypsum and dried gypsum spectra are also plotted as a comparison.

In Figure 6 the narrow, large ellipse encircles FTIR absorbance peaks which may be related to mould fungi and/or wood rot, but this is more uncertain due to the water peak at this location. Note that any microbiological growth may increase the water content. Furthermore, in order to quantify any potential pollution (error) from any astray gypsum powder, the gypsum peaks are also depicted, as these falls in the same wave number range.

Also note that different adjacent neighbour atoms in a compound, e.g. in a polymer chain, will shift the wave number somewhat for the absorbance peak corresponding to the chemical bond in question.

The thick, small ellipse in Figure 6 encircles FTIR absorbance peaks which are found to be characteristic for the mould fungi and wood rot. These peaks, also including the other samples depicted in Figs.2 - 4, lies between 1558 cm^{-1} and 1535 cm^{-1}.

That is, the chemical bonds which is the source for the absorbance peaks at these wave numbers, are found to be present and characteristic for the various mould fungi and wood rot products studied in this work.

Hence, in this preliminary study it has been demonstrated that the ATR-FTIR spectroscopical technique may be applied in order to detect wood rot decay and mould fungi growth on building materials. Further studies and experimental investigations are needed in order to elaborate the suitability, the reliability, the limitations and the future potential possibilities of this method.

In future applications of this experimental method as a detection tool capable of differentiating between various wood rot and mould fungi species, there is a need to build up large reference databases containing FTIR spectra of the different species.

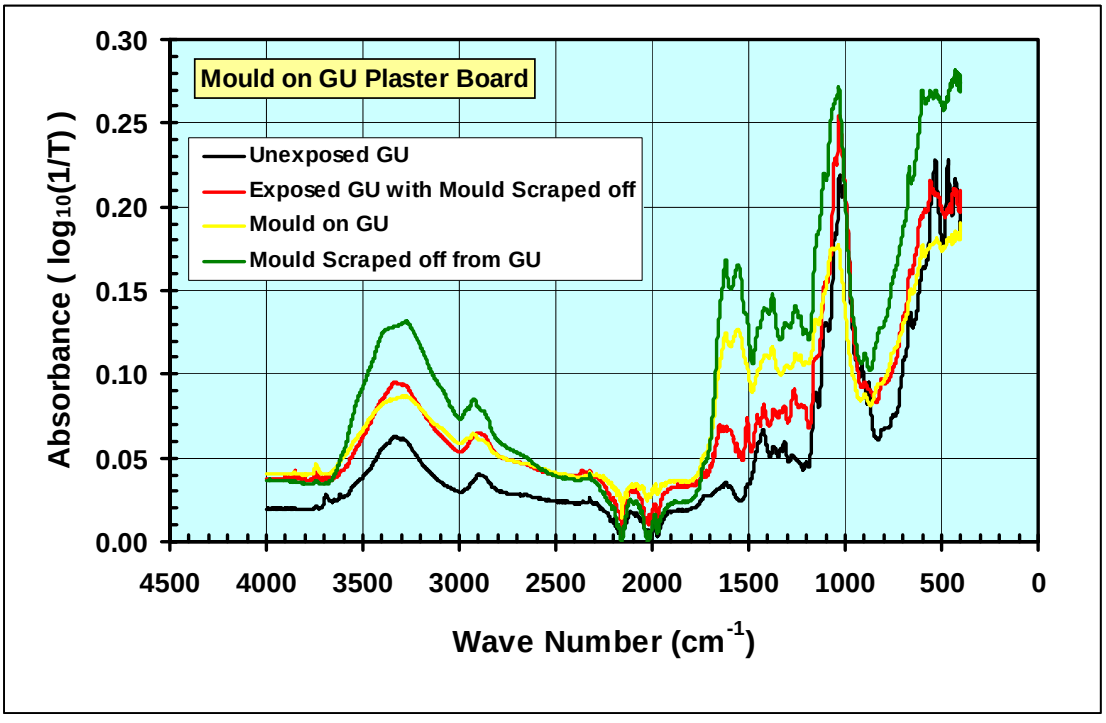

Figure 2. Absorbance (logarithmic) versus wave number between 4000-400 cm-1 for mould fungi at various exposure levels on GU plaster board. (T = Transmittance).

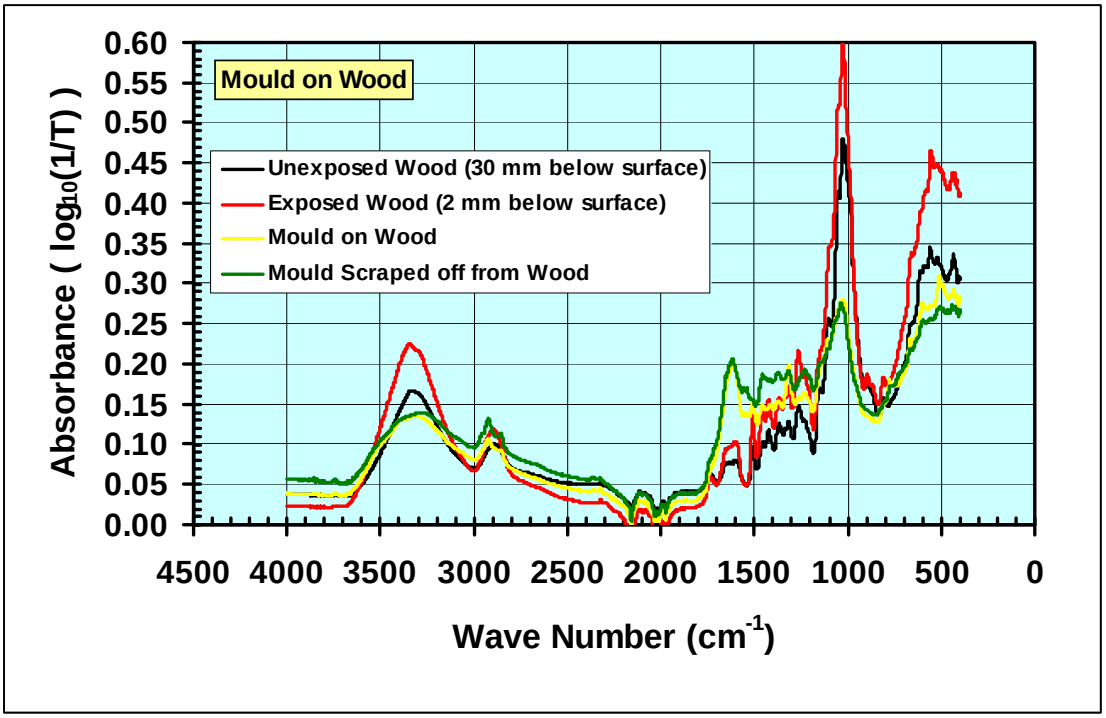

Figure 3. Absorbance (logarithmic) versus wave number between 4000-400 cm^{-1} for mould fungi at various exposure levels on a wood sample.

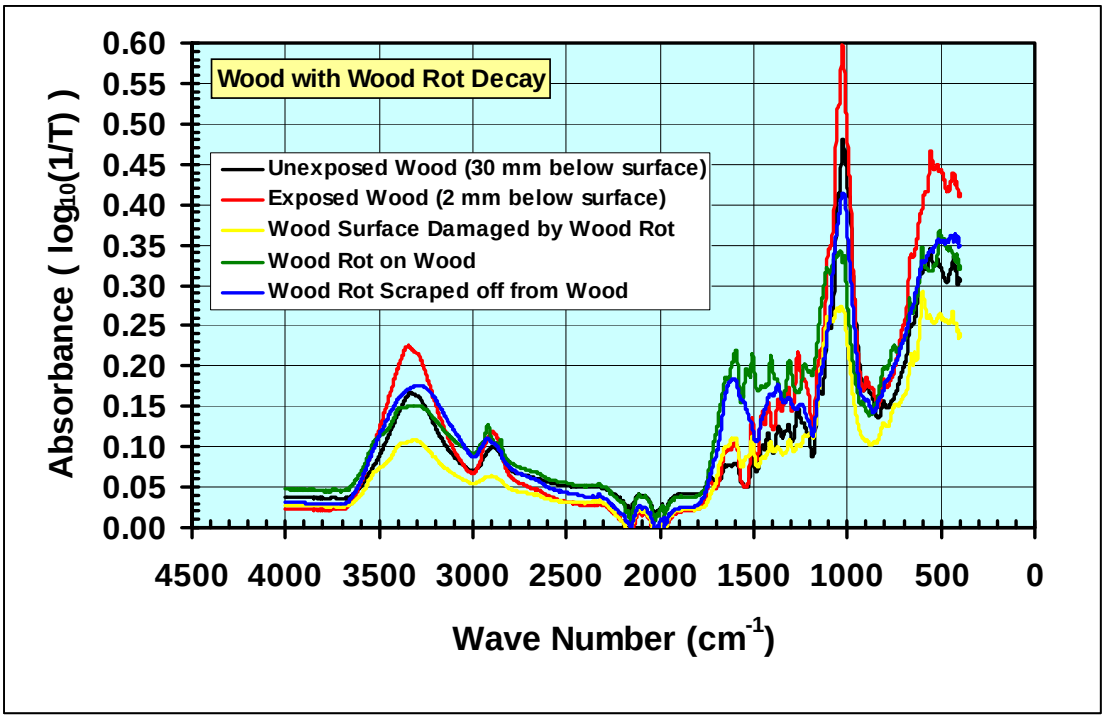

Figure 4. Absorbance (logarithmic) versus wave number between 4000-400 cm^{-1} for wood rot at various exposure levels of wood rot decay.

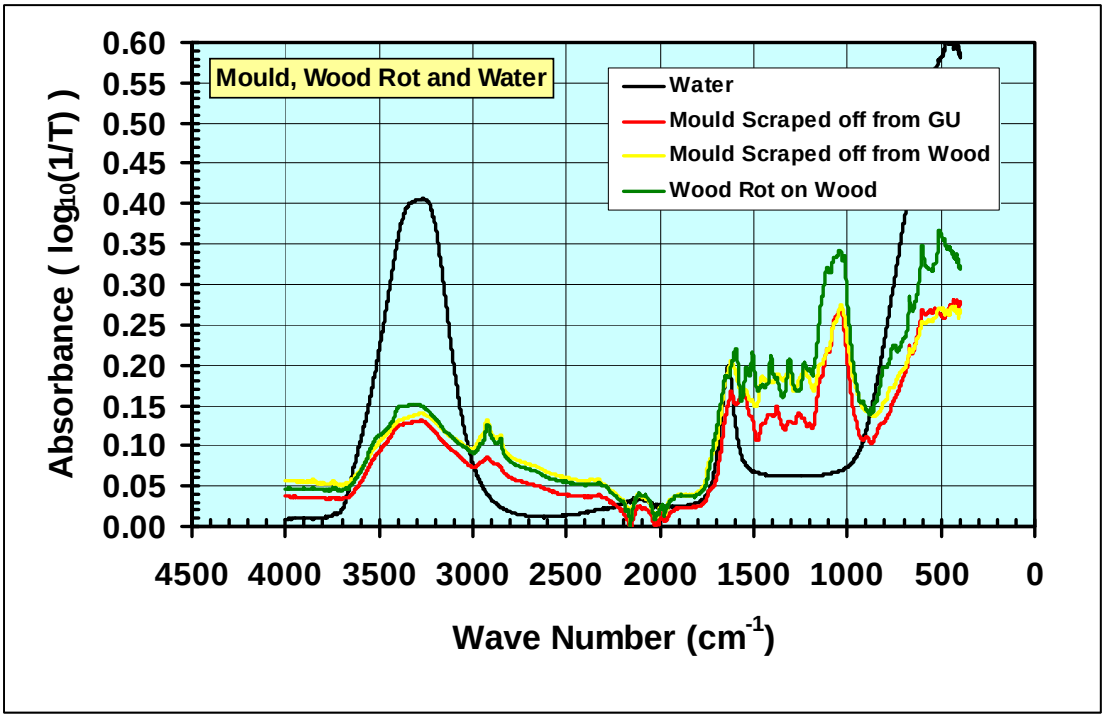

Figure 5. Absorbance (logarithmic) versus wave number between 4000-400 cm^{-1} for mould fungi on GU plaster board, mould fungi on a wood sample and wood rot at selected exposure levels. In addition, the water spectrum is also plotted as a comparison. From Figs.2-4 (except water spectrum).

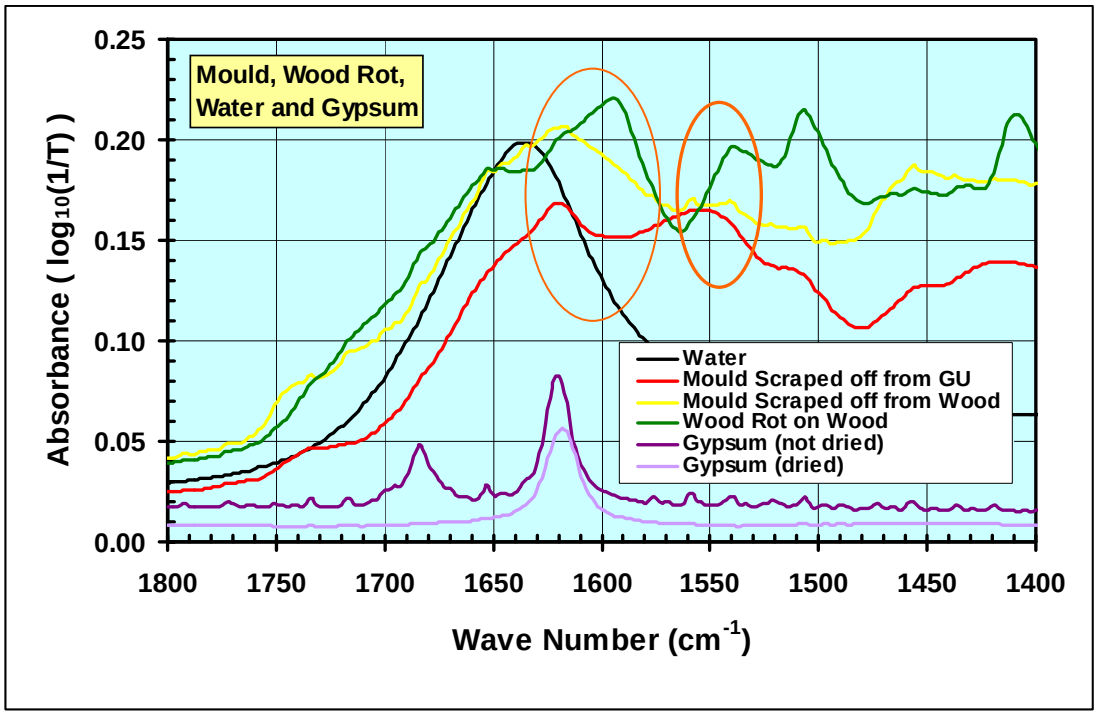

Figure 6. Absorbance (logarithmic) versus wave number between 1800-1400 cm^{-1} for mould fungi on GU plaster board, mould fungi on a wood sample and wood rot at selected exposure levels. In addition, the water, non-dried gypsum and dried gypsum spectra are also plotted as a comparison. From Figure 5 (except gypsum spectra). See discussion in text about the FTIR absorbance peaks within the narrow, large (left) and thick, small (right) ellipse encircling the absorbance peaks.

4 CONCLUSIONS

This preliminary study has demonstrated that the attenuated total reflectance (ATR) fourier transform infrared (FTIR) spectroscopical technique may be applied in order to detect wood rot decay and mould fungi growth on building materials. However, further studies and experimental investigations are needed in order to elaborate the suitability, the reliability, the limitations and the future potential possibilities of this method.

ABSTRACT

The attenuated total reflectance (ATR) fourier transform infrared radiation (FTIR) experimental technique represents a powerful measurement tool on various materials. The ATR technique may be applied on both solid state materials, liquids and gases with none or only minor sample preparations, also including materials which are non-transparent to IR radiation. This facilitation is made possible by pressing the sample directly onto various crystals, e.g. diamond, with high refractive indices, in a special reflectance setup. Thus ATR saves time and enables the study of materials in a pristine condition, i.e. the comprehensive sample preparation by pressing thin KBr pellets in traditional FTIR transmittance spectroscopy is avoided. Ageing processes in building materials, both ageing by natural and accelerated climate exposure, decomposition and formation of chemical bonds and products, may be studied in an ATR-FTIR analysis. In this work the ATR-FTIR technique is attempted utilized to detect changes in selected wood building material substrates subjected to natural weather exposure and various accelerated climate exposure conditions. One aim is by ATR-FTIR analysis to be able to quantitatively determine the length of the wood ageing time before priming/treatment. Climate parameters like temperature (including freezing/thawing), relative air humidity, wind-driven rain amount, solar and/or ultraviolet radiation and exposure duration are controlled in different climate ageing apparatuses. Both impregnated and raw wood samples have been employed in the experimental investigations.

1 INTRODUCTION

Wood deterioration of building materials due to natural climate ageing processes represents a problem. In natural climate ageing the wood materials, e.g. wood claddings, are exposed to several climate factors like for example:

- Solar radiation including ultraviolet (UV), visible (VIS) and near infrared (NIR) radiation.
- Ambient infrared (IR) heat radiation (the resulting elevated temperature increases the rate of chemical degradation reactions, and also the rate of growth of rot and fungus up to limiting temperatures).
- Temperature changes/cycles (relative temperature movements between different materials, number of freezing point passes during freezing/thawing).
- Water, e.g. moisture, relative air humidity, rain (precipitation), wind-driven rain.
- Wind.
- Erosion (also from above factors).
- Pollutions (e.g. gases and particles in air).
- Time (for all the factors above to work).

Note that wood rot and mould fungus are not listed as climate factors, i.e. the wood rot and mould fungus are in this context viewed as (unwanted) results of the specific climate factors moisture and temperature for a certain exposure time with a sufficient supply of nourishment (e.g. wood). Although commonly not regarded as so, the availability of fungal spores may be seen as a special climate exposure factor. Fungal spores are almost always present, except under sterile conditions. See Jelle et al. [2007] for FTIR investigations of wood rot decay and mould fungi growth on building materials.

In this work we are trying to utilize the attenuated total reflectance (ATR) fourier transform infrared (FTIR) radiation technique in order to study wood decomposition in (accelerated) climate aged building material substrates. The ATR-FTIR technique makes it possible to study materials which are non-transparent to IR radiation in a pristine condition. That is, the extensive, time-consuming and often cumbersome sample preparation by pressing thin KBr pellets as in traditional FTIR transmittance spectroscopy is avoided. This traditional technique might even change the sample material in question. The ATR technique is based on a special reflectance setup where the sample is pressed directly onto various crystals with high refractive indices, e.g. diamond. One goal is to be able to quantitatively determine the wood decomposition by performing an ATR-FTIR analysis, including to determine the length of the wood ageing time before priming/treatment of the wood has to be done.

Experimentally the task is challenging. Firstly, it may be difficult to differentiate the wood deterioration products on the attacked wood sample from the wood substrate material itself. Secondly, it may be complicated to be able to distinguish between various wood decomposition products. Thirdly, the wood material is not homogenous, which may complicate the measurements. Finally, with the ATR technique it is important to achieve and ensure a good contact with no air pockets between the sample and the ATR crystal in order to obtain correct quantitative results. With wood samples having relatively hard and rough surfaces such a good contact might be difficult to achieve and especially to ensure that the actual contact is the best one attainable. Several works are carried out applying infrared spectroscopy in studies of wood weathering and wood photodegradation, e.g. by Anderson et al. [1991], Colom et al. [2003], Humar et al. [2006], Mohebby [2005], Pandey and Pitman [2003], Pandey [2005], Sudiyani et al. [2003] and Yamauchi et al. [2004]. Anderson et al. studied the effects of artificial weathering of softwoods and hardwoods with water alone, sunlight (xenon lamp) alone and both water and sunlight applied in conjunction. ATR analyses were performed by Humar et al. [2006] and Mohebby et al. [2005]. The common practice and most widely applied experimental method is the traditional KBr pellet sample technique in infrared transmittance modus. Although there exists many experimental challenges using the ATR-FTIR method on wood, this method is nevertheless very promising and with many advantages and is therefore the subject of our investigations in this work.

2 EXPERIMENTAL

2.1 Sample Materials

Altogether, nine different wood sample materials, five raw, non-impregnated and four impregnated wood samples, have been tested in various accelerated climate ageing apparatuses, in addition to natural outdoor weather ageing. Due to length limitations for this publication, only two samples are discussed in the work presented here. The two wood samples are:

Sample A Norway Spruce, *Picea Abies L. Karst.* (Ruptimal® Surface, mechanically treated surface), measured dry mass density of 0.41 kg/dm^3. Raw, non-impregnated sample.

Sample H Pressure Treated Pine Class NP5 (chemical treated according to EN 351-1:2007), *Pinus Sylvestris L.*, measured dry mass density of 0.50 kg/dm^3. Impregnated sample.

The small wood pieces needed for the FTIR measurements have been collected from the larger samples depicted in Figure 1.

Figure 1. Photos of wood sample A (left) and wood sample H (right) after 115 days of accelerated ageing in the Atlas Solar Simulator climate chamber. Direct solar radiation exposed side shown upwards. Small wood pieces are cut from the samples for use in the FTIR investigations.

2.2 Short Description of the Overall Study

The results presented here is part of a larger on-going study where several different wood samples are being subjected to both natural weather ageing and various accelerated climate ageing apparatuses, including comparisons between the natural and the artificial weathering methods. The various ageing apparatuses include an Atlas SC600 MHG Solar Simulator (see next section for details), a QUV apparatus weathering tester horizontal option with ponding and water spray (The Q-Panel Company, Cleveland, Ohio, USA) and a vertical accelerated climate simulator subjecting the sample area in turns to four different climate zones (1 hour in each climate zone), that is, one UV (UVA and UVB intensities are averaged to 14 W/m^2 and 1.4 W/m^2, respectively) and IR irradiation zone (black panel temperature of 63ºC), one water spray zone (15 dm^3/(m^{2}h)), one freezing zone (-20ºC) and one indoor laboratory climate zone according to Nordtest Method NT Build 495 (”Building materials and components in the vertical position: Exposure to accelerated climatic strains”). However, due to length limitations for this publication, only some of the results from the accelerated ageing in the Atlas Solar Simulator are presented here.

2.3 Accelerated Ageing in Atlas Solar Simulator

The accelerated ageing was carried out in an Atlas SC600 MHG Solar Simulator climate chamber with a 2500 W MHG lamp. The wood samples were tilted a bit from the horizontal (8 ± 2º) in order to let the water run off the surface. The samples were placed in the climate chamber with a distance of approximately 55 cm from the climate chamber glass ceiling to the samples, where the solar radiation intensity is reported to be 1200 W/m^2 at 100 % lamp power intensity. During the ageing period the

UVA and UVB radiation intensity was measured at various times to be lying within the interval 60-80 W/m^2 and 3-6 W/m^2, respectively. The UV measurements were performed with a radiometer/photometer Model IL 1400A (International Light) with an UVA sensor and an UVB sensor. Note that a 6 % UVA fraction (like in sunlight) of the total solar intensity (1200 W/m^2) yields 72 W/m^2 UVA radiation. The exposure duration consisted of 115 whole cycles of 24 hours, each cycle divided into 20 hours with a solar radiation intensity of 1200 W/m^2 and 4 hours with water spray application and no solar radiation exposure. The two water spray nozzles gave each 0.5 dm^3/min, i.e. 1 dm^3/min in total, which gives approximately 1.7 dm^3/(m^{2}min) assuming an even horizontal water distribution at the sample location in the whole climate chamber. Integrated up, the solar radiation (MHG lamp) energy is 24 kWh/m^2 per day and 2760 kWh/m^2 during 115 days. Likewise, assuming 70 W/m^2 as an average, the UVA radiation energy is 1.4 kWh/m^2 per day and 161 kWh/m^2 during 115 days. The temperature and relative air humidity were held constant at 63ºC and 50 % RH during the solar radiation exposure and at 10ºC and close to 100 % RH during the water spray application.

2.4 FTIR Measurements

The FTIR material characterization was carried out with a Thermo Nicolet 8700 FTIR spectrometer with a Smart Orbit accessory, i.e. a horizontal attenuated total reflectance (HATR) accessory (single reflection) with a diamond crystal, in the wavelength range 4000 cm^{-1} (2.5 μm) to 400 cm^{-1} (25 μm) in an atmosphere with minimalized CO_2 and H_2O content through purging by a Parker Balston 74-5041 FTIR Purge Gas Generator. Each FTIR spectrum presented is based on a recording of 32 scans at a resolution of 4 cm^{-1}. In order to ensure satisfactory contact between the ATR diamond crystal and the sample, a minimum of three or more FTIR spectra were recorded at various locations on the sample. Figure 2 shows a wood piece from sample A pressed onto the diamond crystal in the HATR accessory connected to the FTIR spectrometer.

Figure 2. Photos of a wood piece from sample A pressed onto the diamond crystal in the HATR accessory connected to the FTIR spectrometer. In the close-up photo to the right, the lower steel pin is only a reflection of the above steel pin in the polished mirror-like sample plate.

The FTIR spectra given in this work have not been ATR corrected, neither with respect to penetration depths nor absorbance band shifts, which both are dependent on the refractive indices of the sample and the ATR crystal (diamond in this case) and the angle of incident radiation. The penetration depth is in addition also dependent on the radiation wavelength. Note that it should always be stated if an ATR-FTIR spectrum has been ATR corrected or not, e.g. important during computerized database spectra comparison searches.

3 RESULTS AND DISCUSSION

FTIR transmittance spectra versus wave number between 4000-400 cm^{-1} for the sample A and sample H at various accelerated ageing levels are presented in Figure 3 and Figure 4. Further close-ups of these spectra are shown as FTIR absorbance versus wave number between 1900-700 cm^{-1} in Figure 5 and Figure 6. Finally, as a reference to avoid any misinterpretations, the distilled water FTIR transmittance spectrum is plotted together with the fresh and aged 115 days sample A spectra in Figure 7. Note that the irregularities in the FTIR spectra between 2200-1900 cm^{-1} (Figure 3 and Figure 4) are due to the very large absorption in the ATR diamond crystal between these wave numbers, which represents the weak point in an otherwise excellent material choice for ATR applications.

As the absorption of electromagnetic radiation, e.g. IR radiation, follows the Beer-Lambert law, i.e. the radiation is decreasing exponentially with the penetration depth in the actual material, it is often helpful to plot the spectra on a logarithmic absorbance scale vs. wavelength. Hence, a representative spectrum is chosen from each of the samples and plotted on a logarithmic absorbance scale for quantitative studies. Mathematically and physically it follows that a doubling of the logarithmic absorbance, also called optical density, is interpreted as a doubling of material thickness or a doubling of concentration of absorption active agents.

The wood sample material undergoes chemical changes and may then as a result of the chemical reactions change the actual thickness of the sample. In this work the experiments are conducted by applying the ATR equipment with the FTIR spectrometer. Hence, the IR radiation is only penetrating into a thin surface layer of the actual sample. With respect to the experiments carried out in this work, the material thickness will then be regarded as approximately constant, i.e. the change in the IR absorbance is explained by an increase or decrease of absorption active species within the sample material undergoing the chemical transformation.

By inspecting the FTIR spectra (Figs.3-6) more closely it is found that several absorbance peaks in the fresh, non-aged wood samples (both A and H) are diminished and finally vanished during the accelerated ageing in the Atlas Solar Simulator. These absorbance peaks are located around 1730-1710 cm^{-1} (varying with different wood specimens), 1510 cm^{-1}, 1260 cm^{-1} and 810 cm^{-1}. The peak around 1730-1710 cm^{-1} are attributed to carbonyl (C=O) stretching in hemicellulose, whereas the peak around 1510 cm^{-1} arises from the C=C stretching of the aromatic ring in lignin. These two peaks located around 1730-1710 cm^{-1} and 1510 cm^{-1} represent good candidates for studying wood decomposition by climate ageing through FTIR analysis.

In addition, for wood sample H (impregnated sample), the two sharp and distinct characteristic absorbance peaks between 3000-2800 cm^{-1} (CH stretch, which may be attributed to the impregnation agent) disappear after some ageing time. The fresh, non-aged wood sample A does not have these two distinct absorbance peaks, only a broad peak in the same wavelength range (similar to the aged peak for sample H).

There are some other changes (i.e. increase and/or decrease) in the absorbance peaks during the ageing period also, but generally no completely disappearance of peaks and neither appearance of new peaks. Note that the water absorbance peaks are located at 3265 cm^{-1} (broader peak, -OH) and 1637 cm^{-1} (narrower peak, -O-), and changes in the FTIR spectra around these wave numbers might also be due to various moisture levels in the samples. Also note that different adjacent neighbour atoms in a compound, e.g. in a polymer chain, will shift the wave number somewhat for the absorbance peak corresponding to the chemical bond in question.

Hence, in this preliminary study it has been demonstrated that the ATR-FTIR spectroscopical technique may be applied in order to detect different levels of climate induced wood decomposition or ageing. Further studies and experimental investigations are needed in order to elaborate the suitability,

the reliability, the limitations and the future potential possibilities of this method. In future applications of this experimental method as a detection tool capable of differentiating between various wood decomposition or ageing levels, there is a need to build up large reference databases containing FTIR spectra of the different species.

4 CONCLUSIONS

This preliminary study has demonstrated that the attenuated total reflectance (ATR) fourier transform infrared (FTIR) spectroscopical technique may be applied in order to detect different levels of climate induced wood decomposition or ageing. However, further studies and experimental investigations are needed in order to elaborate the suitability, the reliability, the limitations and the future potential possibilities of this method.

Performance-based Specification of Wooden Components

Christian Brischke [1]
Andreas O. Rapp [2]

T 12

ABSTRACT

The need for a unified and harmonised system for performance classification and specification of wood and wood-based products in Europe emanates from requirements of users and the European Construction Products Directive (CPD). A road to a feasible specification system is outlined. Exposure-related performance prediction was worked out as a key task on the way to product specification. Therefore suitable tools, field test methods as well as short-term/laboratory test methods, are sought to allow the determination of reference service lives for different exposure categories. On the one hand, performance factors, which derive from service lives in field tests, allow the specification of wood products. On the other hand, the calculation of inter-site factors may allow the modelling of service lives and the drawing of hazard mappings.

1 INTRODUCTION

A unified and harmonised system for performance classification and specification of wood and wood-based products in Europe is still lacking. At the same time the need for such a system becomes more and more obvious. Users and consumers have a strong interest in reliable information on the expected performance of wooden products. They are the decision makers in the market place and will particularly decide, if wood-based products or substitute building materials will be used.

For the user, the only valuable product information needs to be based on a performance characterisation. For example when attempting to chose among different products, is not very helpful to the user to determine the relative protective effectiveness of a wood preservative as is done according to different European standards, e.g. EN 113 (1996), ENV 807 (2001). For potential customers it is essential to have useful information in a form that helps assess whether the product will meet its performance requirements (*i.e.* the desired service life). Ideally what is needed for this purpose is a reliable service life estimate, but at the very least, a product specification having performance classes would be useful information for a consumer to make an informed choice. Furthermore, such a system should not be limited for a particular group of wood products only, but universally applicable for all wood-based products including, for example:

i. Wood treated with classical wood preservatives
ii. Wood treated with new organic preservatives
iii. Natural durable wood
iv. Modified wood
v. Wood-based composites.

Secondly, the need for performance classification emanates from the European Construction Products Directive, CPD (1988) on the approximation of laws, regulations and administrative provisions of the member states relating to construction products. The CPD requires in particular "products fit for an intended use", which may be translated as meaning, “a sufficient level of performance” over a particular time period – the time period of the intended use.

Thus, for the wood industry, as well as for wood scientists, three important needs may be derived from the CPD:

1. Provide data that are applicable for performance estimations of wood-based products
2. Deliver suitable test methods to assess the performance over time of wood-based products
3. Establish a European-wide harmonised classification and specification system.

The objectives of this work were to identify the necessary steps towards a feasible performance classification system and to provide a roadmap for the specification of wood-based products. The approach presented in the following should be seen as a proposal and a base for the discussion about different aspects related to wood product specifications. Valuable comments and subjects of the discussion, which took place in the frame of COST Action E37 “Sustainability through new technologies for enhanced wood durability”, were considered in this paper.

2 ROADMAP FOR THE SPECIFICATION OF WOOD AND WOOD-BASED PRODUCTS

2.1 General Aspects

A roadmap for the specification of wood and wood-based products to be drawn in this paper can be defined by its start and ending point. The starting point of this road is the expectancy regarding a specification system by the user of wood-based products and the CPD (1988) as described in Section 1. As is shown in Figure 1, a feasible product specification is the final destination at the end of the road intended to meet user requirements. From the beginning it is clear that the end of this road can only be reached by performance prediction, which somehow need to be realized . In the following

sections, the different stopovers on the roadmap to developing a useful product specification will be described and discussed that focus on the steps necessary to achieve performance prediction .

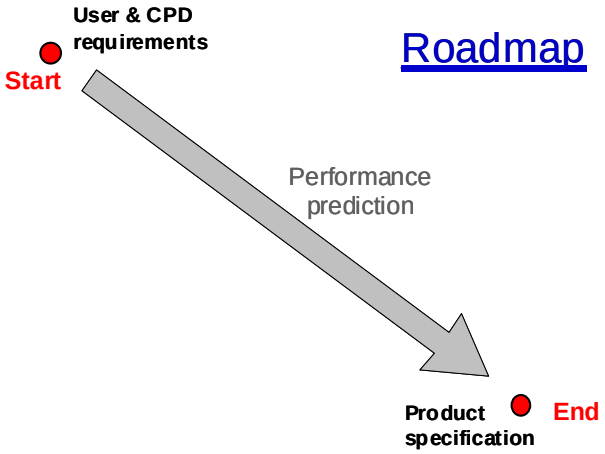

Figure 1. Start and ending point of a road towards the specification of wood and wood-based products.

2.2 Necessary Number of Reference Service Lives

To predict the performance of a wood-based product means nothing else than to predict its service life. The service life of a product ends, when the performance level becomes lower than the performance requirements, whether they are functional, static, or aesthetic. Therefore performance prediction can be equated with service life prediction, and the principles of service life planning as given by the ISO standard 15686 should be considered. According to ISO 15686-1 (2000) a service life can be estimated by considering a reference service life and different modifying factors as follows:

Estimated service life (ESL) = Reference service life (RSL) • modifying factors,

whereby the modifying factors include all conditions that deviate from defined reference conditions, e.g. climate, design measures, or maintenance intervals.

From the laws of error propagation it can be seen that the more unknown variables considered in an equation, the higher the total statistical error to be expected. Therefore, it is obvious, that working with only a single RSL is no solution. Thus, the question arises as to how many different RSLs need to be considered to obtain a reliable service life estimate, and how can these RSLs be determined (i.e. what are suitable test methods?). Different wooden commodities, even if they are made from the same material, can perform very differently. Depending on the exposure situation different service lives will be obtained. Consider, for example, wooden poles in ground contact or the same material used as beams in a roof construction. Table 1 shows information on the relation between commodities, exposure situations, and the expected performance for related use classes described in EN 335-1.

Different commodities can be merged into commodity groups having similar expected performance. At the same time, different exposure categories can be defined and related to the different commodity groups. However, a simple equalisation of exposure and commodity is not possible, as for window joinery, which is usually coated, the same exposure situation is given compared to a cladding, but a completely different performance of these two commodities can be expected. In this case one needs to distinguish between coated and uncoated commodities within the same exposure category "above ground". A second example for the need of a more discerning classification of commodity/exposure groups is the hazard of termite attack. This regionally occurring special hazard concerns nearly all commodities and requires therefore a separate category.

Table 1. Different exposure categories with related use classes according to EN 335-1 (2006), commodities and potentially suitable test methods.

ID	Related to use class	Exposure category	Commodity group	Close to reality Test method
A	1	Interior	Roof beams, rafters	Not known, Not available
B	2	Above ground covered	External walls, ground floor joist	Not known, Not available
C	3.1	Above ground coated	Window joinery	L-joint EN330
D	3.2a	Above ground slight	Cladding, fence rails	Not known, Not available
E	3.2b	Above ground severe	Decks	Double layer / multiple layer
F	4	Ground contact	Poles, posts, sleepers	EN 252
G	5	Sea water contact	Ships, wharfs	EN 275
H		Termite hazard		Not known, Not available

Some exposure categories are identical with the use classes described in EN 335-1 (2006) and may be taken over. However, the range of use class 3 seems to be unacceptably broad and needs therefore to be subdivided. In Table 1 coated and uncoated commodities are first distinguished, and thereafter, slight and severe hazards are distinguished for uncoated materials. The need for further differentiations should be discussed.

To summarize, the essential finding is that the agreement on a certain classification of exposure categories, which represent different commodities close to reality, gives the necessary number of RSLs to be considered for service life prediction. The rule should hence be to distinguish between as

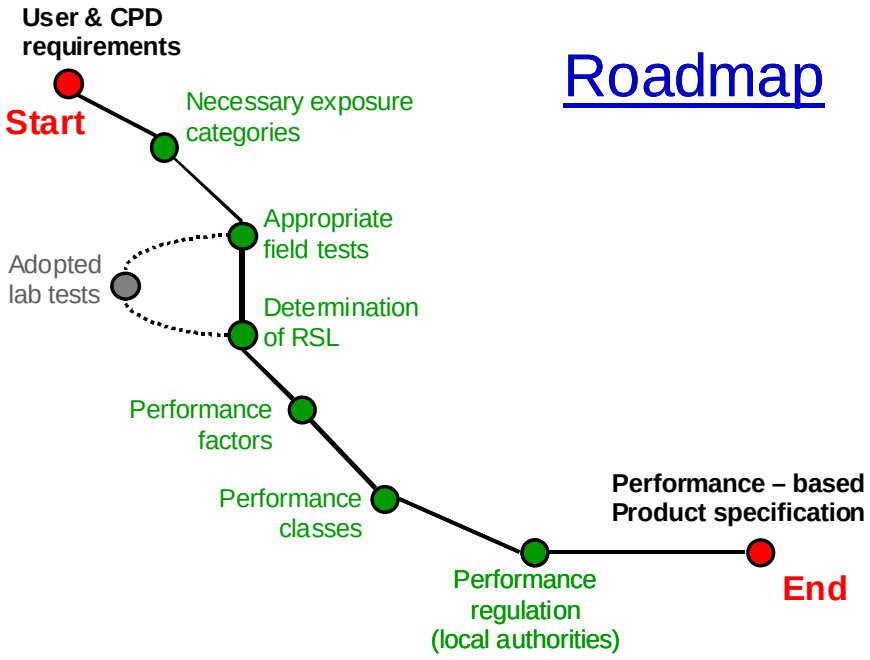

Figure 2. Roadmap for the specification of wood and wood-based products.

many categories as necessary, but as few as possible. Thus, the first stopover "Necessary exposure categories" is reached, as given in Figure 2.

2.3 Determination of Reference Service Lives with Appropriate Field Test Methods

Once a certain number of exposure categories are agreed on, the next task is to determine RSLs for all of them. Therefore, suitable test methods, which represent the different exposure categories, and commodity groups respectively, need to be determined. Table 1 gives some examples for field test methods, which may be helpful to determine RSLs for the particular categories. For example, the EN 252 (1989) test for in-ground exposure and the L-joint-test (EN 330, 1993) for coated window joinery are well-established methods, and a lot experience with these tools exists.

For other exposure categories suitable tools are still missing and the adoption of existing methods or the development of new methods should be the next stopover on the map ("Appropriate field tests", Fig. 2).

2.4 Determination of Reference Service Lives with Adopted Laboratory Tests

Appropriate test methods for the determination of RSLs are not necessarily only field test methods. The wood industry in particular, but also scientists and testing laboratories, are seeking short-term methods that take less time to conduct, not at least to allow a sufficiently rapid approval of a product for specific applications. However, as a starting point in the development of such methods, is that these should replicate in-use conditions as close to reality as possible. These are typically conducted, in general and apart from in-service performance, as field trials.

Some guidance on how to incorporate short-term tests into performance classification is given by the ISO standard 15686-2 (2001). An extract of the systematic methodology for service life prediction of building components, adopted and closely related to wood products is given in the scheme provided in Fig. 3.

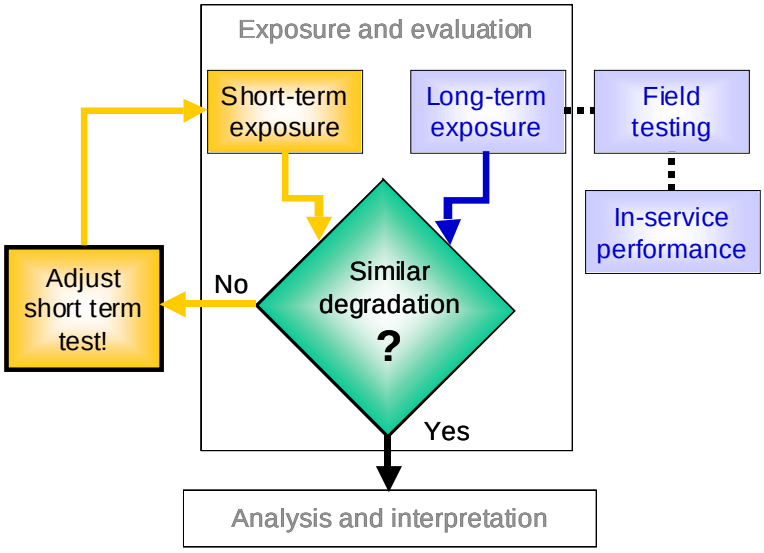

Figure 3. Systematic methodology for service life prediction of building components (according to: ISO 15686 -2 (2001)).

Whenever one wants to make use of the results derived from short-term tests, it is indispensable to compare the degradation patterns between long-term and short-term tests. As long as no similar degradation pattern can be observed, the short-term test should be adopted. However, if similar degradation is provided, nothing argues against the inclusion of laboratory short-term tests. Quite the contrary, there are also some exposure categories conceivable, where short-term tests appear as the only suitable solution: For commodities exposed above ground and protected, e.g. external walls, the occurrence of decay will probably take years or even decades. In this case, moisture measurements over a limited period of time may be an alternative to long-term field trials.

However different the test methods, for the roadmap it is essential that for every exposure category, a method having test conditions closely related to in-use conditions should be established to obtain a RSL for each exposure category, as given in Table 1. From this, “Determination of RSL” is the next stopover on the product specification roadmap provided in "Fig. 2. The adoption of short-term test methods may be seen as a side route on the map.

2.5 Performance Factors

The results of the different tests, representing the different exposure categories, can be used to predict and classify the performance of wood-based products. Actually, the primary result of every field trial is the service life in years of, on the one hand, a material X to be tested, and on the other hand, a reference material. The reference material can be Scots pine sapwood (*Pinus sylvestris* L.), as it is used in many existing European standards, but may be also different for a particular test method. At this stage it is particularly important to note that the service life of a reference material or reference product ($SL_{reference}$) is different from the reference service life (RSL) of a certain material X determined at a particular test site. Thus, two main results arise from each field test:

$SL_{material\ X}$ = service life of a material X to be tested
$SL_{reference}$ = service life of the reference

To become independent from the influence of the different test sites it seems appropriate to express the performance of the test material as a factor, the performance factor (PF), given as:

$$PF = SL_{material\ X} / SL_{reference} \quad [y/y]$$

In accordance to the classification of exposure situations (Table 1) the performance factors must be related to the different exposure categories. For each exposure category a performance factor needs to be determined as the following example shows:

Exposure category F: ground contact Test method: EN 252 (1989)

$SL_{material\ X}$ = 6.9 years
$SL_{reference}$ = 3.0 years

$$PF_F = SL_{material\ X} / SL_{reference} = 6.9/3.0 = 2.3$$

PF_F = 2.3 → 2.3 longer service life than the reference in ground contact (exposure category F)

With the help of performance factors for each exposure category considered, a very detailed and precise characterization for a material to be tested is possible. From the stopover "Performance factor" the final destination is already reachable on the roadmap. In principal, every material can be specified with a certain number of performance factors.

2.6 Performance Classes and Performance Regulation

The use of numerous different performance factors may cause confusion during its implementation in practice. Therefore it could be an option to combine performance factor intervals in performance classes, e.g. according to the classification of durability (EN 350, 1994), as schematically shown in Fig. 4. Again the creation of performance classes needs to be done separately for the different exposure categories.

To define, which product may be used for a certain application, is a task for the local authorities. They need to devise requirements related to the different performance classes (example given in Fig. 4). On the roadmap the final destination is reached. The task "performance regulation" appears as a stopover on the road to a "performance-based product specification".

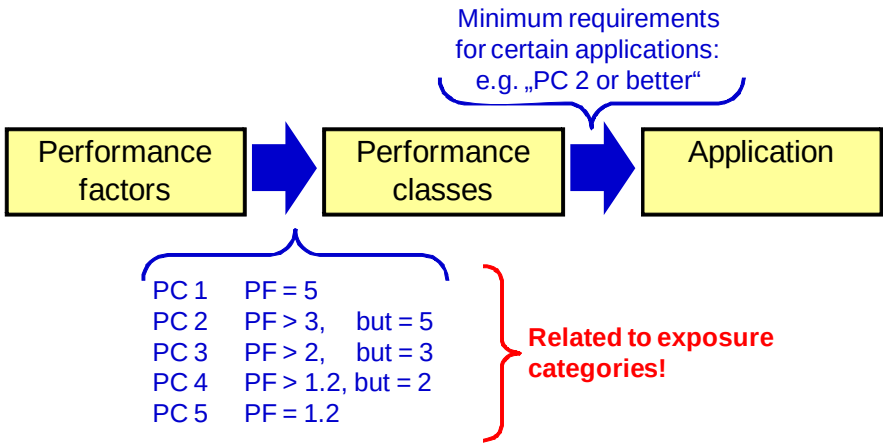

Figure 4. Relationship between performance factors, performance classes, and performance regulation.

2.7 Test-site Relationships

In section 2.5 relating to performance factors, the influence of the test site was not considered. In fact, performance factors were created in order to eliminate the influence of the test site. However, the test site nonetheless has a strong influence on the test results. Testing the same material at different field test sites will inevitably lead to different service lives. Table 2 gives a fictitious example of test results from L-joint tests (EN 330, 1993), carried out at three different test sites, *e*.g. London, Hamburg, and Bordeaux.

Table 2. Fictitious example for the calculation of performance factors from service lives of a material X to be tested and a reference material determined at different test sites.

Test site	$SL_{material\ X}$ [y]	$SL_{reference}$ [y]	*PF3.2a (L-Joint)*
London	18	9	2.0
Hamburg	24	12	2.0
Bordeaux	30	15	2.0

The material X to be tested revealed different service lives at the three sites as well as the reference material. Ideally, the calculation of performance factors leads to the same performance classification (here: $PF_{3.2.a}$ = 2.0) for all test sites. Certain variations of the performance factors determined at different sites should be expected, but may be in an acceptable range.

The relation between two test sites can be calculated from the service lives of the reference material in terms of an inter-site factor, e.g. between London and Bordeaux:

Inter-site factor $_{BDX/LON} = ISF_{BDX/LON} = SL_{reference\ /\ BDX} / SL_{reference\ /\ LON}$ = 15 years / 9 years = 1.67

Another example shows a possible practical use of knowledge related to inter-site relationships. Consider the following:

1. Material X shall be used in Bordeaux
2. Material X is so far tested only in London

A question might be posed as to what the estimated service life (ESL) of material X in Bordeaux would be? With the help of knowing the inter-site factor between London and Bordeaux, the ESL of material X in Bordeaux can be calculated as:

$ESL_{material\ X\ /\ BDX} = SL_{material\ X\ /\ LON} \bullet ISF_{BDX/LON} = 18\ years \bullet 1.67 = 30\ years$

To summarize, two important measures can be obtained as a result of different field tests at different test sites: 1.) The performance factor, which is the service life of a certain material relative to a reference, can be used to specify a product. 2.) As a by-product, inter-site factors, which describe the relation between different test-sites by means of their decay hazard, can be used for service life prediction models and hazard mappings.

For the roadmap a second sideway with the stopover "Inter-site factors" resulted from reflecting on the inter-site relationships (Fig. 2). Together with the tasks "product specification" and "performance regulation" it represents the basis for performance based building, which can be seen as a super ordinate aim, when working on performance prediction and product specification.

3 CONCLUSIONS

A strong need for performance classification derives from the user of wood and wood-based products on one hand, and is required by the CPD on the other hand. On the way to fulfilling these requirements service life prediction can be seen as the link between "user needs" and a feasible "product specification". The results from service life prediction are always numbers in years and consequently satisfy the perceived needs of the user, whereas performance factors, determined for a sufficient number of different exposure categories, can represent the connection between use and hazard classes and durability classes.

The roadmap outlined in this paper shows that all necessary tools for an exposure-related performance specification are, in principal, already available. Different field and laboratory tests need to be adopted to in-service related test situations, but do already exist, as well as the use classes and durability classes, which are adaptable to performance classes. The challenge for the wood industry practitioners and wood scientists is to bring all these single elements together – a proposal is made in this paper. Finally, the cornerstones for a performance-based building can be established on the way to developing a feasible product specification.

Fire Resistance Performance Study on the Compartment Walls in Wood Platform Construction

Chun-Ta Tzeng [1]
Hung-Chi Su [2]
Pang-An Hsiao [3]

T12

ABSTRACT

This study refers to the North America construction methods and adopts the foreign and native materials in Taiwan to fabricate the specimens for experiments. Several full-scale experiments were carried out to explore the effects of factors regarding fire resistance performance according to the fire resistance test for structural parts of building stated in the CNS 12514 which is similar to ISO834-1.The experiments had shown that the covering board materials and the dimensions of studs directly affect the properties of thermal resistively. With covering board material selected, the nail length does affect the fire resistance performance. It was found that by decreasing the nail spacing, the fire resistance performance exhibits improvement. The research results revealed that the wood-framed compartment wall specimens specified as above-mentioned sustain at least one hour fire rating performance according to the current Building Technique Regulations.

1 INTRODUCTION

The wood structure buildings provide with the advantages of low contamination, low energy consumption, swift construction, earthquake-resistace and is beneficial to our health. It also conforms to the sustainable development as well as the green building policy in Taiwan.

According to the mechanical behavior, the system of platform wood-framing wall can be classified into bearing wall and non-bearing wall. The fire prevention division wall is the main structure on prevention of horizontal fire spread, and it plays a extremely important role on fire control and safety evacuation. This research refers to the fire preventing regulations in America, Japan and Canada.

This study carried out several full-scale experiments according to the CNS 12524 standard "method of fire resistance rest for structural parts of building" in Taiwan to investigate the fire resistance of platform wood framing non-bearing wall.

The intent of this research is to provide practical applications and thus make the Taiwan fire resistance performance and standard of wood framing building harmonize with the international.

2 EXPERIMENT LAYOUT

The structure of wood framing compartment wall mainly consists of structural material of wall body, stud cross section and spacing, cover board, insulation material, fastener etc. The study adopts the rock fiber as insulation material in our experiments. The wood material of stud, size of stud section and cover material type are taken as the primary factors in this research. Each factor contained two sets of settings which listed below :

1. Structure material for wall body : the stud had chosen the local material china fir and foreign material SPF which was the compose wood of Spruce (Picea Spp)、Pine (Pinus Spp) and Fir (Abies spp.).
2. Size of stud section(studs pacing) : the section dimension of stud for this experiment used 2 inch × 4 inch and 2 inch × 6 inch.
3. Covering material type and Fastener: the experiment used the level 1 fire resistance gypsum board with thickness of 15mm, which was most commonly used in foreign wood framing cover board, and also the rating 1 fire resistance silicate board with thickness of 12mm, which was used in local production on covering board material for light interval wall. The nails and glues were adopted to fasten the gypsum board and the screw is used for the silicate board. The previous factors with each two setting are shown below on Table1.

Table 1. Setting of experimental factors.

3 TEST CONDITIONS AND PROCEDURE

The heating equipment used for the experiment was the furnace from Architecture and Building Research Institute, Ministry of Interior as shown in Figure 1.The heating control for the experiment was through the 16 thermocouples within the furnace. The relevant standard for heating time and temperature curving were shown below in Figure 2.

The determination conditions for the experimenting fire resistance performance had shown below in Table 2. The specimen wood frame was consisting according to previous conditions. The stud sections for 2 inch × 4 inch and 2 inch × 6 inch are shown in Figures 3 and 4.The positions of thermocouples on the elevation of a wall are shown in Figure 5 and Figure 6. Specimen number and construction material list are shown in Table 3.

4 RESULTS AND DISCUSSION

4.1. Performance Discussion of Fire Resistance for CNS12514

Although the experimental results shown that the heating time for each specimen is different , it does not show any sign of continuous fire last over 10 seconds on non-heating side or any fire penetration from heating side to non-heating side for more than 10 seconds within 60 minutes, this had proved the specimen did have at least 1 hour of fire integrity performance. The construction technical regulation term 70 had listed for fire resistance compartment wall should be at least one hour fire rating , and all the specimen had reach this requirement. Which the related statistic results of fire insulation and fire integrity had shown in Table 4.

Table 4. Experiment results.

Specimen Number	Type	Fire Insulation		Fire Integrity	
		Time for temperature under any position exceed 210□ on non–heating side	Time for average temperature exceed 170□ on non–heating side	continuous fire on non-heating side over 10 seconds.	fire penetrate form heating side to non-side for over 10 seconds

× indicates event did not occur , heating stop at 86 min					

4.2. Temperature Discussion on Non-Heating Side of Specimen

For all specimens, most of the temperature points on non-heating side of specimens did not show large variations through the first 60 minutes of the experiment. Take specimen W6 for example illustrated in Figure7. However, when the heating time exceeded 60 minutes, some temperature points exhibited

sudden increase due to the collapse of the cover board on the heating side and drop of the rock fiber when the supporter was gone. The inner furnace was then directly heated the cover board of non-heating side and caused all the non-heating side temperature points climbed abruptly.

By camparing with the same specimen, the time taken for single point on the non-heating side to reach 210 were shorter then average temperature reached 170. Due to the temperature of single point on the non-heating side reached 210 faster, the time determination of fire insulation should mainly focus on the temperature point reached 210. Thus the analysis for fire insulstion quality is mainly on time taken for single point on non-heating side to reach 210.The range for the fire insulation performance for all specimens were about 64 minutes to 83 minutes, which proved all the specimen possess the performance of fire insulation for at least 60 minutes.

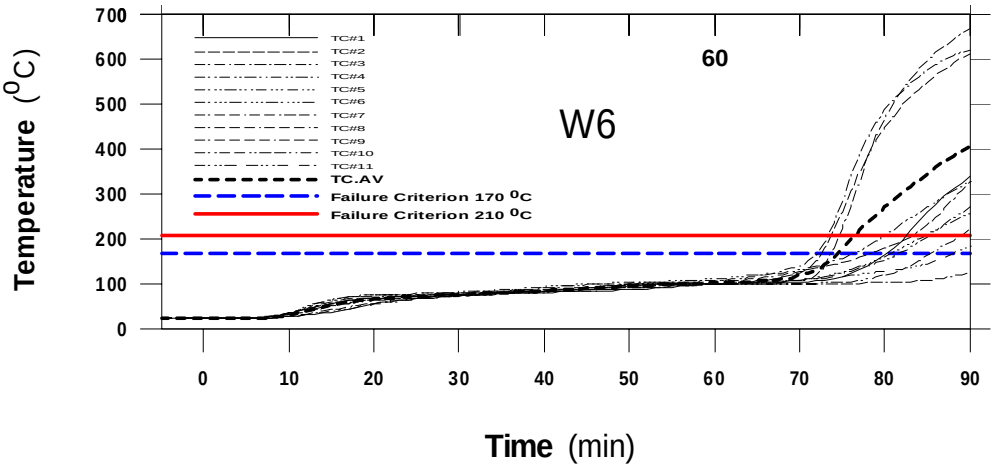

Figure 7. W6 non-heating side temperature recording.

4.3 Inner Furnace Temperature Discussion

The inner furnace temperature curve had fitted the CNS12514 requirement as shown in Figure 8, as for the inner temperature climbed abruptly 40 minutes after the experiment started for specimen W1、W2 and W4 . Through the observation window on the side of furnace, the cause of sudden increase on the inner furnace temperature could be the reason of widely collapse in cover board material, and the wood framing structure burned down on the heating side of the specimen. About 75 minutes after the experiment started, the cover board on the non-heating side for specimen W6 had been half destroyed and collapsed, the temperature of the inner furnace had then leaked from the collapse area and thus caused the inner temperature to drop.

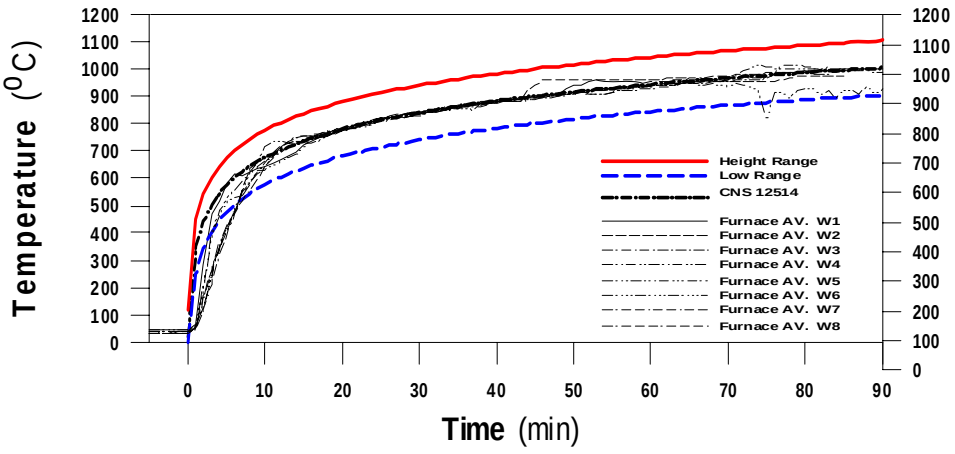

Figure 8. Furnace temperature versus time.

4.4 Experimental Factors

By comparing and analysis the effect of the fire resistance performance for the wood framing compartment wall as shown in Table 5. When the wood material had been changed from SPF to china fir, the fire resistance performance would had a slight reduction about 0.025%. As the size of stud changed from 2×4 to 2×6, the fire resistance performance would had an average increase of 18.88%. As for the cover board material, the observation had shown that by switching gypsum board to calcium silicate board, the fire resistance performance would have an average increase of 15.17%.

Table 5. Comparison of experimental factor.

Comparison of structure material					
Group	1	2	3	4	**Average**
【S】：SPF	W1（3590sec）	W3（4810sec）	W5（4620sec）	W7（4960sec）

【6】：Size Of Stud 2×6	W3（4810sec）	W4（4660sec）	W7（4960sec）	W8（5000sec）	
【6】-【4】	1220sec	770sec	340sec	630sec	740 sec
（【6】-【4】）/【4】×100%	33.98%	19.79%	7.35%	14.41%	**18.88%**
Comparison of covering board					
【G】：gypsum board	W1（3590sec）	W2（3890sec）	W3（4810sec）	W4（4660sec）	-
【C】：silicate board	W5（4620sec）	W6（4370sec）	W7（4960sec）	W8（5000sec）	-
【C】-【G】	1030sec	840sec	150sec	340sec	590 sec
（【C】-【G】）/【G】×100%	28.69%	21.59%	3.11%	7.29%	**15.17%**

Under the condition of using 2×4 stud wood frame, the change of cover board material had conspicuous increased on fire resistance performance. The fastener could be the factor that caused the difference since both type of the cover board had conform the term of level one fire resistance, thus the construction method altered from increasing the length of nail from 31.8mm to 50.0mm and spacing distance between each nail from 300mm down to 150mm should applied on the same 2×4 stud. In this case, when the wood frame was under the same carbonize rate. The calcium silicate board would had longer and more fixed nail which extended the time taken till the cover board collapsed from the wood frame, thus increased the fire resistance performance.

5 CONCLUSIONS

This research focused on the subject of wood framing compartment wall, Referenced from foreign standard, and combined foreign and localize wood material to run a full scale experiment on verify the fire resistance performance of wood framing compartment wall . The experimental results had pointed out the type of cover board material and size of stud had greater effect on the performance of fire insulation then material of stud. This study had found that the fire resistance performance for wood framing compartment wall rely mainly on the cover board material and insulation. The change size of stud factor would also alter the element of fastener. By extended the time for the cover board to stayed fixed on the wood frame would also increased the fire resistance performance. During the heating progress, the wood frame material would gradually carbonize. At the same the wood frame would lost the bond strength of fastener, and thus the shear stresses of fastener would gradually disappeared; the nail spacing distance reduced meaning the number of nail amount increased, relatively the shear

stresses every nail had to bear would decreased, thus the longer the nail length is and shorter the spacing distance is between each nail would enhance the fire resistance performance conspicuously.

As for the use of the cover board material, the fire insulation for calcium silicate board was slightly better than gypsum board. Except considering the nature of the material itself, the difference in fastener for both of the materials could cause variety factors for fire insulation. The gypsum board only used screw, where the calcium silicate board had higher density and heavier in weight, thus screw stabilized would be un-appropriate. The metal frame when stabilized normally used screw, but the kind of screw were not suitable for wooden materials, thus by using the glue to bind and stabilized by adding nail during the construction, were considered to be the practical method for calcium silicate board. Our results had also indicated that the fire resistance performance by adopting foreign and localize wood material, and the fabricated wall refer to foreign construction standards can satisfy the technical building regulation of one hour fire resistance performance.

DURABILITY OF EXTERNAL WOOD-FRAME DOOR SYSTEM, A CASE STUDY

Fatih Yazıcıoğlu [1]
Kevser Coşkun [2]

T12

ABSTRACT

The aim of this paper is to determine the causes of the damages occurred in the external wood frame door systems. Environmental agents affect external wall systems of buildings. Hence, external wall systems are one of the most risky components of the buildings. On the other hand wood is the most used material in buildings in the history. Wood is commonly used in the structure systems, claddings, floorings, doors, and windows of the buildings. Wooden components used in the doors and windows are the most damageable parts.
Some external wood-frame door systems in the Taşkışla Building were studied in this study. In order to determine the durability of these wood-frame doors, firstly a process-oriented study in which damages are observed has been done. In this study the design, construction and usage processes of the doors are examined. Afterwards an object oriented study has been made and in this study survey conducted. In this survey, exact damages were analyzed and the reasons of these damages were classified. Lastly, environmental agents that affected these doors are analyzed. In conclusion, the classification of these damages will be used to evaluate the design of external wood-frame doors.

1 INTRODUCTION

The deterioration and demise of one building element critically affects the function of the entire building. External walls, which are parts of the envelope systems, are mainly designed to be a barrier between the natural outdoor and the artificial indoor, and they may perform a structural role. On the other hand, external walls are far more inclined to be pierced with holes, better known as windows and doors (2). In this study, damaged exterior doors are examined and causes of deterioration and principles of diagnosis and cure are explained.

The durability of building elements and materials is a massive subject. The failures of a building component is usually due to one of the following four factors: The first factor is poor design, the second factor are failures which are related to construction, the third factor is environmental agents and the last one is usage, user behavior and the lack of maintenance and its frequency. Principles of diagnosis process are respectively; information gathering, site investigation and last step is diagnosis and evaluation of collected data (1).

The doors of the courtyard of the southwest tower of Taşkışla Building are bad in condition and a diagnosis and cure process is needed to be applied to them. In order to determine the most suitable process, damage of the doors are examined and photographed, a survey has been conducted and the possible reasons of the damages are determined. At the end of the study proposals are given to increase the overall condition of the doors.

2 DAMAGE TYPES OF THE WOOD FRAME WINDOWS & DOORS

The nature of deterioration mechanisms is that not only are they progressive, but the resulting damage is cumulative and irreversible (2). From the time the construction process finishes, a building starts, albeit usually very slowly, to decay. Estimating the expected life of a building component is often a complex and difficult task (1).

The door system, which is the subject of this study, is made of wood. And the most serious effect is loss of structural integrity which occurs with the decay of the wood, which usually occurs both externally and internally (1). There are two common environmental factors with related to wooden made external door systems: *a)* agents is related to water: water, moisture, condensation and rain, *b)* agents is related to sun: solar radiation, sunlight and temperature.

Generally the moisture content is the predominant factor when considering the durability of a building element. The chemical agent that is most prevalent is water. It is probably also the agent with greatest influence on the properties of materials, particularly when it is combined with extremes of temperature. In many instances the presence of moisture is necessary to enable physical, chemical or biological reactions to take place. The agency of decay is fungal attack is the other important factor.

The orientation of the joinery and whether it is exposed to full sunlight is one of the other important factors that effects wooden doors. The ultraviolet radiation causes degradation of the surface, particularly of softwood species, which will affect the adhesion of paint and other finishes. Many organic dyes, bituminous materials and some synthetic polymers such as those used in sealant are degraded by ultraviolet light. Changes of temperature are also relevant when assessing the consequences of thermal expansion and contraction-such as stresses within materials when changes of size are restrained and strains imposed on jointing materials when components are free to change size. Thermal radiation can also act from within a component. When timber is used externally it must be remembered that most species are susceptible to damage from prolonged exposure to sunlight. The ultraviolet radiation causes degradation of the surface, particularly of softwood species, which will affect the adhesion of paint and other finishes (1). Blistering, cracking, peeling and flaking of the paint coating, deterioration of stains or varnishes, resin exudation and the rot of the timber are the causes of the deterioration of the external wood doors.

3 A CASE STUDY: 1940 DATED WOODEN DOORS

Taşkışla building is approximately 140mx100m sized, and it has a 70mx40m sized main courtyard. There are also four other 9mx7m sized courtyards in the four 26mx20m sized towers of the building. Taşkışla Building has many obsolete parts and the sixteen external wood-frame doors of the south-west tower courtyard are some of them. These wood-frame doors are dated to 1944 and they are the doors which was studied. The damages that is determined about the external doors of the courtyard of Taşkışla can be categorized in three groups:

3.1 Damage of the Dye of the Doors

The dye of some different parts of the doors are cracked, expanded and spilled. The deterioration of the doors increases in the parts which are nearer to ground level (Figure 1a). The dye of the horizantal components are totally spilled (Figure 1b).

Figure 1. (a) The damage of the paints of the doors increases near to ground level
(b) All of the horizontal elements of the doors are damaged

3.2 Damages Of The Wooden Components Of The Studs

Damage of the wooden structural components can be categorized in two main groups: Decay of wood, especially in parts near to ground level (Figure 2). Surface and pattern deteriorations of wood which can be seen as dye is spilled (Figure 3a).

Figure 2. Decay in the components near to ground level.

Figure 3. (a) Damage on the surface of wooden components of doors.
(b) Deformation of door handle.

3.3 Damages Of The Accessories Of The Stud

Secondary structural components of the doors like hinges and door handles are deteriorated because of getting old. The connection of door handle to door has become loosen and deteriorated from its axe. The locking mechanism of some of the doors do not work and some of the doors can not be closed properly. Most of these doors are screwed to eachother. Some hinges are rusted and make sound while opening or closing (Figure 3b).

4 ANALYSIS OF CAUSE OF DAMAGES OF 1940 DATED EXISTING DOORS

At the end of this study, which is about the doors of the administrative tower of Taşkışla building, realistic results have been determined. The method of the study is; making an analysis which is based upon experience and comparing this analysis with other similar analysis about doors which are found from literature.

4.1 Damages Related With The Design Of The Doors

Water related agents, which are determined as the major damaging factors of doors, effect doors negatively because of the failures and deficiency about the design of them. The first failure about design of doors is about the shape of door sills which cover the intersection point of horizontal wooden components and glasses (Figure 4). Water related agents can not escape from these points easily and force intersection points and as time went by pass over these points and reach to the core of the wooden components which are not protected with paints.

The second failure about the design of doors is; the most near to ground level parts of doors, which lean on the doorsteps, was not designed water proof. Water related agents that pass the sills and that is pushed with the wind can not pass the intersection point of door and doorstep and accumulated in these points. The accumulated water demolished wooden components in time (Figure 5a).

The third failure about the design of doors is; the deterioration of the plumb line of doors (Figure 5b). One of the reasons of this situation is the wrong decision about the connection type of horizontal and vertical components. Another reason of this situation is about the sizes of horizontal wooden components. These elements are smaller than needed for the moment effect effecting the doors. Also the type of the wood of doors, which is determined as pine, may be a reason for this failure.

Figure 4. Failure about the design of the connection point of glass and wooden components of door

Figure 5. (a) Failure about the design of the connection point of doors and ground
(b) Failure about the plumb line of the door

4.2 Damages Related With the Production and Assembly

In this study, one sample door from each direction was disassembled in order to determine possible failures related with the assembly. With this experiment it was understood that doors are good examples of traditional wooden door craftsmanship. Every connection was made with tongue & grooves, wooden connectors & nails, and glue. No extra metal material is used and all the connections stayed tight. Further more, the cores of wooden studs are also stayed well. The middle horizontal wooden components and the surfaces are problematic parts but as doors are dated to 1950 and haven't had any maintenance, it can be said that they stayed well. The assembly of the doors with the walls were also examined but no failure could be observed (Figure 6, Figure 7).

Figure 6. Detail of wooden nail for connection of the stud

Figure 7. Detail of wooden connector for connection of the stud

4.3 Damages Related With the Environmental Effects

The effects of the environmental effects change according to the direction of the facades of the Taşkışla building's administrative courtyard, which is located in Istanbul, Sisli. Environmental effects can be categorized in two main groups; water related and sun related environmental effects. Water related environmental effects effect doors negatively because of the design failures which were discussed in section 4.1. but in addition to the information given in that section, it can be said that the negative effect of water related environmental agents increase on the south and north facing façade and decrease in the north and east facing façades as the dominant wind and rain directions in Istanbul is form north and south.

Another problem with the south facing façade is the direct sun light in the entire sunny days. Direct sun light effects firstly paint and then combining with water related agents decay the wooden components. The east and west façades also get direct sunlight but not for entire day and so they are not effected as bad as the south facing. The north facing façade is not effected negatively with the sun, as it does not get any direct sunlight (Figure 8).

4.4 Damages Related With the Usage

In order to analyze failures related with usage, the characteristics of the surrounding spaces of courtyard should be examined. Courtyard is surrounded by administrative rooms from north and west, a private restroom for lecturers from east and a hall to sit and rest, which is mostly used by lecturers, from north. Students usually use these places as a transition space, they rarely use to sit and rest, and they mostly use if they have something to do with administrators. So, the primary users of courtyard and surrounding places are lecturers and administrators. The interaction of them with these places can be categorized in two seasonal periods, winter and summer. In winter courtyard is usually not used and its doors are kept closed, whereas in summer courtyard is both used for sitting and resting and passing. On the other hand both in winter and summer, same doors of same facades are used which are; the doors in the middle of the south, east and west facing facades and the far eastern door of the north facing façade. In conclusion, the user profile of courtyard and surrounding places is mostly formed with lecturers which expose that a failure related with usage is hard to say.

Figure 8. Examples of doors looking different directions. From left to right; north facade, east facade, south facade and west facade. All the examples are the doors which is positioned in the middler of the facades. Doors belonging to north and east are the worst in condition, door of south facade have some painting related problems and door from the west facade is the best.

5 PROPOSALS FOR CURE

The proposals for cure, which are made considering their costs and application duration, are listed below:

The paint of all doors should be stripped or burnt off and the timber should be protected until it has dried out. But as it is not possible to leave the openings without a door until they are dried a micro porous paint can be applied to doors which would allow doors to dry while stop surface water entering the timber.

Condensation which occurs on the inner face of the glasses of doors should be prevented to enter the core of the studs. A bead seal of clear silicone sealant to BS 5889 type B can be used to avoid the condensation water enter the core. But the best solution for this problem is to stop condensation occur, for this the glasses of the doors may be changed with double glazed glasses.

Two common causes of blistering of paint finish are resin exudation from knots and resin pockets in the timber, and water vapors expansion from moisture in the timber. For the resin exudation, which will show as brown sticky resin or, when dried, as a whitish powder, then the cure is to strip affected areas and apply shellac knotting. An aluminum primer should be used before repainting, with a light color. If it is vital to avoid recurrence, the timber component should be replaced by one in a different species of timber, that contains less resin.

The treatment of timber with chemical preservatives, preferably through pressure impregnation, will protect it from both insect and fungal attack (1). The rotten parts of the wooden components of the doors must be cut out and replaced with preservative-treated timber, the new timber being spliced into the old or being fitted to replace complete sections. Adjacent timber can be injected with solvent based preservative or drilled and fitted with borax rods. When repairs are being undertaken, rebates and exposed and grain should be sealed with a primer coat.

6 CONCLUSION

Environmental agents, design, production and user behavior oriented damages, and absence of maintenance & repair program are the main reasons of failures in buildings. The failures should be correctly determined and effective precautions which will end the reasons of the failures should be

taken. It should always be kept in mind that diagnosis & cure of an existing product is a better approach, but costs and application duration of a diagnosis & cure process should be carefully examined and the product should be renewed as a last way.

Water and sun related agents are found out to be the reasons of the damages of the doors. Failures about the decisions that was made in the design process of the doors combined with the absence of a maintenance and cure program made the doors have damages. These failures made the paints of the doors demolish, wooden components of the doors decay, and accessories of the studs fray. Cure proposals were made according to the types of the failures.

In conclusion, in order to use building elements successfully, diagnosis and cure of them should be made periodically. The diagnosis and cure of building elements can be summarized as fallows: To avoid decay, these applications are used; using timbers of suitable durability or employ preservative treatment, any dowels used should be of a durable timber or pretreated with a water-repellent preservative, designing to avoid water traps and horizontal surfaces, avoiding jointed sills and bottom rails, sealing effectively all joints between components and the edges of plywood, using durable glues, not doing fit mortise locks in the region of a dowelled joint. If condensation has been the chief cause of decay then, apart from repairing the door frame, a drainage channel should be incorporated that will allow the condensation to drain to the outside. In situations where there is heavy moisture production, more ventilation and/or heat may be necessary in addition. For provision of a drainage channel in a timber door sill to reduce the risk of wood decay. If decay is localized, cut away the affected parts and renew them with preserved timber. Allow the timber to dry and then repaint. If decay is extensive, renew the door completely. It is important that any migration from the masonry to the timber frame is prevented.

ABSTRACT

Wood is a renewable, biodegradable and sustainable composite of cellulose, hemicelluloses, lignin, extractives and inorganics in a three-dimensional matrix. Nature is programmed to recycle it, in a timely way, back into its basic building blocks of carbon dioxide and water through biological, thermal, aqueous, photochemical, chemical, and mechanical degradations. The properties of wood are the result of the chemistry of its cell wall components and the matrix they are in. If the chemistry is changed at the molecular level, the properties change and performance changes. Based on performance requirements of wood, chemical modifications can be carried out to change properties and performance. Dimensional stability, resistance to decay fungi and destructive insects, as well as other positive performance improvements can be greatly increased by reacting wood with acetic anhydride (acetylation) resulting in a new generation of value added wood-based products that perform very well in adverse environments.

1 INTRODUCTION

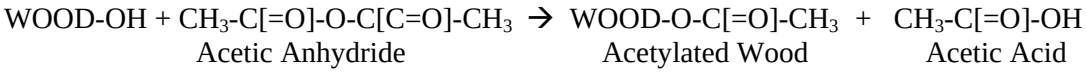
Wood changes dimension with changing moisture content because the cell wall polymers contain hydroxyl and other oxygen-containing groups that attract moisture through hydrogen bonding. The hemicelluloses are mainly responsible for moisture sorption, but the accessible cellulose, noncrystalline cellulose, lignin, and surface of crystalline cellulose also play roles. Moisture swells the cell wall which expands until it is saturated with water (fiber saturation point, FSP). Beyond this saturation point, moisture exists as free water in the void structure and does not contribute to further swelling. This process is reversible, and the fiber shrinks as it loses moisture below the FSP. Wood exposed to moisture frequently is not at equilibrium, having wetter areas and drier areas within the same board. This exacerbates the moisture problem resulting in differential swelling followed by cracking and/or compression set. Over the long term, wood undergoes cyclic swelling and shrinking as moisture levels change resulting in more severe moisture effects than those encountered under steady moisture conditions.

Wood is degraded biologically based on an organisms' ability to recognize a potential food source mainly in the carbohydrate polymers [primarily the hemicelluloses] in the cell wall and having both non-specific chemical and highly specific enzyme systems capable of hydrolyzing these polymers into digestible units. Biodegradation of both the matrix and the high molecular weight cellulose weakens the fiber cell wall. Strength is lost as the matrix and cellulose polymer undergoes degradation through oxidation, hydrolysis, and dehydration reactions. As degradation continues, removal of cell wall content results in weight loss. All of these biological reactions take place in a high humidity condition.

Wood exposed outdoors undergoes photochemical degradation caused by ultraviolet radiation. This degradation takes place primarily in the lignin component, which is responsible for the characteristic color changes. The surface becomes richer in carbohydrate polymer content as the lignin degrades. In comparison to lignin, carbohydrate polymers are much less susceptible to ultraviolet degradation. After the lignin has been degraded, the poorly bonded carbohydrate-rich fiber surface easily erodes which exposes new lignin to undergo further degradative reactions. In time, this "weathering" process causes the surface of the composite to become rough and can account for a significant loss in surface fibers.

2 CHEMICAL MODIFICATION

Chemical modification of wood has been used to improve performance properties of wood. Many chemical reaction systems have been published for the modification of wood, however, the reaction of wood with acetic anhydride has been the most studied. The reaction with acetic anhydride with wood results in esterification of the accessible hydroxyl groups in the cell wall with the formation of byproduct acetic acid [Hill, 2006, Rowell 1983, 1984, 2005, 2006]. The byproduct acid must be removed from the product as the human nose is quite sensitive to the smell of acetic acid. While this is easily done in the case of wood particles and fiber, it is somewhat difficult to do in solid wood.



Acetylation is a single-site reaction that means that one acetyl group is on one hydroxyl group with no polymerization. This means that all of the weight gain in acetyl can be directly converted into units of hydroxyl groups blocked.

All woods naturally contain acetyl groups. In general, softwood has an acetyl content between 0.5 to 1.5% and more durable hardwoods between 2 to 4.5%.

3 HISTORY OF WOOD ACETYLATION

The acetylation of wood was first done in Germany in 1928 by Fuchs using acetic anhydride and sulfuric acid as a catalyst. He found an acetyl weight gain of over 40% which meant that he decrystalized the cellulose in the process. He used the reaction to isolate lignin from pine wood. In the same year, Horn [1928] and Suida and Titsh [1928] acetylated beech wood to remove hemicelluloses in a similar lignin isolation procedure. In 1929, Suda and Titsch acetylated powdered beech and pine using pyridine or dimethylaniline as a catalyst and got an acetyl weight gain of 30 to 35% after 15 to 35 days at 100 ºC. In 1945, Tarkow first demonstrated that acetylated balsa was resistant to decay [Tarkow 1945]. In 1946, Tarkow, Stamm and Erickson first described the use of wood acetylation to stabilize wood from swelling in water. Since the 1940's, many laboratories around the world have looked at acetylation of many different types of woods and agricultural resources.

In spite of the vast amount of research on chemical modification of wood, and, more specifically, on the acetylation of wood, commercialization has not come easily, The first patent on the acetylation of wood was filed by Suida in Austria in 1930. Later, in 1947, Stamm and Tarkow filed a patent on the acetylation of wood and boards using pyridine as a catalyst. In 1961, the Koppers Company published a technical bulletin on the acetylation of wood using no catalysis but with an organic cosolvent [Goldstein et al. 1961, Dreher et al. 1964]. In 1977, in Russia, Otlesnov and Nikitina came close to commercialization but the process was discontinued presumably because it was not cost-effective. In the late 1980's, Daiken, in Japan, started a small commercial production of acetylated wood for flooring called alpha-wood that is still in production today.

There is one large commercial-scale production facility of acetylated wood today. It is produced by TitanWood in The Netherlands [www.titanwood.com] at an expanding 30,000 m^3 pa plant capable of acetylating lumber up to 100mm thick Their technology is being used to build additional facilities with capacities in excess of 100,000 m^3pa each.

5 PRODUCTION OF ACETYLATED WOOD

In large scale production of acetylated wood, lumber is stickered and placed in a high pressure vessel using advanced handling equipment for efficiency. Acetic anhydride is introduced into the vessel and the temperature raised to the reaction temperature. Pressure is applied as needed. After the reaction is complete, the excess anhydride is recycled and the by-product acetic acid is processed back into anhydride. The acetylated wood is then dried, removed from the vessel and stored until shipment. The entire process has minimal by-products which have ready end-uses and is environmentally benign. When combined with the use of sustainable grown wood from certified sources as input, acetylated woods provide and improved building material that address a range of environmental factors.

6 PROPERTIES OF ACETYLATED WOOD

The properties presented in this paper are mainly a combination of results on southern yellow pine, aspen, radiata pine, poplar, beach and birch, demonstrating that wood acetylation properties apply to a range of species.

6.1 Volume Changes

Table 1 shows the increase in volume of pine after reaction with acetic anhydride and the calculated volume of chemical added to the cell wall after re-drying the wood. Since the volume increase due to reactions with acetic anhydride is equal to the calculated volume of chemical added, this shows that the reaction has taken place in the cell wall and not in the void spaces of the wood.

Table 1. Changes in pine volume and volume of chemical added as a result of chemical reactions.

WPG[1]	Increase in wood volume[2]	Calculated volume of added chemical[3]
17.5	3.0	2.9
22.8	3.9	4.0

[1] Weight Percent Gain [2] Difference in oven-dry volume between reacted and non-reacted wood.
[3] Density used in volume calculations: acetic anhydride 1.049

There is a change in color due to acetylation. Light colored woods tend to darken slightly while dark colored woods become slightly lighter.

6.2 Acetyl Stability

Table 2 shows the stability of acetyl groups in southern yellow pine and aspen to cyclic exposure to 90% and 30% relative humidity [RH] [Rowell et al. 1992]. Each cycle represents exposure for three months at 30% RH and then three months at 90% RH. Within experimental error, there is no loss of acetyl over 41 cycles of humidity changes.

Table 2. Stability of acetyl groups in southern yellow pine and aspen flakes after cyclic exposure between 90% relative humidity [RH] and 30% RH.

Wood	Acetyl content [%] after cycle [number]				
	0	13	21	33	41
Pine	18.6	18.2	16.2	18.0	16.5
Aspen	17.9	18.1	17.1	17.8	17.1

This data was collected starting in 1992 and this experiment has continued to this day. After more than 20 years of cycling these samples from 30 to 90% RH, analysis shows that there is still no loss of acetyl resulting from humidity cycling and thus other benefits reviewed below are likely to, or have been proven in separate field tests, to be ongoing as well.

6.3 Moisture Properties and Dimensional Stability

By replacing some of the hydroxyl groups on the cell wall polymers with bonded acetyl groups, the hygroscopicity of the wood material is reduced. Table 3 shows the fiber saturation point for acetylated southern yellow pine and aspen. As the level of acetylation increases the fiber saturation point decreases in both the soft and hard wood.

Table 3. Fiber saturation point for acetylated southern yellow pine and aspen.

WPG	Pine [%]	Aspen [%]
0	45	46
6	24	--
8.7	--	29
10.4	16	--
13.0	--	20
17.6	--	15
18.4	14	--
21.1	10	--

Figure 1 shows the sorption isotherm of control Pine and acetylated Pine. The lower curves are for the acetylated pine shows much lower moisture content at a given relative humidity as compared to non-acetylated pine.

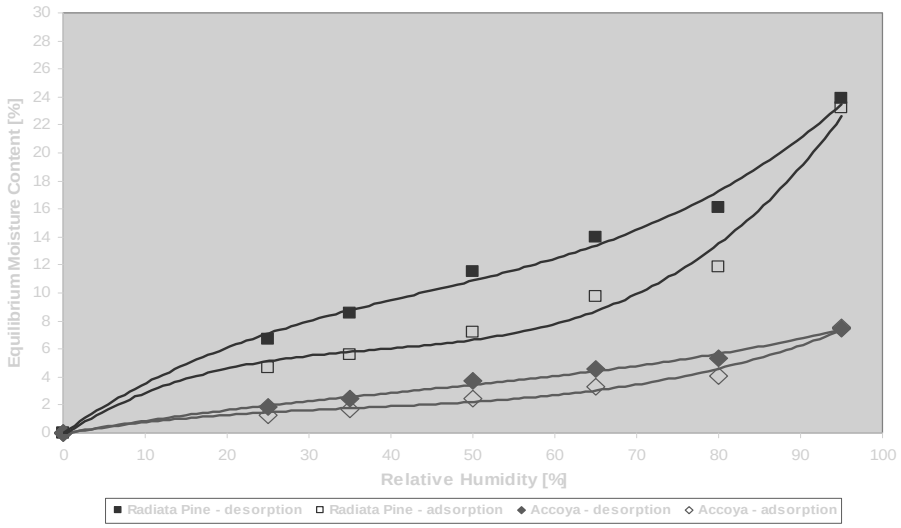


Figure 1. Sorption isotherm of control and acetylated pine.

Table 4 shows the equilibrium moisture content [EMC] of control and acetylated pine and aspen at several levels of acetylation and three levels of relative humidities. In all cases, as the level of chemical weight gain increases, the EMC of the resulting wood goes down.

Table 4. Equilibrium moisture content of acetylated southern yellow pine, aspen and radiata pine.

Specimen	WPG	Equilibrium Moisture Content at 27 ºC		
		30%RH	65%RH	90%RH
Southern Yellow Pine	0	5.8	12.0	21.7
	6.0	4.1	9.2	17.5
	10.4	3.3	7.5	14.4
	14.8	2.8	6.0	11.6
	18.4	2.3	5.0	9.2
	20.4	2.4	4.3	8.4
Aspen	0	4.9	11.1	21.5
	7.3	3.2	7.8	15.0
	11.5	2.7	6.9	12.9
	14.2	2.3	5.9	11.4
	17.9	1.6	4.8	9.4
Radiata Pine	0	5.1	11.9	22.2
	15	2.3	5.4	10.6
	20	2.2	4.1	8.7

Dimensional stability is recorded as antishrink efficiency [ASE] [Stamm 1964]. It is calculated as:

$$S = \frac{V2 - V1}{V1} \times 100$$ [S = Swelling coefficient; V1 = Volume dry; V2 = Volume wet]

$$ASE = \frac{S1 - S2}{S1} \times 100$$ [S2 = Acetylated; S1 = Control]

Figure 2 shows the reduction in swelling in control and acetylated pine. The un-acetylated pine shows much greater shrinkage especially in the tangential direction as compared to acetylated pine. Less shrinkage is observed in the radial direction.

Table 5. Dimensional stability of acetylated southern pine.

WPG	ASE
10	35
15	55
17	63
20	72

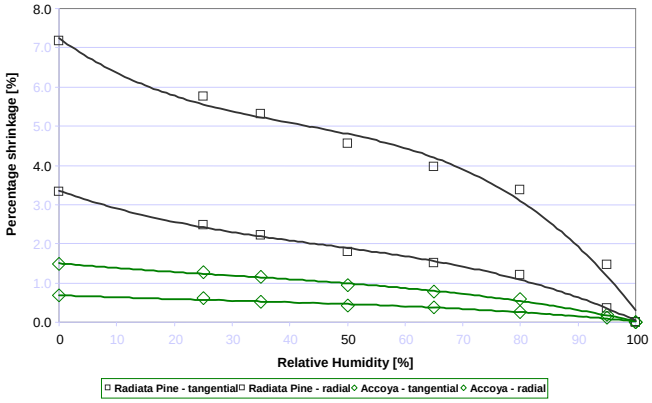

Figure 2. Reduction in shrinkage in radiata pine.

6.4 Resistance to Biological Attack

6.4.1 Fungi

Various types of solid wood, particleboards and flakeboards made from acetylated wood have been tested for resistance to several different types of organisms [Imamura et al. 1987, Rowell et al. 1987, 1989, 1997, Beckers et al. 1994, Militz 1991, Wang et al. 2002].

Acetylated radiata has been tested against several types of decay fungi in an European Union standard [EN 113] decay test using the brown rot fungus *Gloeophyllum trabeum* and white rot fungus *Coriolus versicolor*. Table 6 shows the resistance at several levels of acetylation to attack by brown- and white rot fungi. As the level of acetylation goes up, the resistance to attack goes up.

Table 6. Resistance of southern yellow pine against fungi.

WPG	Weight Loss After EN 113 test	
	Brown-rot Fungus	White-rot Fungus
[%]	[%]	[%]
0	58.8	7.3
6	32.7	4.1
10	6.3	2.2
15	2.7	<2
20	<2	<2

Another test for fugal and bacterial resistance that has been done on acetylated composites is with brown-, white-, and soft-rot fungi and tunneling bacteria in a fungal cellar. Control blocks were destroyed in less than 6 months while samples made from acetylated wood above 16 WPG showed no attack after 1 year. [Nilsson et al. 1988, Rowell et al. 1988]. This data shows that no attack occurs until swelling of the wood occurs [Rowell et al. 1988]. This fungal cellar test was continued for an additional 5 years with no attack at 17.9 WPG. This is more evidence that the moisture content of the cell wall is critical before attack can take place [Ibach and Rowell 2000, Ibach et al. 2000].

In-ground tests have also been done on acetylated solid wood and flakeboards [Rowell et al.1997, Larsson Brelid et al. 2000]. Specimens have been tested in the United States, Sweden, and New Zealand . The specimens in test in Mississippi are showing little or no attack after 10 years.

Acetylated fiberboards in three in-ground locations in Gulf Port, Mississippi show no attack after 14 years. Recent results show that acetylated pine at a WPG of 21.2 is outperforming CCA [copper-chromium-arsenic] at 10.3 kg/m^3 after 8 years in test in Sweden [Larsson Brelid et al. 2000].

Table 7. Fungal rating data on control and acetylated stakes in Gulf Port, Mississippi test plot.

WPG	Rating at [years]									
	1	2	3	4	5	6	8	10	12	14
0	3	4	--							
20	0	0	0	0	0	0	0	0	0	0
Rating system: 4=Destroyed, 3=Badly attacked, 2=Some attack, 1=Evidence of attack, 0=No attack										

6.5 Other Properties

6.5.1 Strength

Table 8 shows the bending stiffness [MOE] and bending strength of [MOR] of acetylated radiate pine. The table shows strength properties are retained even after of acetylation.

Table 8. Bending stiffness [MOE] and bending strength of [MOR] of control and acetylated radiata pine.

Specimen	Density [Kg/m^3]	Moisture [%]	MOE [N/mm^2]	MOR [N/mm^2]
Radiata Pine	417	12.2	9664	43
Acetylated Radiata Pine	492	5.2	8788	39

6.5.2 Hardness

Table 9 shows the Janka hardness of acetylated and control radiata pine. Acetylated radiata is much harder in all directions as compared to unacetylated pine but this is partly due to the lower moisture content of compared to unacetylated radiata pine.

Table 9. Janka hardness of samples according to ASTM D143.

Specimen	Density	Moisture Content	Janka hardness ASTM D143		
			Radial	Tangential	End Grain
	[Kg/m^3]	[%]	[N]	[N]	[N]
Radaita Pine	479	12.1	2750	2748	3637
Acetylated Radiat	521	4.2	4046	4187	6595

6.5.3 Machinability

In general, acetylated wood has the same machining properties [sawing, planing, drilling, routing] as unacetylated wood. Gluing and coating properties are also similar to unacetylated wood using the present industrial gluing and coating systems. Due to the dimensional stability of wood acetylated to its core, coatings typical have a life of 2-3 times that of control samples.

The surface of acetylated wood after planing is smoother than unacetylated wood resulting in less sanding before coating application.

7. PRODUCTS IN TEST AND APPLICATION

Acetylated wood has been in commercial use for several years. As an early test acetylated poplar was placed in test in the walls of one of the canals in The Netherlands [Figure 4 (left)]. After 13 years it was removed and determined to have minimal damage due to UV or biological degradation Figure 4 (right).

Figure 4. Acetylated poplar in test in a canal [left]
and the sample after 13 years [right].

Leading applications of acetylated wood include use in windows doors, siding, decking, and exterior load-bearing glulam beams for buildings, bridges and other structures. Acetylated pine is now being used by many manufacturers for windows and doors [Figure 5] in the European market.

Figure 5. Examples of acetylated wood applications.

Acetylated wood has also been successfully tested for use in load-bearing glulam structural beams for multiple purposes. As an example, two 40 meter long heavy road traffic bridges are currently under construction in Sneek, Netherlands due for completion in 2009.

All beams have been produced for the projects. This following extensive testing for the application by leading independent institutes. Laminated beams up to 1080 x 1400 mm were produced. Superior strength-to-weight, durability, dimensional stability and low maintenance costs were cited as reasons for selection.

8 CONCLUSIONS

Acetylation of both softwoods and hardwoods gives a product which has a very high degree of dimensional stability and durability. Strength properties and hardness are not reduced. This technology provides an environmentally safe method of protecting sustainable common woods to give a new generation of value-added products with increased stability and durability without the use of toxic chemicals. This method can take stress off of endangered tropical hard wood species that have been the traditional means of meeting durability requirements.

Development of an Automated Artificial Ageing Test Apparatus for Sealants and Comparison with Outdoor Exposure Testing

Hiroyuki Miyauchi [1]
Yoshiaki Takemoto [2]
Michael A. Lacasse [3]
Kyoji Tanaka [4]

T 14

ABSTRACT

The long-term performance and degree of deterioration of sealants due to ageing effects is currently evaluated using artificial accelerated test methods such as those described in JIS A 1415. However, there are many issues related to correlating the deterioration of sealants subjected to outdoor tests that are not yet resolved. In this study, a computer-controlled, automated artificial ageing test apparatus was developed that subjected sealants to a deterioration process similar to exposure outdoors. Three kinds of sealant product were selected: a 1-component modified silicone, a 2-component modified silicone, and a 1-component polyurethane, all manufactured in Japan. Outdoor environmental data was collected over one year that included, joint movement of the dynamic outdoor exposure test apparatus and specific weathering factors such as temperature of the sealant, and quantity of solar radiation and rainfall at the exposure site. The data acquired from the outdoor test was simultaneously transferred to the artificial ageing test apparatus. As a result, the movement, temperature, total radiation and wetting conditions of the artificial ageing test were nominally the same as those extracted from the outdoor test with the exception of the wavelength distribution for solar radiation. Comparing results of the deterioration of the sealant, the artificial ageing test apparatus offered a high degree of correlation to results obtained in outdoor tests for both of the modified silicone products but not for the polysulphide product. The results suggest that the development of the proposed indoor test using the automated artificial accelerated test method appears promising given the degree to which results can reproduce those obtained from ageing sealant products outdoors.

1 INTRODUCTION

Factors causing the deterioration of construction sealants may be classed as, e.g., weathering, i.e. due to ultraviolet radiation, temperature and rainfall, and due to movement, that occurs by the behaviour of external walls to solar radiation [Wolf 1990; Wolf 1996]. Evidently these are the most significant factors that influence the performance of sealants over time [Wolf 1999]. Typically it is necessary to evaluate the durability of sealant products by testing before the sealant is used in building construction. At present, a dynamic outdoor exposure testing apparatus has been used at an outdoor exposure test site in Japan that provides information on the simultaneous deterioration due to weathering and movement [Enomoto et al. 2006a; Enomoto and Tanaka 2007]. However, outdoor exposure tests take considerable time to perform since the deterioration of sealants in such tests occurs in real time and from natural environmental conditions.

On the other hand, it is of evident practical importance to evaluate the durability and deterioration of sealants using test that can be completed in a short period of time and in this context, various artificial weathering tests have previously been developed and carried out in Japan [Ito et al. 2004; Miyauchi et al. 2004]. However, being able to provide verification that results derived from outdoor exposure tests reasonably correlate to those from accelerated weathering test remains a significant research issue and a challenging task and despite the fact that a number of studies have been carried out on resolving issues regarding correlation of outdoor and accelerated weathering test results [Beasley 1996; Wolf et al. 1999; Enomoto et al. 2006b].

Various studies have been carried out to investigate the durability of sealed joints against joint movement of external walls in Japan and from these fatigue tests for sealants have been developed [Matsumoto et al. 1981; Koike et al. 1983; Miyauchi and Tanaka 2004]; this highlights the importance of joint movement in the durability of sealed joints. Hence, when considering an accelerated weathering test for sealants, it is necessary to include movement in the weathering test and to match the movement conditions with those that may be derived from the outdoors. However, it is very difficult to evaluate the deterioration of sealants using an accelerated weathering test method without outdoor test data that can be used as a basis of correlation. Therefore, in was considered that for the first stage of this study, the deterioration effects used in the artificial weathering test and their rate of application would be the same as that of the outdoor test such that the deterioration of sealants subject to both tests could be compared and the results correlated. Thereafter it is supposed that the accelerated weathering test method can be used to evaluate the deterioration of sealants given the relationships derived from correlation between test methods.

Hence, for this study, a dynamic outdoor exposure apparatus incorporating an integral joint movement system was used in outdoor exposure test [JSIA 2004] and a prototype, computer-controlled, automated artificial test apparatus was developed that permitted subjecting sealant products to a deterioration process that was similar to that obtained from outdoor exposure. Using both apparatus, the condition of sealants exposed to outdoor and artificial (indoor) testing was compared by visual observation, and by observation with a light microscope.

2 OUTLINE OF TEST METHOD FOR THE DETERIORATION OF SEALANTS

2.1 Deterioration Factors and Method of Evaluation of Sealants

There are several factors that cause deterioration in sealants however, of these factors, those selected as the basic test parameters for weathering included: solar radiation, temperature, moisture and the expansion–contraction brought about by joint movement. Figure 1 shows the basic notions from which was developed a method for the performance evaluation of sealants based on artificial deterioration of products combined with outdoor environmental conditioning. First of all, environmental factors causing deterioration are divided into two components: (i) weathering effects, i.e. effects such as total

solar radiation, material temperature, and moisture, and (ii) movement. Both these set of factors are measured by the dynamic outdoor exposure testing apparatus as shown in Figure 2. Next, the data obtained from the outdoor exposure testing apparatus in respect to the test parameters are input to instruments on the artificial test apparatus (fabricated by TiTech*) and are automatically synchronized to the outdoor conditions. The sealant surface conditions showing deterioration as characterised by both visual observation and observation by light microscope, permitted correlating results derived from either test method. Tests were carried over a 1-year period under two conditions: weathering alone and combined weathering and movement.

2.2 Test Specimen

Three kinds of sealant products were selected as shown in Table 1. The tensile testing was carried out in accordance with conditions specified in JIS K 6251 [2004] and the test specimens were prepared with a

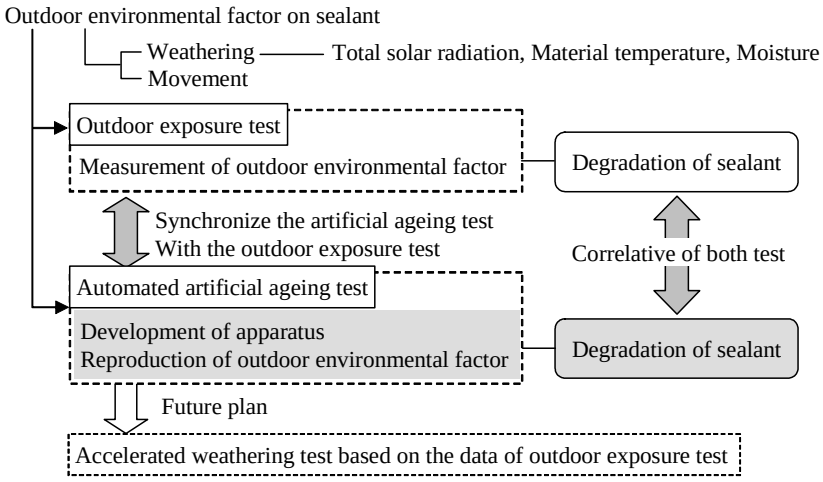

Figure 1. Artificial ageing test philosophy synchronized outdoor environmental condition

* TiTech – Tokyo Institute of Technology, Yokohama, Japan

joint width and depth of 12 mm, conforming with conditions specified in ISO 13640 [1999]. The sealant
was cured in accordance with conditions specified in JIS A 5758 [2004]. The surface of PU-1 was not painted to evaluate the deterioration condition of the sealant in the short term.

2.3 Dynamic Outdoor Exposure Test

2.4.1 Dynamic Outdoor Exposure Testing Apparatus

The dynamic outdoor exposure testing apparatus, shown in Figure 2, is able to evaluate the influence of weathering and joint movement on sealants. It is composed of a steel frame of white colour and a black coloured acrylic board. The joint movement occurs by virtue of the difference between the coefficients of linear thermal expansion of the steel frame as compared to the acrylic board.

2.4.3 Method of Measuring Outdoor Environmental Data

Total horizontal solar radiation was measured by installing a pyranometer (wavelength: 305-2800 nm) in front of the test apparatus. The surface temperature of the sealant was measured with a thermocouple embedded in the sealant 1-mm from the surface. Joint movement of test specimen was measured and calculated as follows: (i) The joint movement between the fixed and the movable structural member of the test apparatus was measured with a displacement sensor; (ii) The movement of the test specimen was calculated considering the measured value of displacement and the length of an acrylic board. The displacement sensor is protected with a metal cover to avoid the effects of solar radiation and rainfall. The presence of rainfall was measured with the rainfall sensor that made the principle of the difference of the electrical resistance between metallic needles. The amount of ultraviolet radiation was measured with a portable type UV dosimeter (UV-A type sensor).

3 OVERVIEW OF AUTOMATED ARTIFICIAL AGEING TEST APPARATUS

3.1 Method to Deteriorate Sealants

The automated artificial ageing test apparatus is shown in Figure 3 and in Figure 4, the method for installing test specimens and the measurement-control method for the test apparatus is provided. This test apparatus operates by a purposely designed control program, that is synchronized to the dynamic outdoor exposure testing apparatus.

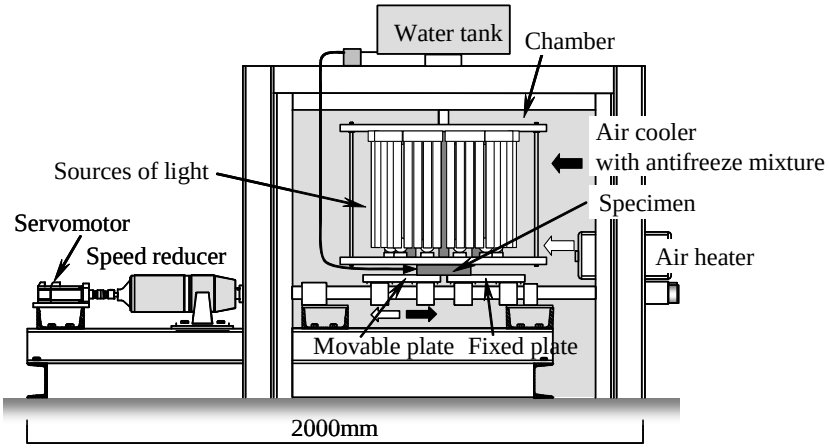

Figure 3. Artificial wweathering and movement apparatus (Side view)

Solar radiation in the apparatus was recreated using three sources of radiation each providing for different wavelength spectrums; the ultraviolet region was re-created using a black light, the visible region with a fluorescent lamp, and the infrared region re-created with a high-intensity filament lamp. The spectral irradiance of sunlight was used as reference. Given that the spectral irradiance differs is

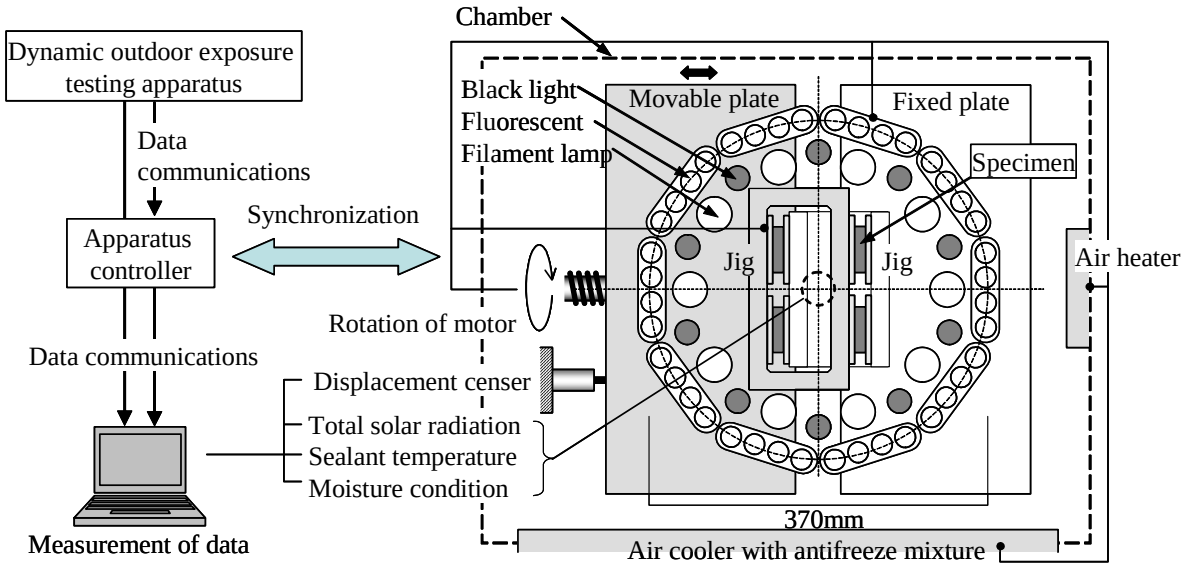

Figure 4. Specimen arrangement details and method of controlling deterioration factors
（Only the specimen given movement is shown in the figure.）

according to specific weather conditions, the amount of irradiation from the artificial light sources was controlled by measuring the total solar radiation obtained from the pyranometer attached to the dynamic outdoor exposure testing apparatus. The quantity of total solar radiation for each weather condition was re-created by changing the number of operable sources of artificial light. The temperature condition within the apparatus was based on the surface temperature of the sealant in the outdoor test apparatus. A heating-cooling system was used to maintain the specified temperature in the test chamber. Distilled water contained atop the apparatus in a water tank was the source of moisture used to wet the sealant surface; water was admitted via a solenoid valve through a silicon tube to the surface of the sealant as required to provide the wet conditions. A servomotor and the movable plate connected to the motor controlled joint movement. Joint movement was measured with a displacement sensor installed on the moveable plate; monitoring the movement permitted synchronization of joint movement to that of the dynamic outdoor exposure testing apparatus.

3.2 Testing Period and Condition

The testing period was one year (May 18, 2005 - May 17, 2006) and the deterioration in the surface condition of the sealant was investigated after 3, 6 and 12 months exposure. Test specimens were exposed to two (2) types of deterioration effects: weathering and the combined effects of weathering and movement. The temperature condition when initiating the test influences the behaviour of the expansion-contraction joint movement after the test. In this research, the temperature at the reference position (0 mm) was 20 °C, and the test started when the temperature was 20 °C on May 18th at 17:00 hrs. The data from both the outdoor and artificial deterioration tests were recorded every ten minutes.

3.3 Measurement Result of Outdoor Exposure Test

Figure 5 shows the results of measurement of relevant climate data and joint movement for a one year period using the dynamic outdoor exposure testing apparatus. The quantity of total solar radiation is relatively high from spring to summer, reaching a maximum of 0.97kW/m^2 on the 25th and 27th July, 2005. The highest sealant surface temperature was 61.4 °C on 27 July, 2005 and the lowest surface temperature was -6.6 °C obtained on 24 January, 2006. The maximum difference in sealant surface temperature over one year was 68.0 °C. In regard to the moisture condition on the sealant surface, considerable amounts of rain fell over the rainy and the typhoon season. The maximum value of joint movement in compression was -4.35 mm on 27 July, 2005 and the minimum value in expansion was 2.12 mm, occurring on 24 January, 2006. These results indicated that there was direct correlation

between the temperature and joint movement; the higher the temperature, the smaller the joint opening. Given that the joint movement for the "zero-point" was calibrated at a temperature of 20 °C, the degree of movement in compression was larger than that in extension.

4 REPRODUCIBILITY OF DETERIORATION EFFECTS OF TEST APPARATUS

Figure 6 provides a comparison between results of test conditions obtained from the automated artificial ageing test apparatus (indoor) and the dynamic outdoor exposure testing apparatus. Comparative information over the test period (11 to 17 August, 2005) is provided in regard to total solar radiation ($kW \cdot m^{-2}$), ultraviolet radiation ($W \cdot m^{-2}$), sealant surface temperature (°C), surface moisture condition (rain or dry), and joint movement (mm). It can be observed that the amount of ultraviolet radiation from the artificial ageing test apparatus is smaller than that derived from the outdoor exposure test and consequently, the UV-radiation spectrum from the artificial test does not completely recreate that of the outdoors.

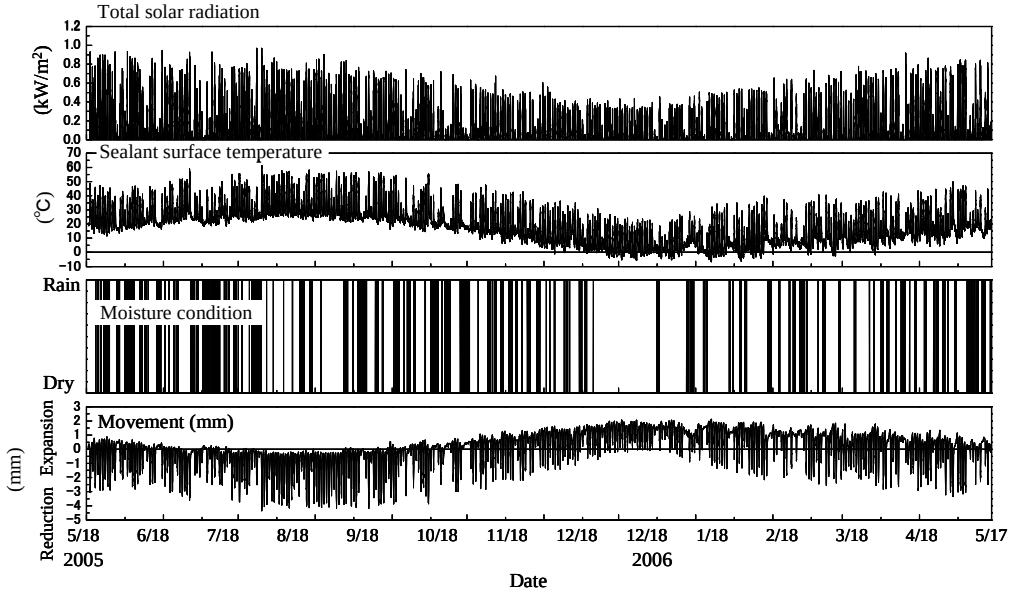

Figure. 5 the Results of meteorological observation and movement occurred in joint for 1 year (2005.5.18 – 2006.5.17)

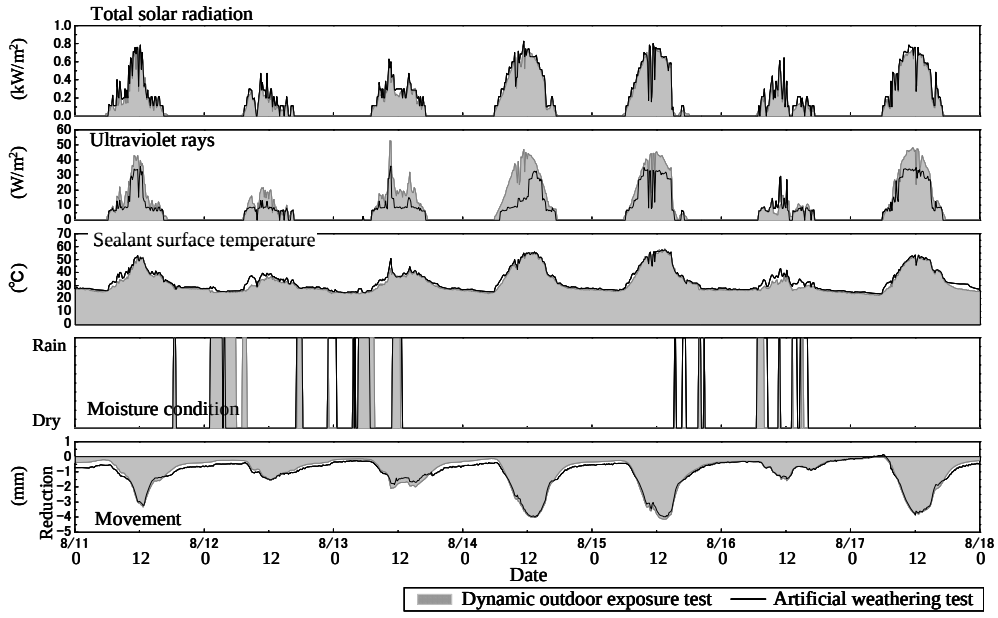

Figure.6 comparison of artificial weathering test and dynamic outdoor exposure test (2005.8/11～8/17)

5 COMPARISON OF SEALANT DETERIORATION FROM BOTH TESTS

5.1 Method of Observation for Surface Cracks on Sealants

The presence of surface cracks on sealants was investigated by two methods: that observed by using a digital camera (visual) and that with the use of an optical microscope having an attached digital scanning instrument. The detection of the presence or absence of cracks on the surface of the sealant with the optical microscope was determined by visual observation with the same magnification. The differentiation between areas having or not having cracks was determined using a light-contrasting binarization technique in which areas containing cracks appeared black and those not having cracks white in colour.

5.2 Result of Observations of Surface Cracks of Sealants

Table 2. The crack condition of sealants

Sealant	*Term (month)*	*Weathering*		*Weathering + Movement*	
		Outdoor	*Indoor*	*Outdoor*	*Indoor*
MS-1	12	12mm No crack	No crack		
MS-2	3	No crack	No crack		
	6				
0.1 0.5mm	12				
PU-1	3		No crack		No crack
	6		No crack		No crack
0.1 0.5mm	12				

Table 2 shows the sealant crack condition for the three (3) sealants investigated (i.e. MS-1; MS-2; PU-1), the upper most set of digital photographs for MS-1, and those of sealants MS-2 and PU-1, characterised by binary imaging, provided in the lower two sets of images. The images in all three sets are those taken of the surface of the respective sealant products following exposure to outdoor testing and the corresponding artificial ageing test (indoor) for three (3), six (6) or twelve (12) months. The test results are arranged such that images can be compared between products having been subjected to only “weathering” or with “weathering and joint movement” combined.
In regard to product MS-1, large cracks occurred to same degree in the sealant specimens exposed to the “weathering and movement” conditions of both test apparatus; that is, the crack depth on the

surface of sealants exposed in the outdoor test was 6.5 mm and for the artificial (indoor) ageing test, 5 mm. For product MS-2, the small cracks on the surface of sealants subjected to "weathering" conditions alone occurred with both test apparatus after 6 months exposure and only after 3 months when subjected to combined "weathering and joint movement". However, larger crack sizes were evident for the same sealant exposed to the dynamic outdoor exposure testing procedure as compared that of exposure to the artificial (indoor) ageing test. For product PU-1, the surface cracks occurred after 3 months of dynamic outdoor exposure testing, whereas this occurred after 1 year for the same sealant subjected to the artificial ageing test.

5.3 Correlation of Dynamic Outdoor Exposure Testing and Artificial Ageing Test

The degree of surface crack formation of sealants subjected to the combined action of "weathering and movement" occurs earlier than those subjected to "weathering" alone. Hence the results of tests on MS-1 suggest that the joint movement has a significant influence on the occurrence of surface cracks of this product. Additionally, and most significantly, it was observed that the surface crack pattern of sealants changed from a generalised random cracking (crazing) to a series of parallel cracks by the influence of joint movement.

From a comparison of results of the sealant crack condition derived from the two test methods, it appears that the degree of factors casing deterioration in the artificial ageing test is slightly less important than that achieved with the dynamic outdoor exposure testing apparatus. It was surmised that the reason for the differences between test methods were most likely due to the influence of ultraviolet rays, specifically, the difference in UV-spectrum between outdoor and artificial ageing methods. However, other factors might also be considered to influence ageing results; e.g., the harmful effects of gas and that of acid rain. In the future it will be useful to further examine the influence of different factors causing deterioration in sealants by combining the lesser effects with the effect of UV radiation.

Additionally it would be useful to test different types of products not as susceptible to deterioration from joint movement given that for product MS-1, the influence of joint movement on the formation of cracks was clearly evident. However, it was not easy to discern differences in the degree of deterioration achieved using either test method on the basis of results of tests on this product.

Nonetheless, the results suggest that the test method that incorporates both "weathering and joint movement" best recreates outdoor exposure and hence most closely replicates natural exposure conditions.

6 CONCLUSIONS

The following conclusions were obtained.

(1) The sun light spectrum of the artificial ageing test differs from the dynamic outdoor exposure test, the difference, in particular, being the ultraviolet radiation spectrum of the artificial ageing test. However, the total solar radiation, sealant surface temperature and moisture condition from the outdoor environmental conditions were readily replicated in the artificial ageing test apparatus..
(2) The surface crack condition for the PU-1 sealant product when subjected to the artificial ageing test was different than that of the same product exposed to the dynamic outdoor exposure test, however, the surface crack condition of sealant products MS-1and MS-2 resulted in nominally the same conditions from the artificial ageing as compared to that of the outdoor exposure test.
(3) The degree of crack propagation in similar sealant products occurs earlier in those sealants subjected to the combined action of weathering and joint movement as compared to those subjected to weathering alone.

Quantification of Effect of Dynamic Movement for Weatherability of Construction Sealants

Noriyoshi Enomoto [1]
Kyoji Tanaka [2]

T 14

ABSTRACT

Construction sealants are materials that ensure the waterproofing function of external joints of building, and the weatherabilty of sealant is a very important performance to sustain the functional performance of the joint. Sealant deterioration is a complex phenomenon influenced by factors such as joint movement and environmental agents whose intensity depends on the regional climate. Though many studies related to the weatherability of sealants have previously been completed, the evaluation of the surface degradation of sealants requires quantitative performance criteria. Prior to this study, a new type of test specimen was developed to assess the weatherabilty of sealants. The configuration of the test specimen is such that extension and of the joint can be applied continuously on a single specimen. For the quantitative evaluation of the surface degradation of sealants an equation based on the ISO 4628 assessment criterion was used. The approach adopted in this study for the quantitative evaluation of sealant degradations due to weathering thus included the new test specimen configuration and the ISO assessment method. The weatherability of sealants was considered to be composed of three factors: degree of degradation in the static conditions: increased rate of degradation due to joint movement, and: effects of environmental agents derived from the regional climate to which the sealant is exposed. In this study, eight sealants, commercially available in Japan, were subjected to a 4-year weathering test program carried out in the Yamanashi Prefecture, Japan. The exposure of sealants in this location was intended to exclude the effects of regional environmental factors on the degradation of the sealants. A functional equation is proposed that gives a surface degradation index of sealants subjected to static and dynamic conditions after a given exposure time. The following results were obtained in regard to the deterioration of sealants subjected to this weathering test program: silicone sealants did not deteriorate, though modified silicone sealants deteriorated slightly in static conditions. The degradation was greatly accelerated by adding joint movement. The degradation of polyurethane sealants was less influenced by joint movements as compared to the degradation of other types of sealant evaluated in this study.

1 INTRODUCTION

Construction sealant is the material used to maintain the waterproof and airtight functions over the long term, and the weatherability is an important performance criterion for maintaining these functions. Though the degradation of sealants in the outdoors proceed by UV irradiation, heat, water and many factors in general, the dynamic movement to which the sealant is exposed in actual joints accelerates the degradation. Many reports concerning outdoor exposure test employing testing device providing dynamic movements have been published, but there were usually large devices and only a limited number specimens could to be attached to them. [Matsumoto & Ono 1981][Koike & Tanaka 1983] This report presents information on the weatherability of construction sealants based on a newly developed test specimen [Enomoto & Tanaka 2006] that allows simultaneous exposure of the sealant to forced movement and outdoor environment.

2 TEST PROCEDURES

2.1 Sealants and Test Specimen

Eight commercially available sealants (see Table 1), typically used in Japan , conforming to JIS A 5758 [2004] and tested in accordance with JIS A 1439 [2004], were used to carry out the exposure test.
The configuration of the test specimen that enabled exposure of the sealant to continuous degrees of extension and compression in a single specimen is shown in Figure 1.

Table 1. Sealants tested.

Sealant	Mark	Physical Properties*		
		50%M (N/mm2)	Tensile Strenght (N/mm2)	Elongation (%)
2 part Silicone	SR-2	0.14	0.81	1170
2 part Polyisobutylene	IB-2	0.11	0.38	490
2 Part Modified silicone (General Purpose type)	MS-2(GP)	0.13	0.49	550

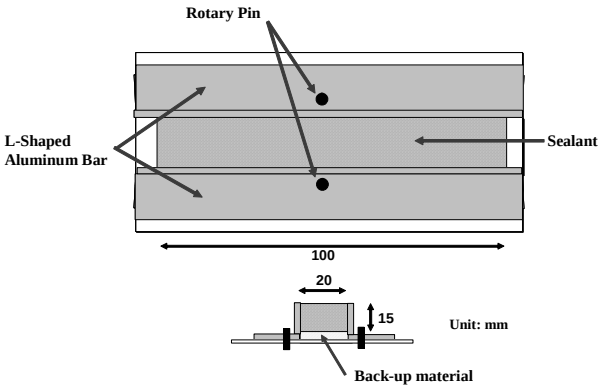

Figure 1. Test specimen.

2.2 Outdoor Exposure Conditions

The exposure test was carried out at one single site of Yamanashi Prefecture, located in central Japan. The choice of this exposure location permitted excluding variations in regional exposure factors. The exposure conditions and a summary of the weather at the exposure site are given in Table 2 and 3 respectively. The test specimen was exposed to both static and dynamic conditions, i.e. the static condition was without movement and the dynamic condition exposed the specimen to extension and compression cycle that were periodically reversed twice every week. The evaluation of surface degradation on the specimen was determined at four locations: i.e. for the static specimen, at ±0% movement amplitude, and: for the dynamic specimen, at ±1.5%, ±15% and ±25% movement amplitude as shown in Figure 2. The centre of the dynamic specimen was exposed to a movement of ±1.5% due to the gap between the rotary pin and the edge of the specimen.

Table 2. Exposure conditions

Location of exposure	Term of exposure	Direction/Angle	Interval of extension/compression exchange	Position of evaluation
Yamanashi Pref., Japan	2003.01.16 – 2007.01.15	South/30°	* Non (Static) * Twice/week (Dynamic)	* ± 0% * ± 1.5% * ± 15% * ± 25%

[Extension/Compression: Non] [Extension/Compression : Twice/week]

Figure 2. Evaluation position of test specimen.

3 EVALUATION

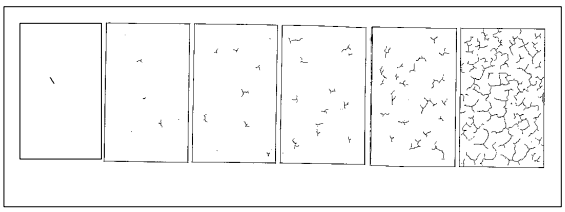
3.1 Determination of Degradation

The determination of the degradation was based on the rating scheme provided ISO 4628-4 [2003] with additional rating criteria introduced to determine the influence of minute cracks on the surface of the sealant. (see Table 4 – indicated by Italic letters, and Figure 3)

Table 4. Crack Rating index.

Rating	Quantity of cracks (Q)	Rating	Size of cracks (S)
0	None	0	*Not visible × 100 magnification*
0.5	*Trace*	*0.3*	*Only visible under magnification up to× 50*
1	Very few	*0.5*	*Only visible under magnification up to× 30*
2	Few	1	Only visible under magnification up to× 10
3	Moderate	2	Just visible with normal corrected vision
4	Considerable	3	Clearly visible with normal corrected vision
5	DEnse	4	Large cracks generally up to 1mm wide
		5	Very large cracks generally more than 1mm wide

*Italic letter : new added rating to decide minute cracks



0.5 1 2 3 4 5

Figure 3. Crack patterns for quantity.

3.2 Evaluation of Degree of Degradation

The degree of degradation (QS-value) was based on the product of the rating of quantity (Q) and Size (S) of cracks as provided Equation 1. The approximate relationship between the QS-value and the surface condition is indicated in Figure 4. The digital photo of the crack surface given in Figure 4 illustrates the effectiveness of the QS-value to assess the state of degradation of the sealant.

$$QS(t)=Q(t)\times S(t) \quad (1)$$

where QS(t): QS-value after t months, Q(t): rating of Q after t months, S(t): rating of S after t months.

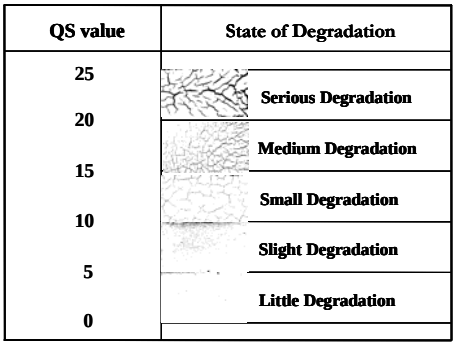


Figure 4. Surface degradation condition rating.

4 TEST RESULT

The changes in QS-value for the different sealants are provided in Figure 5. A summary of the test results is given below.

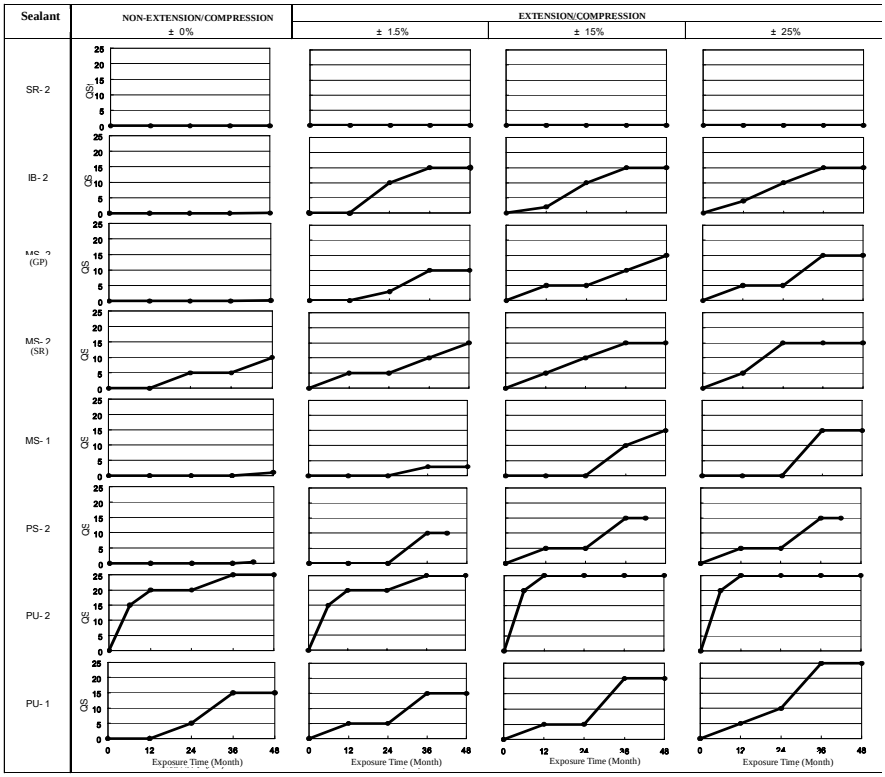

Figure 5. Changes of QS-value of sealants.

1) 2-part silicone sealants did not show degradation for any of the test conditions.
2) Though 2-part polyisobutylene, 2-part modified silicone (general purpose type), 1-part modified silicone and 2-part polysulfide showed a reduced rate of degradation in the static condition, the enforced movement in the dynamic condition accelerated the degree of degradation.
3) The degradation of 2-part modified silicone (stress relaxation type), 2-part polyurethane and 1-part polyurethane showed a gradual degradation with an increase in degree of movement.

5 DISCUSSIONS

5.1 Quantification of Degradation

A three dimension model (response surface) of the QS-value as a function of exposure time and extension-compression ratio was generated from the test results as shown in Figure 6.

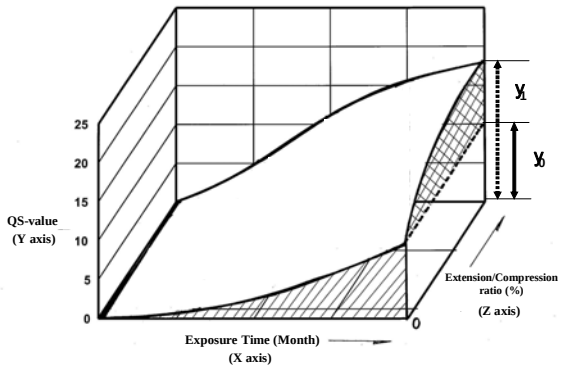

Figure 6. Response surface model of change in QS-value.

5.1.1 Degradation in Static Conditions

The change in QS-value with weathering in the static conditions is given in Equation 2.

$$QS_0(t)=a \cdot t^{b} \quad (2)$$

where, $QS_0(t)$: QS-value obtained from weathering in static conditions after t months; t: exposure months; a and b: constants.

5.1.2 Effect on Degradation due to Dynamic Joint Movement

When sealants as subjected to dynamic joint movement conditions, the equation for the acceleration of degradation due to movement is described in Equation 3. The relationship is derived from the response surface model given in Figure 6.

$$B=y_1/y_0 \quad (3)$$

where, B: coefficient of acceleration, y_0: QS-value on the static condition after t months, y_1: QS-value on the dynamic condition at the ε % of extension-compression ratio after t months.

From the model provided in Figure 7, the relation between the increased QS-value to that of y_0 induced by movement can be described by equation 4.

$$(y_1-y_0)/y_0=c \cdot \varepsilon^{d} \quad (4)$$

where, ε : extension-compression ratio, c and d: constant.

Substituting Equation 4 into Equation 3 yields Equation 5.

$$B=y_1/y_0$$
$$=(y_0+y_0\times c\cdot \varepsilon^{d})/y_0$$
$$=(1+c\cdot \varepsilon^{d}) \quad (5)$$

The change of value of $c\cdot \varepsilon^{d}$ for each year is shown in Figure 8. The parameters c and d are constants that were obtained from an average of each year.

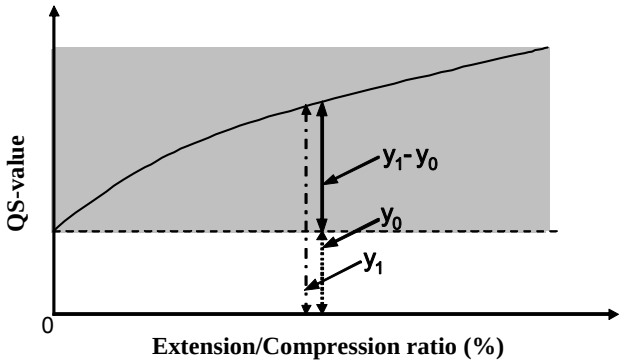

Figure 7. Model of QS-value change for movement.

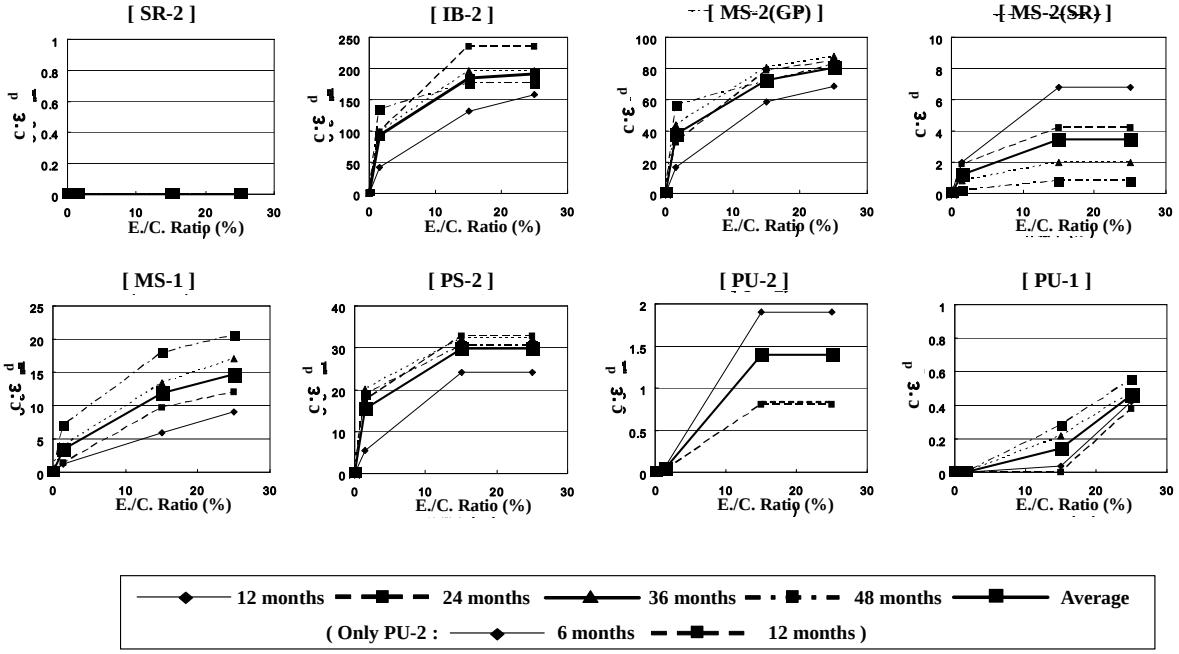

Figure 8. Change of $c\cdot \varepsilon^{d}$ value.

5.2 Proposal for The Equation of Degradation

Based on Equation 2 to 5, the equation for the QS-value was expressed as shown in equation 6.

$$QS(\varepsilon \cdot t)=QS_0(t)\times B$$
$$=(a\cdot t^{b})\times(1+c\cdot \varepsilon^{d}) \quad (6)$$

where, QS(ε ・ t): QS-value at ε % after t months, $QS_0(t)$: QS-value on the static condition after t months, t: exposure months, ε : extension-compression ratio, a,b,c and d: constant. The equation derived for each sealant is given in Table 5.

5.3 Comparison between Calculated and Observed Results

The relationship between QS-value and those calculated are shown in Figure 9.

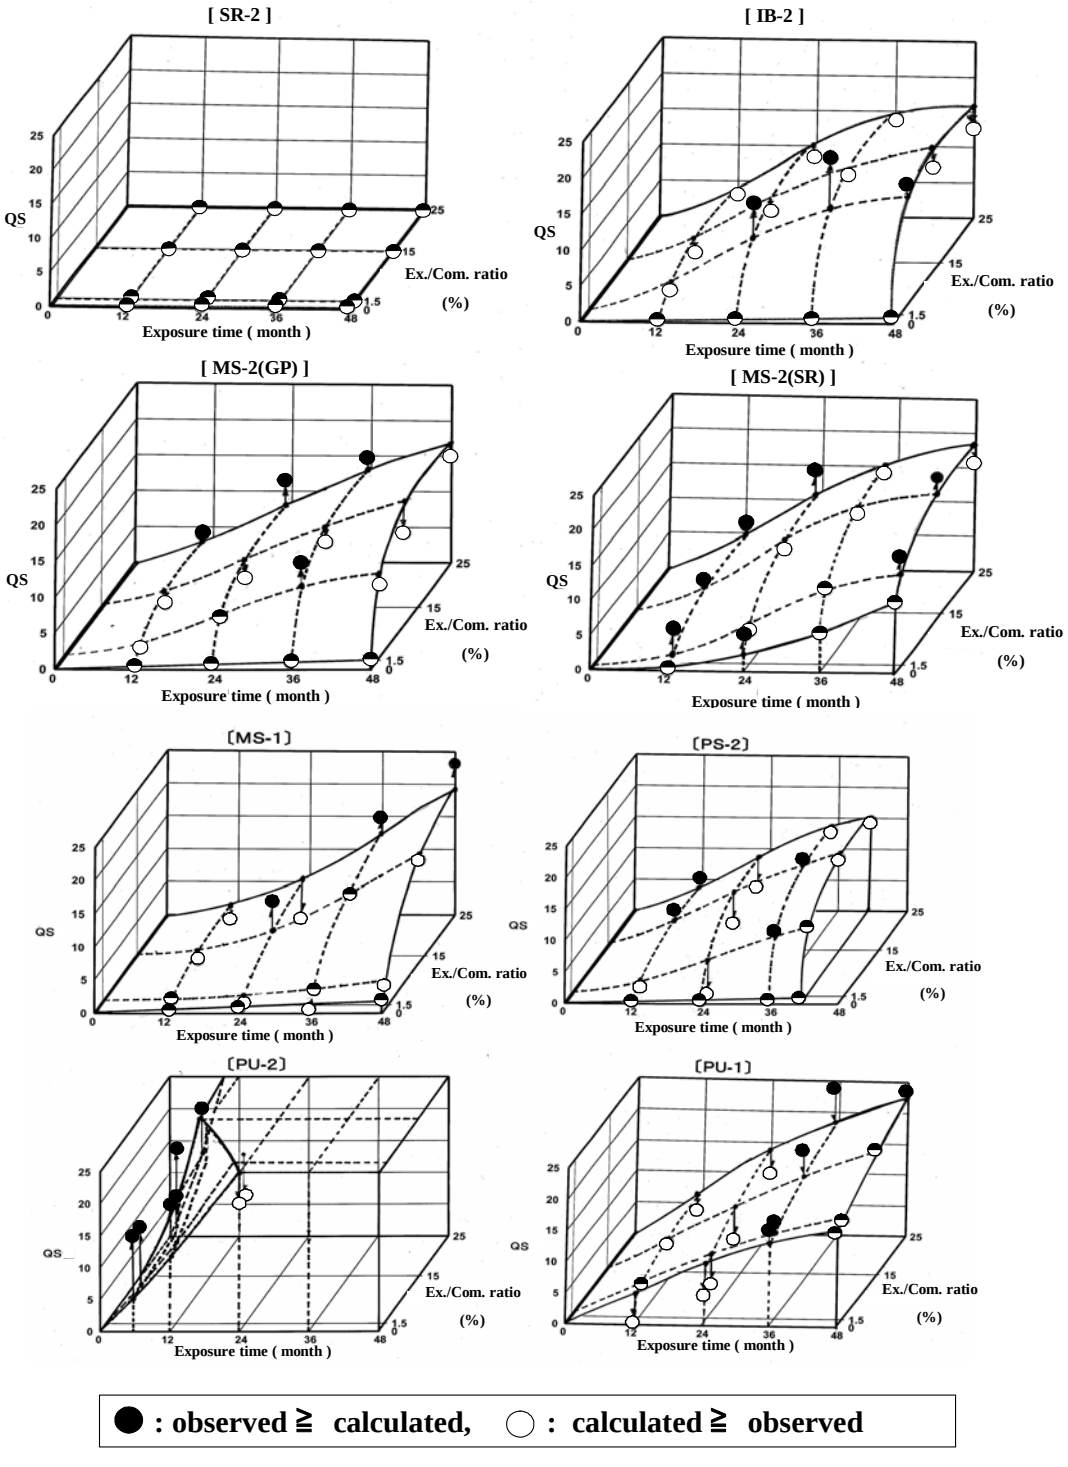

Figure 9. Relationship of QS-value between observation and calculation.

Table 5. Equations of degradation for each sealant.

Sealant	Equation for $QS(\varepsilon \cdot t)$
SR-2	$QS(\varepsilon \cdot t) = (0 \times t^{1.0}) \times (1 + 0 \times \varepsilon^{1.0})$
IB-2	$QS(\varepsilon \cdot t) = (0.002 \times t^{1.0}) \times (1 + 104 \times \varepsilon^{0.2})$
MS-2(GP)	$QS(\varepsilon \cdot t) = (0.005 \times t^{1.0}) \times (1 + 40 \times \varepsilon^{0.2})$
MS-2(SR)	$QS(\varepsilon \cdot t) = (0.005 \times t^{1.9}) \times (1 + 1.6 \times \varepsilon^{0.3})$
MS-1	$QS(\varepsilon \cdot t) = (0.02 \times t^{1.0}) \times (1 + 4 \times \varepsilon^{0.4})$
PS-2	$QS(\varepsilon \cdot t) = (0.01 \times t^{1.0}) \times (1 + 18 \times \varepsilon^{0.2})$
PU-2	$QS(\varepsilon \cdot t) = (3.8 \times t^{0.6}) \times (1 + 0.4 \times \varepsilon^{0.4})$
PU-1	$QS(\varepsilon \cdot t) = (0.7 \times t^{0.8}) \times (1 + 0.003 \times \varepsilon^{0.9})$

6 CONCLUSIONS

1) The new rating criteria for determining minute cracks on the surface of sealants were an effective means to evaluate the degree of degradation of sealants.
2) The equation for the QS-value of the sealant products provides a reasonable relationship between experimental observations and the calculated index of degradation of sealants over the exposure period of this test program.

Acrylic Foam Structural Glazing Tapes

Steve Austin [1]
Uwe Manert [2]

T 14

ABSTRACT

The use of Acrylic Foam Structural Glazing Tapes to replace conventional structural silicone sealant and conventional structural glazing tape for 4-sided structural glazing applications has grown rapidly over the last few years. While the use of Acrylic Foam Structural Glazing Tapes is new in many parts of the world they have been used successfully since 1990 across the globe. Thousands of buildings have been successfully glazed around the world in countries such as USA, Germany, Brazil, Israel, India and Thailand with Acrylic Foam Structural Glazing Tapes.

Conventional structural glazing methods of bonding glass lites to a metal frame use either one-part or two-part structural silicone sealants. Acrylic Foam Structural Glazing Tape provides an alternative bonding method with the performance needed for the application yet with some significant benefits over conventionally glazed systems. The successful application history of Acrylic Foam Structural Glazing Tapes and the testing of glass lites bonded with Acrylic Foam Structural Glazing Tape at third party test institutes demonstrate this alternative bonding material has the capability to meet established requirements for the application. Test results according to application specific ASTM standards show that select Acrylic Foam Tapes have acceptable performance when compared to more traditional structural silicone sealants. Additional testing of Acrylic Foam Structural Glazing Tape according to EOTA ETAG 002 was conducted by the CSTB in France. UV accelerated weathering studies have also been conducted demonstrating the strength and durability of Acrylic Foam Structural Glazing Tapes compared to structural silicone sealants.

1 INTRODUCTION

The use of an adhesive to attach glass lites to glazing profiles independent of mechanical fastening began in the mid 1960s as described by Schmidt et al [1988] in a paper titled Performance Properties of Silicone Structural Adhesives published in ASTM STP 1054 Science and Technology of Glazing Systems. This method of attaching glass lites gained popularity over the next few decades as architects and building owners desired the clean look of an adhesively bonded curtain wall system. This method of glazing is now commonly called structural glazing. Structural silicone sealant was the first adhesive to be used in a structurally glazed curtain wall system. The structural glazing industry has done an excellent job of developing test methods, standards and quality control procedures that has lead to a wide acceptance of this type of glazing method. More recently beginning in 1990 according to 3M™ VHB™ Structural Glazing Tapes Technical Guide [2007], acrylic foam structural glazing tapes have been successfully used in thousands of buildings globally as the adhesive bonding glass lites to glazing profiles in curtain wall and commercial glazing window systems.

The use, composition and performance of an acrylic foam structural glazing tape is significantly different than that of a conventional structural glazing tape also known as a spacer tape. Conventional structural glazing tapes are employed in a structural glazing system to create a space between the glass and a typical metal glazing profile. The thickness of the structural silicone sealant is determined by the thickness of the conventional structural glazing tape. This tape keeps the space or face clearance constant during the curing of the liquid applied structural silicone sealant. It does not provide a structural bond of the glass to the glazing profile. The structural bond is provided by the structural silicone sealant once it is fully cured. Conventional structural glazing tapes are characterized by a foam core with a thin adhesive skin on two opposing sides. The only adhesive portion is the thin skin which contacts the glass and glazing profile. The internal foam strength of a conventional structural glazing tape is generally low as high strength is not required from this tape in this application.

Conversely, an acrylic foam structural glazing tape used in this application must assume the same bonding role of a structural silicone sealant as it replaces both the sealant and the conventional structural glazing tape. That role is to adhesively bond the glass lite and transfer incidental windloads to the building facade structure. Acrylic foam structural glazing tapes are adhesive throughout their entire construction including the foam core. It is this unique construction that give acrylic foam structural glazing tape the strength and performance properties suitable to be used as the primary structural bond in a structural glazing system.

As with the use of a structural silicone sealant, the use of an acrylic foam tape for structural glazing applications requires careful consideration. The performance and durability of any adhesive used for this application should be well demonstrated before ever being considered for a structural glazing project. The objective of this paper is to demonstrate the performance and durability of a class of acrylic foam tapes known as 3M™ VHB™ Structural Glazing Tapes. The primary criteria used to demonstrate this performance is based on the test methods and design standards developed specifically for this application by the structural silicone and commercial glazing industry.

1.1 History of Acrylic Based Pressure Sensitive Adhesives

Early use of pressure sensitive adhesives began in the 1800s and was focused on attachment solutions for the medical industry according to Satas in the Handbook of Pressure Sensitive Adhesive Technology [1989]. The early examples were based on simple resins and beeswax. Rubber was later introduced in this century as a key component in pressure sensitive adhesives. Satas also states that more recent advancements were made in the automotive area when designers were looking for a method to hold paper sheets or masks during the painting process. The area of masking tapes was invented by 3M Corporation to address this need in the 1920's and is now widely accepted for this and many other uses. This tape generation was based on natural

and later synthetic rubber often characterized by a short shelf life and durability. In the early 1960s 3M also developed a special long lasting cellophane office tape which could remain on paper without turning yellow. The basis for this new tape was acrylic adhesive chemistry. This new acrylic based adhesive technology was also used to make thick double coated tapes for mirror bonding applications. The first thick double coated tapes consisted of a polyurethane or polyethylene foam core. In this construction the only adhesive component is the thin outer skin of the tape. The 1980s saw further advancement of the acrylic adhesive technology. For example, thick double coated acrylic foam tapes which were based solely on acrylic adhesive technology were developed by 3M as described in 3M™ VHB™ Durability Technical Bulletin [2001]. This construction was different than the previous thick double coated tapes as the acrylic foam tapes were adhesive throughout the entire construction. This characteristic is what leads to its unique viscoelastic high strength properties. These products were named 3M™ VHB™ Tapes as they exhibited higher dynamic and static load strength than conventional double coated foam tapes.

1 ETAG 002 TEST STUDY

The European Organization for Technical Approval (EOTA) developed the ETAG 002 Guideline for European Technical Approval for Structural Sealant Glazing Kits (SSGK). A part of this European guideline contains the manner and methodology to which structural silicone sealants are tested and characterized for a structural glazing application (kit). This methodology has acted well to characterize structural silicone sealants and is also a good initial method of evaluating an alternative bonding agent such as acrylic foam structural glazing tapes. However, structural silicone is a cold liquid applied, chemically curing sealant while acrylic foam structural glazing tapes are a fully cured, ready to apply tape. Thus, not all listed test procedures are directly applicable for an evaluation of an acrylic foam structural glazing tape. It must also be noted that 3M™ VHB™ Structural Glazing Tapes have a lower dynamic tension design strength of 85 kPa which is lower than that of a structural silicone sealant which is most commonly listed as 140 kPa.

The CSTB institute in France was consulted to conduct an independent evaluation of VHB™ Structural Glazing Tape according to ETAG 002. This study focused on an evaluation according to the appropriate test methods that would help to determine the performance and suitability of this acrylic foam tape for a structural glazing application. The mechanical properties evaluated in this test regime were tensile strength, shear strength, cyclic fatigue, UV accelerated aging resistance and water immersion strength retention characteristics.

2.1 CSTB Test Reports According to ETAG 002 on ER4 – Safety in Use

The following tables summarize the data from the standard test regime conducted at the CSTB. All test samples consisted of aluminum bonded to glass. While 3M™VHB™ Structural Glazing Tape is more temperature and rate/time sensitive due to its viscoelastic characteristics than structural silicone sealants this data demonstrates its ability to meet the performance demands of this application. The final version of the EOTA approval will take more time to complete but only to make a precise specification for acrylic foam structural glazing tapes which have different properties than those of liquid applied, chemically curing structural silicone sealant.

Table 1. Dynamic tensile and shear strength at -20°C, +23°C & +80°C (ETAG 5.1.4.1.1&2). Additional testing was conducted at 100°C.

Aluminum/Glass	**-20°C (-4°F)**	**+23°C (73°F)**	**+80°C (176°F)**	**+100°C (212°F)**
Shear Strength	706 kPa	562 kPa	409 kPa	-
Tensile Strength	3130 kPa	412 kPa	185 kPa	221 kPa

Table 2. Dynamic tensile strength after UV exposure - 4000 hr (ETAG 5.1.4.1.1).

Aluminum/Glass	**0 hr**	**1000 hr**	**2000 hr**	**3000 hr**	**4000 hr**
Tensile Strength	412 kPa	387 kPa	394 kPa	422	453

Table 3. Dynamic tensile strength after high temperature (45°C) water immersion & UV exposure (ETAG 5.1.4.2.1).

Aluminum/Glass	**0 hr**	**504 hr**	**1008 hr**
Tensile Strength	412 kPa	400 kPa	325 kPa

Table 4. Dynamic tensile strength after NaCL immersion (ETAG 5.1.4.2.2).

Aluminum/Glass	**0 cycles**	**5350 cycles**
Tensile Strength	412 kPa	406 kPa

3 VISCOELASTIC NATURE OF 3M™ VHB™ SRUCTURAL GLAZING TAPE

The main purpose of the test study according to ETAG 002 was to gain a further understanding of the mechanical properties of 3M™ VHB™ Structural Glazing Tape. The challenge now with the data is to take the viscoelastic properties of this unique adhesive into consideration. Adhesives typically are elastic in nature. This means in general it is easy to determine maximum stress and modulus. This changes significantly if testing is done with a viscoelastic adhesive like 3M™ VHB™ Structural Glazing Tape. In Fig. 1 is an example of a stress/strain curve of a typical elastic adhesive compared to 3M™ VHB™ Tape when they are extended to a certain point of strain. This graph also demonstrates the capability of 3M™ VHB™ Structural Glazing Tape to stress relax when a constant strain is applied to a glazing joint for example from a differential thermal expansion and contraction type stress. This unique property of a viscoelastic adhesive will act to protect the bond line interface. This property is not typical of elastic adhesives and the associated stress relaxation effect would not be expected as observed with a viscoelastic adhesive.

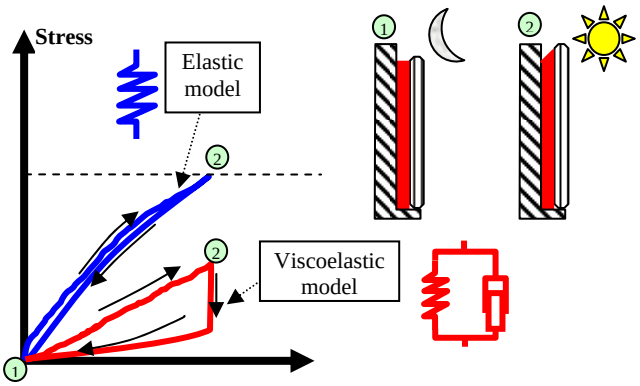

Figure 1. Typical stress vs. strain curves of elastic adhesive compared to viscoelastic adhesive for concept representation.

As stated earlier the main challenge is to find a significant characterization model for these types of adhesives and to accurately describe viscoelastic behavior. The following characteristic of viscoelastic 3M™ VHB™ Tape is used to help explain this. 3M™ VHB™ Tape will exhibit

different modulus and ultimate strength based on the rate (speed) of the applied load. This means that 3M™ VHB™ Structural Glazing Tape tested at 500 mm/min shows much higher values than when tested at a slower rate of 5 mm/min (an elastic adhesive would be relatively constant). It also must be noted that a faster strain rate is associated with a high wind event as described in a section titled "Pull Rate" by the Schmidt et al [1988] paper referenced earlier in Section 1 of this paper. Tests conducted with 3M™ VHB™ Structural Glazing Tape at various strain rates yield a logarithmic curve as described below in Fig. 2.

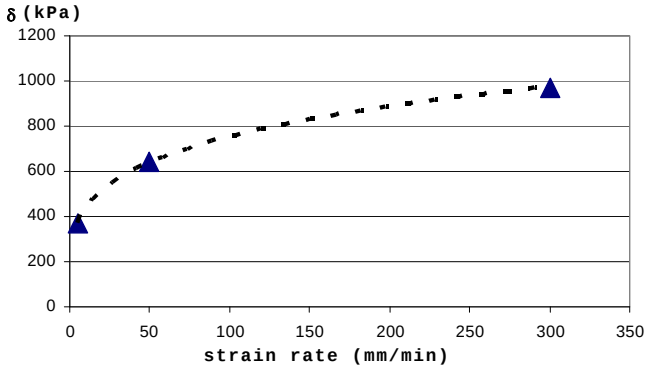

Figure 2. Ultimate stress vs. strain rate of 3M™ VHB™ Structural Glazing Tape.

Figure 2 is an accurate depiction of the viscoelastic adhesive. By using the maximum elongation (strain) for each strain rate one can then calculate the load duration. This graph is then transferred into an exponential formula. This formula is used to calculate the dynamic and the static design strength of 3M™ VHB™ Structural Glazing Tape. This characterization data confirms the currently used 3M design guideline strength values of 85 kPa for dynamic loads such as windload and 1.7 kPa for static loads such as panel bonding for curtain walls.

4 ASTM STRUCTURAL PERFORMANCE MOCK-UP TEST STUDY

The test study conducted by the CSTB demonstrates several of the material property characteristics of 3M™ VHB™ Structural Glazing Tape and the methodologies used for determining appropriate and safe design guidelines. A test study was also conducted at an accredited independent 3rd party test facility (Winwall Technology Pte Ltd - Singapore) to demonstrate the validity of these design guidelines in a real life based on ASTM mock-up tests under stresses and environmental conditions that glass panels would typically experience in a glazed curtain wall system.

This test study consisted of bonding double glazed unit glass panels (insulated glass) as well as monolithic glass panels to a typical structural glazing metal profile. A side by side comparison was conducted comparing glass panels bonded with 3M™ VHB™ Structural Glazing Tape to samples bonded with a one-part structural silicone sealant - Dow Corning® 795. The glazed panels were constructed following the respective design guidelines for both 3M™ VHB™ Structural Glazing Tape and the structural silicone sealant for a windload design pressure of 2.9 kPa. The first test sequence consisted of a polyvinyl butyral (PVB) laminated glass panel bonded with 3M™ VHB™ Structural Glazing Tape, a double glazed unit (DGU) bonded with 3M™ VHB™ Structural Glazing Tape and a DGU bonded with the structural silicone sealant.

The test protocol began with air infiltration testing according to ASTM E 283 *Standard Test Method for Determining Rate of Air Leakage Through Exterior Windows, Curtain Walls, and Doors Under Specified Pressure Differences Across the Specimen* and water penetration according to ASTM E 331 *Standard Test Method for Water Penetration of Exterior Windows, Skylights, Doors, and Curtain Walls by Uniform Static Air Pressure Difference*. Thermal cycling was also conducted for 20 cycles from -25°C to 70°C followed again by the air infiltration and water penetration test methods. After these initial tests there were no water or air leakages identified in any of the three window units. Testing then progressed with the same glazed panels

tested according to ASTM E 330 *Standard Test Method for Structural Performance of Exterior Windows, Doors, Skylights and Curtain Walls by Uniform Static Air Pressure Difference.* No failure was observed with either the 3M™ VHB™ Structural Glazing Tape glazed panels or the structural silicone sealant glazed panel in this wind load structural test at ambient as well as cold and hot temperatures (32ºC, -25ºC, and 70ºC) up to the design pressure of 2.9 kPa, corresponding to a wind speed of 250 kph (155 mph). After this, positive and negative pressures were gradually increased in 1 kPa increments up to 8.4 kPa at ambient temperature conditions. At this negative pressure point the laminated glass failed and blew out of the chamber. However, glass was still attached and bonded to the 3M™ VHB™ Structural Glazing Tape around the perimeter of the glazing frame. Testing was then stopped at this point.

A second test sequence patterned after the first test sequence was run consisting of two monolithic tempered glass lites bonded with either 3M™ VHB™ Structural Glazing Tape or the structural silicone sealant. The DGU panel bonded with 3M™ VHB™ Structural Glazing Tape was also subjected to this second test sequence after surviving the first test sequence. No failure was observed with either the 3M™ VHB™ Structural Glazing Tape glazed panels or the structural silicone sealant glazed panel in any of the tests including wind load structural tests up to a positive and negative pressure of 10 kPa which corresponds to a sustained wind speed of 467 kph (290 mph). The ability of the panels to survive pressure loads well beyond the original design pressure demonstrates the use of safety factors for both structural silicone sealant and 3M™ VHB™ Structural Glazing Tape. This testing protocol also demonstrated that no air or water leakage can be obtained with proper assembly methods. The glazed panels constructed with the acrylic foam structural glazing tape provided excellent performance overall compared to control panels glazed with a well accepted one-part structural silicone sealant. Table 6 below is a summary of this 3rd party test study.

Table 6. Summary of application specific performance tests.

Test Sequence	Test Method	Laminated Glass - 3M VHB SGT	Insulated Glass (DGU) - One Part SS	Insulated Glass (DGU) - 3M VHB SGT	8mm Tempered Glass - One Part SS	8mm Tempered Glass - 3M VHB SGT
Air Infiltration	ASTM E283 (at +0.3kPa)	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel
Water Penetration	ASTM E331 (at +0.72kPa)	No water leakage	No water leakage	No water leakage	No water leakage	No water leakage
Temperature Cycling	20 cycles (-25^{0}C to 70^{0}C)	For each cycle, temperature is maintained at -25^{0}C for 15 minutes and 70^{0}C for 15 minutes		Subjected to 40 cycles	For each cycle, temperature is maintained at -25^{0}C for 15 minutes and 70^{0}C for 15 minutes	
Air Infiltration	ASTM E283 (at +0.3kPa)	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel
Water Penetration	ASTM E331 (at +0.72kPa)	No water leakage	No water leakage	No water leakage	No water leakage	No water leakage
Windload Structural	ASTM E330 (-25^{0}C, 32^{0}C, 70^{0}C, hold for 1 minute)	+/-2.9kPa (60psf, 250kph)		+/-2.9kPa (60psf, 250kph)	+/-2.9kPa (60psf, 250kph)	
Air Infiltration	ASTM E283 (at +0.3kPa)	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel	No air leakage from panel
Windload Structural Max.	ASTM E330 (32^{0}C, hold 10 sec)	+/- 6kPa (125psf, 360kph)	+/- 6kPa (125psf, 360kph)	+/- 8kPa (167psf, 416kph)	+/- 8kPa (167psf, 416kph)	+/- 8kPa (167psf, 416ph)
Windload Structural Destructive	Maximum Pressure (+/-)	Glass burst at -8.4kPa (175psf, 426kph)	> -8.4kPa (175psf, 426kph)	>10kPa (209psf, 465kph)	>10kPa (209psf, 465kph)	>10kPa (209psf, 465kph)

Subjected to 2x test cycles

5 DURABILITY OF 3M™ VHB™ STRUCTURAL GLAZING TAPES

The best measure of the durability of a structural silicone sealant or acrylic foam structural glazing tape is how it performs in real life applications. Structural silicone sealants have demonstrated durable performance over the last four decades when used properly in structural glazing applications. Acrylic foam structural glazing tapes such as 3M™ VHB™ Structural Glazing Tape has demonstrated durable performance since 1990 for this same application. Thus, it was appropriate to conduct an accelerated weathering study to evaluate the durability of 3M™ VHB™ Structural Glazing Tape compared to that of a two-part structural silicone sealant -Dow Corning® 983.

This test study was conducted at the 3M Weathering Resource Facility in St. Paul, Minnesota. Test samples consisted of 6 mm clear float glass bonded to black anodized aluminum with either the two-part structural silicone sealant or 3M™ VHB™ Structural Glazing Tape. These samples were then placed in a high intensity UV light chamber (Xenon Arc lamp) with cycling heat and humidity (water spray). Samples were then taken out of the chamber at various time intervals and tested for tensile strength. The maximum exposure time in this cycling chamber was 10,000 hours. Figure 3 below depicts the tensile strength retention of both the two-part structural silicone sealant and 3M™ VHB™ Structural Glazing Tape in this test study.

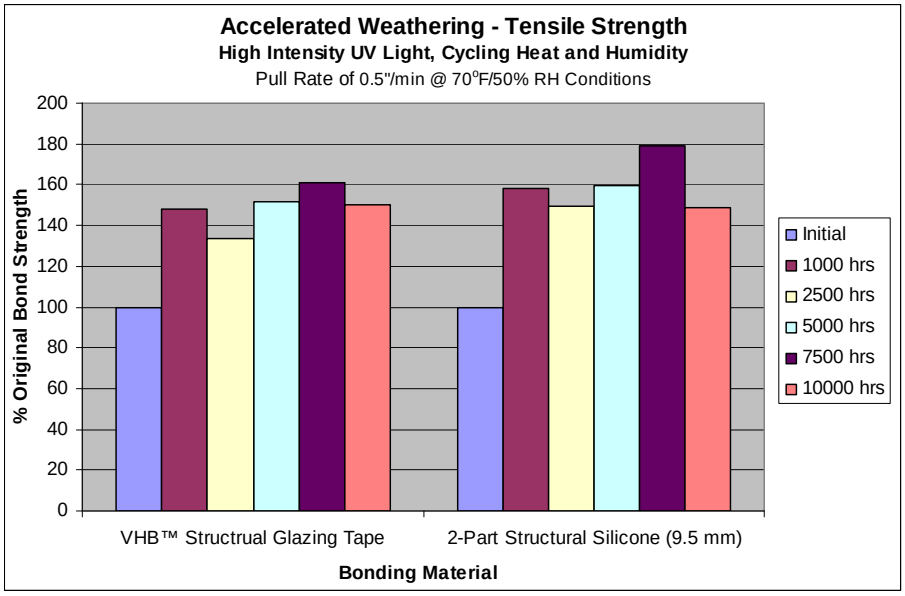

Figure 3. Tensile bond strength after accelerated weathering.

Both the two-part structural silicone sealant and the 3M™ VHB™ Structural Glazing Tape exhibit good tensile strength retention even after 10,000 hours in this harsh accelerated weathering chamber. This 10,000 hour test is a more severe UV cycling test with a higher total dose of radiation than that of the accelerated weathering tests described in both ETAG 002 and ASTM C 1184 *Standard Specification for Structural Silicone Sealants*.

6 SUMMARY

Select grades of Acrylic Foam Tapes have proven their performance and durability for structural glazing applications since 1990 as described earlier in Section 1 Introduction of this paper. While these tapes may be new to the world in some locations they have earned acceptance in the marketplace in other parts of the world and their growth continues.

The data presented in this paper demonstrates the properties, performance and durability of an Acrylic Foam Structural Glazing Tape. The contract glazer, fabricator or curtain wall designer must be sure to use only an appropriate Acrylic Foam Structural Glazing Tape if they intend to use a tape for glass bonding in structural glazing applications. It is also critical to follow the design guidelines and quality control procedures as outlined by the Acrylic Foam Structural Glazing Tape manufacturer.

The material properties of a viscoelastic Acrylic Foam Structural Glazing Tape are different than those of a structural silicone sealant. Both have demonstrated their performance in structural glazing applications for many years. The standards, codes and specifications currently written for structural glazing are focused on the properties of cold liquid applied, chemically curing elastomeric structural silicone sealants. While these documents are useful as a starting point to help characterize an Acrylic Foam Structural Glazing Tape, there exists a great need to develop appropriate standards, codes and specifications for Acrylic Foam Structural Glazing Tapes to ensure only suitable products are used for this critical application.

Non-Destructive Testing of Elastomeric Joint Sealants in Construction

Huff, Daniel N. [1]

T 14

ABSTRACT

Durability of buildings depends on adequate testing and quality assurance programs during construction. Lack of good testing during construction can result in construction defects. In the United States, construction lawsuits have become so costly that construction insurance in now one of the largest costs of doing business for contractors.

This is particularly true in the field of leaking buildings and toxic mold related lawsuits. For that reason, the author has spent the past 7 years in research and development of a comprehensive 100% capable non-destructive method and device for evaluating weather seal sealants. Recently, the author has developed a similar test system that can be used on SSG (Silicone Structurally Glazed) sealants as well.

This paper is focused on the use of non-destructive Quality Assurance systems for sealants in construction that can perform at the rate of 100% if necessary. The current industry standards call for testing of these sealants at the rate of one destructive "pull test" per 1000 lineal feet [305 m]. It is the belief of the author that this standard is woefully short of the needs of the industry. On one project alone, where the author was able to conduct 100% testing, it was discovered that a 0.2% failure rate of the weather seal resulted in over 400 potential leaks on the 227,000 square foot [69,190 m] building, in 35,000 lineal feet [10,668 m] of wall sealant. Statistics related to perfect versus real life application of sealants are also discussed in this paper. ASTM C1521 is cited as a new approach to seal and sealant testing.

1 INTRODUCTION

Imagine that you belong to a family that suffers from a genetic flaw that can cause serious health problems. However, your doctor has good news; a test exists to find out if you have any of the health problems associated with the gene. After the test, you will be issued a report of the test results. The problem is that the test is only accurate from between one chance in 4,000, and one chance in 192,000, depending on how you figure the odds.

Now imagine that you are a sealant installer on a construction project that relies on sealants for weatherproofing or safety. A manufacturer's sealant warranty can be obtained if certain project specific tests for substrate compatibility, primer requirements, and field adhesion are performed. An official report follows each test, proving your due diligence. Unfortunately, the odds of finding a seal continuity problem using the industry standard field test is between one in 4,000, and one in 192,000, depending on how you figure the odds. Later, when the building leaks or glass is dislodged, you find yourself in the position of trying to defend your installation with test reports, but you are told that the problems are caused by installation error.

This paper focuses on adhesion field-testing of construction sealants. This is because durable and functional building facades using construction sealants in critical areas require continuous adhesion of the sealant in all joints at all locations.

2 INCONVENIENT STATISTICS

Dr. Joseph Lstiburek,a principle of Building Science Consulting stated: *"It may be possible to install sealant in one joint perfectly –but how about installing sealant perfectly in 10 joints? Now how about 100 joints? Recall, that the joints must be perfectly prepared and installed. How about 1,000 perfect joints? Or 10,000 perfect joints? To put this into perspective, there are more than 1,000 sealant joints per building in most commercial buildings. Many of the joints leak from day one. More joints leak as the building ages."* [Lstiburek 2007].

An associate of the author, a principle of Morrison Hershfield, Ltd., Canada, & Morrison Hershfield Inc., USA, made the following comment when presented with some of the data included in this paper: *"Even with above average workmanship, there will always be a failure rate. Even if sealant joints on any given project are as good as 99.5% successful (an extraordinary achievement in any human endeavour), the remaining 0.5% can cause significant damage. Submarines have bilge pumps to catch the leaks from the 0.5%. There needs to be a second line of defence. Nothing we do is perfect enough to rely on a sealant joint 100% of the time, and in my opinion, this is a foolhardy approach to building design"* [Gallant 2005].

The average commercial building in the United States contains about 35,000 lineal feet [10,668 m] of sealant, or 6.62 miles [10.7 km]. With volumes of face-sealed joints this high, a very small failure rate can result in significant trouble for the building.

In 2002, the American Society for Testing and Materials (ASTM) Committee C24 ("Building Seals and Sealants") adopted a new Field Practice C1521 ("Standard Practice for Evaluating Adhesion of Installed Weatherproofing Sealant Joints") that codified several testing procedures that were already considered industry standards [ASTM 2002]. These procedures include the destructive tail and flap "pull tests", a water immersion procedure, and a non-destructive joint probe procedure that uses a blunt instrument to induce strain to the bond line of the sealant.

The frequency of the destructive pull testing recommended by ASTM is one test per 100 lineal feet [30.48 m] for the first 1000 feet [304.8 m], and one test for every 1000 lineal feet thereafter. This is the recommended test procedure by all of the major sealant manufacturers worldwide. Most

manufacturers recommend cutting a 3-inch tab into the sealant bead, and then pulling the tab either to an elongation percentage keyed to the movement capabilities of the particular sealant, or to cohesive failure [Dow Corning 2007].

Assuming that the full 3 inches qualify as the test parameters, the odds of finding continuity problems in the sealant installation is 4,000 to 1. In actuality, the true test is taking place at the interface of the tab to the sealant at the bottom of the tab in perhaps 1.6 mm [1/16"]. This means that the true statistical odds of finding a continuity problem in the sealant joint with this test is closer to approximately 192,000 to 1. Even at the once every 100 feet frequency (impractical, material waste, costly), the odds of finding a problem is 19,200 to 1.

The destructive testing procedure is concerned with, A) the quality of the sealant, and B) whether or not it is able to adhere to the substrate. It is a sealant material Quality Assurance process, not a seal continuity Quality Assurance process.

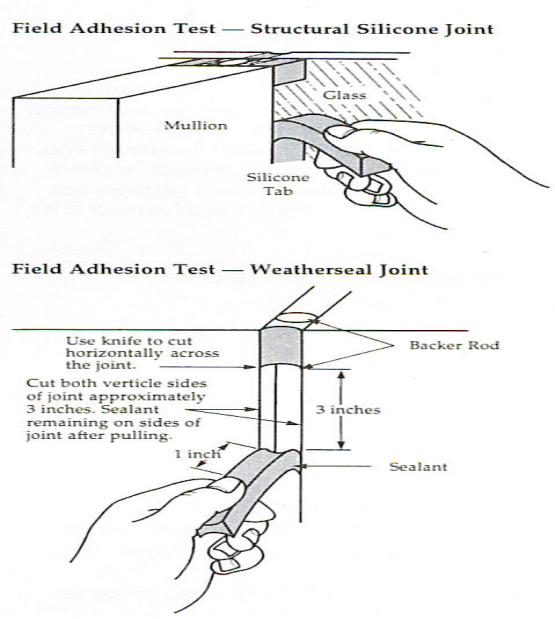

Figure 1. These are depictions of the hand pull test recommended by sealant manufacturers as a standard Quality Assurance program for sealant adhesion for weather seals and SSG. Frequency of the test as recommended by manufacturers varies, but the ASTM recommendation in C1521 is one test per 100 lineal feet [30.5 m] for the first 1000 lineal feet [304.8 m] tested, and one test per 1000 feet thereafter.

3 CONTINUOUS TESTING USING A ROLLING DEVICE – TRUE CONTINUITY QUALITY ASSURANCE

In the ASTM document C1521, a non-destructive procedure is outlined that offers an alternative to the pull test. It suggests that the evaluator subject the sealant bead to pressure with a blunt probe. The objective is to strain the sealant bead inducing stress on the sealant bond line in order to reveal failed or poor adhesion. Put simply, one pokes the sealant with a blunt instrument, with a goal of depressing the bead 50% of its movement capability.

For the reasons discussed above, some Building Enclosure Professionals have been using simple rolling devices such as a window screen roller or a "backer rod placement device" to affect the non-destructive procedure mentioned above. Notably, David Nicastro, principle with Engineering Diagnostics, Inc. and the former chair of ASTM Committee C24, and Patrick Gorman of Gorman

Moisture Control and former Vice Chair of C24 have been using the screen roller approach for a number of years. Currently, C24 has taken under consideration adding rolling devices as a test option. This will be in addition to the "blunt instrument" in the current C1521 Non-Destructive test protocol. The advantage of being able to determine the relative condition of a sealant joint using this approach is obvious – a 100% evaluation of the sealant is now possible.

The problem with any of the un-controlled rolling devices is that they generate non-reproducible subjective test data. For that reason, the author embarked several years ago on a quest for a scientific, objective approach to this idea by creating an adjustable, controlled, and calibratable device.

4 DESCRIPTION OF CONTROLLED CALIBRATED CONSTANT PRESSURE DEVICE

The device is a hand held instrument able to exert pressure in a controlled manner to the sealant joint. Extending from the housing at the front of the device is an armature with a roller at the tip. Behind the armature is a piston charged with compressed gas delivered from a pressurized tank. The amount of pressure behind the piston translates directly into the amount of force that is applied to a surface to which the roller probe is engaged. The amount of gas pressure delivered from the pressurized tank is adjusted with a regulator. Pressure within the device and behind the piston is monitored from a gauge visible on the control box. Within the pressure control box the gas is manipulated in such a way that the pressure is constant within the entire stroke of the piston in the hand held portion of the device. Pressure in the apparatus as derived from the gas source resulting in strain at the probe contact point is maintained if the armature is somewhere within the stroke of the piston. The operator pushing in or pulling away from the joint with the device during operation cannot alter the pressure at the probe contact point. This means that the pressure that the test probe exerts on the sealant remains constant. To maintain constant pressure, the piston must simply be kept within its' 3-inch [7.6cm] stroke range.

Using this device, accurately applied pressure to the joint is not dependant on adjacent surfaces (as in the case of a backer rod placement style device) or the judgment of the user (as in the case of a screen roller or similar device) when testing. The result is a reproducible and objective evaluation system. The user simply dials up the predetermined pressure for the device to operate on and then lets the device do the rest. A predetermined pressure is set for the specific sealant through calibration of the device.

Figure 2. The picture is a depiction of the pressure-controlled as discussed in this paper.

Calibration of the device is aimed at a 50% elongation of the sealant based on the sealant movement capability, following the guideline for the non-destructive procedure found in ASTM C1521. The calibration numbers used in the field are an average based on the particular sealant and the average joint width on the building. If the test practitioner wishes to, adjustments for joint width changes can

be made as often as is necessary, but as a practical matter, using an average pressure is more efficient. When testing organic sealants, it is important to consider temperature changes. Reporting all of the pressures used is important for the archive in order for future reproducibility.

To obtain calibration data, sealant calibration specimens are constructed in three rectangular joint configurations held within a rigid metal grid. Joint configurations are constructed as follows:

- [12.70 mm by 6.35 mm] 500 mil by 250 mils
- [19.05 mm by 9.52 mm] 750 mil by 375 mils
- [25.4 mm by 12.70 mm] 1000 mil by 500 mils

Each specimen is approximately 508 mm (20 inches). Various colors are used in order to factor batching and pigmentation (during the initial 6-month calibration study, pigmentation was discovered to have a slight but detectable effect on sealant movement capability). Movement dial indicators are spaced evenly along the underside of the specimen in order to record the deflection created during a pass of the roller through the sealant on the topside. Differing pressures are used to strain each specimen. A significant number of passes with the roller probe are completed and the deflections recorded. The information is reduced and translated into "target deflections". These target deflections are a percentage of elongation as defined by the specific sealants' movement capability. For example, a target of 50% elongation in a 50% movement capability sealant in a 1 inch (25.4 mm] wide joint would be ¼ inch (6.35 mm) deflection. The result of this process is sealant specific calibrations chart such as is depicted in the example below (Table 1). The table describes the calibration of sealant #1, average Shore "A" Durometer Hardness 28, movement capability ± 50%. Numbers following targets are calibration numbers for the device as a percentage of available force in the control box.

Table 1. Calibration of Sealant #1.

Joint:	Target Deflection:	50%	75%	100%
500 by 250mil (12.70 by 6.35 mm):		40	55	73
750 by 375mil (19.05 by 9.52 mm):		32	51	68
1000 by 500 mil (25.4 by 12.7 mm):		26	43	62

5 STATISTICS FROM FIELD USE

Experience using this device in the field has demonstrated that if at least 5% to 10% of a building is sampled, and the sampling is conducted in a thoughtful scientific manner, the results are usually representative of the entire sealant installation.

For example, on an 11-story building, with 24 grid locations for suspended scaffolding, two grids were sampled. This represented an 8.3% sampling rate. Found were 14 adhesion failures on 1 grid section, and 20 on the other, for an average of 17 failures per grid section. From this sample, it was predicted that 408 failures would be found on the entire building. 427 adhesive failures were uncovered during the ultimate 100% evaluation process. This means that sampling has a solid basis for obtaining a realistic view of the sealant installation on a building.

Figure 3. This is an example of the type of "invisible" seal failure uncovered by using the non-destructive method and device described elsewhere in the paper. Prior to finding this seal breach, the entire sealant bead depicted looked exactly like the area above and below the breach.

What did we learn from sealant testing at the rate of 100%? In the case cited above, the failure rate was a mere 0.2%. Yet it resulted in 427 breaches in the building seal. This demonstrates that a very low failure rate can pose a significant potential problem for a building simply because the volume of sealant used is typically a large number. A 99.8% successful installation is not a bad job, and as Mr. Gallant suggested, a 99.5% rate of success is all one could ever hope for in a "human endeavour".

On one project, a twin 18 story condominium in Long Beach, California, we found a 5.6% failure rate in the Exterior Insulation and Finish System. We started with a 1% sample, and then sampled 5%, then 10%. What was significant is that the failure rate remained constant despite the sample size. This has been a consistent finding on all of the projects where this system has been used. As a result, we recommend that sampling be conducted at a minimum rate of 5% to a maximum of 10% prior to 100% testing as a way of determining the severity of the problem and determining the reasons for the failures. This can also provide the practitioner information for establishing a protocol for using the test system as a repair program. The failed samples should be removed for analysis. This will reveal the reasons for the failure, most often from contaminated substrates, but in some cases, laboratory analysis is appropriate. We have also found that when full scale testing is undertaken, it is often cost effective to coordinate the testing with a contractor able to implement repairs. After the repairs are made, a 10% re-sample is useful in confirming the success of the test and repair program.

The information in Table 1 provides basic statistics obtained during a 100% sealant evaluation of the newly constructed building (specimen A) using the pressure controlled and calibrated device and used in accordance with the principles of the non-destructive test protocol outlined in ASTM C1521 [ASTM 2002a].

Table 2. Statistics Generated from Sealant Testing (Specimen A).

Number of Lineal Feet of Sealant:	35,000 feet [10,668m]
Number of Adhesive Failures:	427
Average Length of Failure:	two inches [50.8mm]
Failure Rate in Lineal feet:	one in 82 feet [25m]
Total Lineal feet of Sealant Failure:	71 feet [21.6m]
Percentage Rate of Sealant Failure:	**.2% Failure**
Percentage Rate of Sealant Success:	**99.8% Success**

The author is currently involved in an adaptation of the non-destructive testing technology described in this paper for use in evaluating Silicone Structural Glazing (SSG). This new test system is designed for non-compressible sealant joints and gaskets.

6 CONCLUSIONS

The future of field-testing of sealants should therefore necessarily include non-destructive procedures that have the ability to test 100% of sealant joints. Continuous testing using rolling devices have been demonstrated to be a good choice. The program should have a goal of finding the seal breaches and simultaneously repairing them immediately. This approach to building seal verification has the potential to save many dollars in building maintenance, litigation, health care costs, insurance, and owner borne construction costs, to name a few. In the case of SSG applications, life safety issues are involved. Improved testing technology can provide all concerned with a new level of confidence that durable building seals and structural silicone glazing adhesives can be realized. The question now is not whether we have methods and technology to accomplish durability of construction, the question is whether we have the will to use it.

The Sandstone Conundrum

Edward Gerns [1]
Rachel Will [2]

T 15

ABSTRACT

In the Midwestern United States, the use of Lake Superior sandstone was very popular at the end of the 19th Century. The rich red color and ease of workability resulted in many architects, owners and builders choosing Lake Superior sandstone as a cladding material. While the stone was quite attractive, the physical characteristics of the stone, as well as quarring methods, have resulted in numerous and dramatic failures. Severe erosion and delamination of the bedding planes became a widespread problem beginning in many instances as early as the beginning of the 20th Century.

This paper will be divided into two parts. The first will discuss the physical characteristics of sandstone in general and specifically Lake Superior sandstone. This will include a discussion of deterioration mechanisms and repair techniques which have been implemented or proposed in an attempt to maintain the original material as well as the desired aesthetics. These include chemical treatments, patching, pinning, selective replacement, substitute materials and alternate stone materials.

The second part of the paper will present a case study of a residence in Chicago and the approaches considered and finally implemented to address severe deterioration of the stone. The residence provides a dramatic example of previous unsuccessful repairs and the process of developing a new facade system which was sensitive to the original design intent while employing more durable materials. The process of the facade reconstruction will be discussed from investigation of the existing conditions, alternative approaches considered, design development and installation of the new cladding system.

1 INTRODUCTION

Like many cities, Chicago experienced dramatic changes in the later part of the 19th Century. Following the Great Fire of 1871, Chicago experienced significant population growth becoming the second largest city in the United States by 1900. The fire had virutally cleared the slate for the introduction of new building technologies and styles. Residential construction, in what is now known as the Gold Coast area of Chicago, began shortly after the fire as the city center continued to expand. In response to the fire, numerous changes in construction practices and building codes were introduced to reduce the risk of fire. Residential construction never fully embranced the notion of fireproof construction largly because of economics, as well as, the scale of the structures. In Chicago, lots sizes ranged between 8 and 10 m wide and between 40 m and 60 m deep. As a result, row houses were a popular residential form borrowed from European archetypes. The row houses in Chicago typically had a highly adorned main facade facing the street and, where exposed, the remaining utilitarian load bearing facades were monolithic multi-wythe common brick walls. In the midwestern United States, decorative residential cladding materials of the time included stone, brick and terra cotta. Of these materials, stone was the most desirable and therefore many of the most prestigious residences of the late 19th century incorporated facades of richly carved limestone, granite and sandstone ornament. The main facades were typically monolithic walls with the decorative outer wythe of masonry and a multi-wythe clay brick backup wall. Floor and roof systems were typically wood joists spanning parellel to the main facade.

2 LAKE SUPERIOR SANDSTONE

Sandstone is a sedimentary stone consisting of deposits of sediment materials in prehistoric river and lake beds. The sediment is the result of the decomposition and erosion of other rocks, minerals and organic matter which are bonded together through compaction and naturally created cementitious products. The cementing material can consist of silica, calcarious materials, iron oxide or clay and generally determine the color of the stone [Merrill 1889]. Distinct bedding planes between individual layers of material and grain size characterize sedimentary stone. Lake Superior sandstones, generally classified as a ferruginous sandstones [Ashurst 1990], compositionally vary depending on the specific formation of the region, but generally are composed of quartz cemented with iron oxide, calcite, authigenic quartz or silica [Ekert 2000].

The durability of sandstone is generally dependant on exposure, water shedding details, orientation of the bedding planes as well as the cementing agents which hold the quartz grains together. Natural weathering will erode the surface of the stone through continued cycles of rain and freeze thaw deterioration will breakdown the cement bond over time. The rate of deterioration changed as a result environmental changes of the 19th and 20th centuries with increasing concentrations of carbon dioxide, sulfates and nitrates in the air. If the particles of the stone are held together by calcareous materials, the bond is easily broken by the polutants present in acid rain [Warland 2006].

3 LAKE SUPERIOR SANDSTONE IN CHICAGO

Lake Superior sandstone was first used as a building material in Chicago just prior to the Great Fire of 1871. At the time, Lake Superior sandstone was touted to resist the detrimental effects of fire when compared with other contemporary stones. As a result, it gained great popularity throughout the city as a durable, fireproof, decorative and coveted building material. In the wake of the Chicago fire, builders and architects sought durability above all else in materials, as evidenced by the Tribune Building constructed in 1872 by Burling and Adler as the first Tribune Company Building, constructed of Niagara limestone and cast iron had been destroyed by the 1871 fire [Eckert 2000].

Lake Superior sandstone, while not indigenous to the region of Chicago, was made more readily available through the canal system and more so with the introduction of the Chicago, St. Paul Minneapolis, and Omaha Railroad in 1883 [Chicago Tribune 1873].

The Boyce Block (now demolished), located at the corner of Madison and State streets was partially finished at the time of the fire which led to the many conclusions about the durability of the stone in relation to fire. It was touted as one of the best examples displaying the texture and building capacities of Lake Superior sandstone [Chicago Tribune 1871]. The Masonic Temple on Forrest Avenue between 32nd and 33rd Streets also illustrates the splendor of this material, thus indicating this material was not primarily limited to commercial, residential or religious structures.

Prestige and regard for Lake Superior sandstone were also gained through the opinions of architects in Detroit, Chicago and Cleveland on the value of Lake Superior sandstone. Cudell and Blumenthal of Chicago, architects of the Cyrus McCormick House, spoke highly of the stone, as described below:

> Having used [Marquette brownstone/Lake Superior sandstone] to a considerable extent, we consider it an excellent building stone, especially adapted to elegant residences and structures where its beautiful color appears to an advantage. This latter feature must ever secure it favor with the true artist, being rich and warm, and suggestive of vitality. As a working material, it is all the artist can desire, being soft and tenacious, thus enabling the stonecutter to cut and carve the most elaborate and intricate designs of the architect…[Eckert 2000]

The beauty, warmth, sculptural qualities and perceived durability of Lake Superior sandstone caught the attention of many architects, builders and wealthy residential commissioners. Among the costly residences constructed of Lake Superior sandstone are the Hough House on Prairie Avenue, the W.M. Crilley House on Michigan Avenue, the Cyrus McCormick House [Eckert 2000], the Crane House on Wabash Avenue, the Boughton House on Indiana Avenue, the Boyington House on Indiana Avenue, the Henry Furst House (one of the early distributors of Lake Superior sandstone) and the Potter Palmer House [Chicago Tribune 1871]. Unfortunately many of these structures have not survived, for various reasons, one being the extensive deterioration of Lake Superior sandstone.

4 REPAIR APPROACHES

Several options exist to address deterioration of sandstone. These range from topical application of chemicals to complete replacement. When considering replacement materials given the poor performance characteristics of Lake Superior sandstone, a cursory review of the various preservation philosophies is worth considering. The Secretary of Interior's Standards for Rehabilitation stresses matching and blending replacement materials with the adjacent original material:

> *Deteriorated architectural features shall be repaired rather than replaced, wherever possible. In the event replacement is necessary, the new material should match the materials being replaced in composition, design, color, texture and other visible qualities.* [NPS 1992]

This contrasts to Venice Charter which states:

> *Replacements of missing parts must integrate harmoniously with the whole, but at the same time must be distinguishable from the original so that restoration does not falsify the artistic or historic evidence.* [US/ICOMOS 1992]

In many instances, the state of extreme deterioration of the stone results in having to reconsider traditional preservation approaches. "Preservation is defined as the act or process of applying measures necessary to sustain the existing form, integrity, and materials of an historic property." [NPS 1992]. Preservation respects the historic material and enables the structure to continue to age. "Rehabilitation is defined as the act or process of making possible a compatible use for a property

through repair, alterations, and additions while preserving those portions or features which convey its historical, cultural, or architectural values." [NPS 1992]. Both of these approaches were can be unrealistic given the extreme state of deterioration that many Lake Superior sandstone facades experience. "Reconstruction is defined as the act or process of depicting, by means of new construction, the form, features, and detailing of a non-surviving site, landscape, building, structure, or object for the purpose of replicating its appearance at a specific period of time and in its historic location." [NPS 1992]. Reconstruction effectively eliminates the original time line and introduces a completely new element which is a gesture to a past element [Murtagh 1997]. This is generally considered the approach of last resort due to loss of original fabric as well as economics.

4.1 Chemical Treatments

Chemical treatments are divided into four main groups, according to their composition. These groups are inorganic materials, alkoxysilanes, synthetic polymers, and resins. These products are generally inexpensive to apply, but require extensive testing and evaluation to determine if they are appropriate and effective treatments. Even if effective, chemical treatments do not reverse the loss of detail of the ornamant due to erosion and freeze thaw damage.

Inorganic stone consolidants were extensively used during the 19th century and are still being used. Most inorganic consolidants produce an insoluble phase within the voids and pores of a stone, either by precipitation of a salt or by chemical reactions with the stone. It has been rationalized that the development of a new matrix similar in composition to the matrix of a stone will bind together the particles of deteriorated stone. Little success has been achieved in consolidating stone with inorganic materials, and in some cases their use has greatly accelerated stone decay. Among the problems are formation of a shallow and hard crust, the formation of soluble salts as reaction by-products, the growth of precipitated crystals, and the inability of some of them to bind stone particles together.

Alkoxysilanes are being highly regarded because of their ability to penetrate deeply into porous stone and polymerization can be delayed until deep penetration has been achieved. In addition, the polymerize produces materials similar to the binder in siliceous sandstone [Clifton, 2007].

Two general types of polymer systems are used to treat stone. In the first, monomeric molecules are first polymerized, dissolved in appropriate solvents, and then applied to stone. They are deposited within the voids and pores of the stone as the solvent evaporates. The second type is monomeric molecules, either pure or dissolved in a solvent, which are polymerized within the voids and pores of a stone [Clifton, 2007].

Resins have been applied to stone for over 2,000 years. Resins are effective in increasing the water repellency of stone. Many other water repellents of various more complex compositions have been developed and employed in attempt to reduce water absorption and subsequent deterioration.

4.2 Patching

Various proprietary patching materials are commercially available. These products combine various polymers in a cement-based blend of select graded aggregates, additives fillers and pigments.

Patches are installed by first removing all deteriorated areas of stone to solid stone substrate which will receive the patch material. Depending on the depth of the patch, anchors may be installed to provide a mechanical connection of the patch to the substrate. Another approach is to install screws that project to within about 1 cm of the finished surface and installing a net of corrosion resistant wire to provide mechanical bond for the patch.

4.3 Selective Replacement

Performance characteristics of the original sandstone may make retaining replacement material very difficult. The appropriateness of installing a less durable material is philosophically not appropriate in

most instances. If only limited units required replacement, salvaging, harvesting and recycled material could be considered.

Appropriate substitute materials, depending on the extent of replacement required, could include terra cotta, limestone and alternative sources of sandstone. Each option offers advantages and disadvantages both economically and philosophically as will be discussed in the case study presented.

5 CASE STUDY

The project presented in this case study is representative of the issue currently being addressed by owners of sandstone buildings. The three story residence was constructed in the 1880s. The west facade fronts the street and is clad almost entirely with Lake Superior sandstone except for areas of ornament at the roof level which is composed of terra cotta units. The east, north and south facades are mostly concealed by adjacent buildings with the exposed areas clad with Chicago common brick.

Figure 1. Representative example of previous repair which has subsequently failed and face bed unit.

The sandstone units were installed with a multi-wythe common brick backup wall varying between two and four wythes. Galvanized metal ties were installed into the backup wall and engage the bed joints of the sandstone. The sandstone units varied in thickness between 10 cm and 40 cm.

Deterioration of the sandstone has been an ongoing issue with many buildings in the area. Ongoing deterioration was the result of prolonged exposure to rain and erosion of the binders between the sand particles. Several of the units also appear to have been face bedded. Deterioration was further exacerbated by the physical characteristics of Lake Superior sandstone which contains shale and clay within some of the bedding planes as well as susceptibility of face bedded units to rapid failure.

In the 1990s, a repair campaign was undertaken which included the removal of deteriorated and delaminated areas of sandstone. A proprietary cementitious patching material was used to reform the areas which had been severely eroded. The depth of deterioration in many instances exceeded 4 cm with significant loss of carved detail. The patch material was installed over a stainless steel wire mesh that was fastened to self drilling-self tapping fasteners driven into sound substrate as shown in Figure 1. Massive failure of the repairs by 2005 prompted the owner to seek alternative repair approaches. Deficiencies in the patch material included fading of the color and bond failure at the interface of the material and the substrate.

A survey of the facade revealed that more than 75 percent of the units had been previously patched. In many instances the entire exposed surface was composed patch material. The majority of units which had not been previously patched were ashlar units or units which were protected by water tables or drip courses.

The owner had retained a masonry restoration contractor that recommended another campaign of patching be considered. The authors were retained by the owner to provide a second opinion regarding possible repair approaches. The owner expressed the desire to comprehensively restore the facade and achieve a very durable restoration. Several alternatives were presented for consideration which while being more expensive would provide the 75 year restoration that the owner had requested. It was the author's opinion that a restoration which included patching and limited repair could potentially achieve the owner's goals, but the patches would likely not last more than 10 to 15 years regardless of the quality of the installation. Further, availability of replacement Lake Superior sandstone is very limited since most of the quarries have been long closed. Given the poor performance history of the material, the wide spread installation of a poor quality material was not an appropriate approach for the restoration. Alternative cladding materials were considered included terra cotta, limestone and other sandstones.

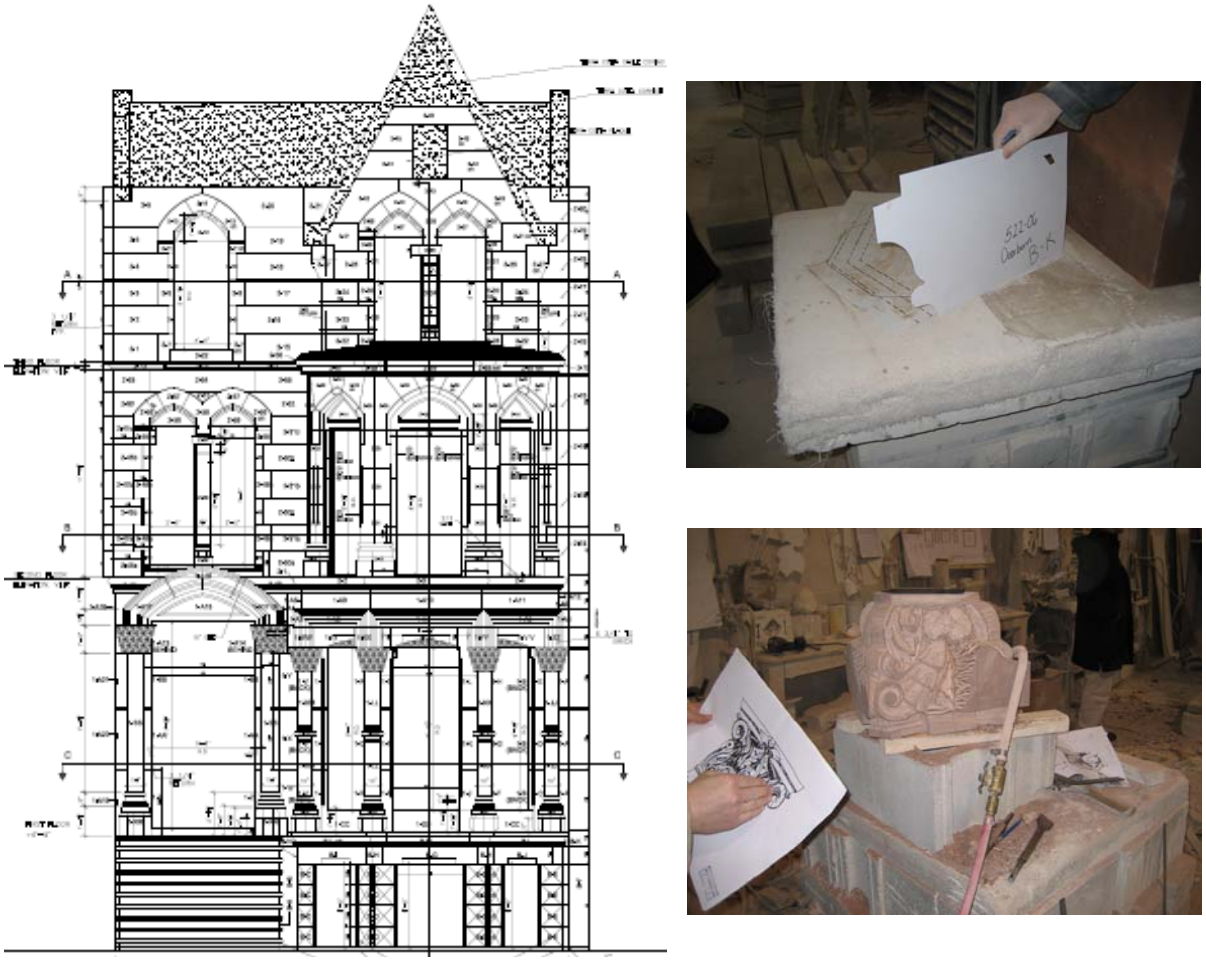

Figure 2. Shop drawing and stone fabrication process

Terra cotta was deemed an appropriate substitute material if the replacement units could be grouped to maintain a cohesive appearance. Regardless of the skill of the glaze formulation, the ability to match the sandstone was recognized to be limited. Had the severely deteriorated units been limited to the column capitals, water tables and window surrounds, terra cotta may have been appropriate. The extent of deterioration however would result in limited areas of sandstone and large areas of terra cotta.

A very common and economical replacement cladding material in the Midwest United States is Indiana limestone which has a long history of successful applications. The obvious drawback of Indiana limestone is the uniform gray color. Staining the limestone, to match the sandstone, was considered, but matching the color and the long term stability of the stain was difficult to accurately predict to achieve the desired 75 year service life.

Another option considered was using red sandstone which was more durable than Lake Superior sandstone. Like Indiana limestone, the sandstone would be closer in color, but would not match the texture and hue of the original material.

Ultimately, the owner opted to entirely reclad the main facade of the building using an alternative red sandstone; St. Bees Red sandstone, which is quarried in England. The new sandstone had excellent physical characteristics and the color and texture were similar to Lake Superior sandstone. Due to the quantity of feldspar, St. Bees is described as sub-arkose, a well consolidated medium grained sandstone primarily consisting of quartz (80 percent), alkali feldspar (10 percent), chert (3 percent), muscovite (1 percent) and a matrix of approximately 5 percent clay.

A detailed survey of each unit on the building was performed by the stone fabricator, masonry contractor and owner. Material was shipped from England to Toronto Canada where it was cut, caved and sculpted to match the original units as shown in Figure 2.

Figure 3. Representative example of new sandstone installation.

A systematic cataloging approach for removing the original units, taking necessary and appropriate dimensions and stockpiling the units was employed by the masonry contractor. The original galvanized ties were cut flush with the brick backup wall and open joints in the backup wall were repointed.

During the fabrication process, a temporary enclosure was installed to allow the residence to remain in use during the recladding. Pipe scaffolding had been in place and remained in place as further protection for the interior.

During the installation of the new sandstone, limited areas of the backup had to be modified to accommodate the new sandstone units. In general, a minimum of two wythes of the backup wall existed, but in many areas as many as four wythes existed. To accommodate some of the larger units, some of the backup wythes were removed. New sandstone units were installed using stainless steel lateral anchors which were fastened using stainless steel straps into the repaired backup wall as shown in Figure 3.

Installation of the stone offered several challenges for the fabricator and contractor. Though durable, the new sandstone was very soft and easily damaged during handling. To minimize damage during shipping, units were carefully packaged together or in some instances individually packaged and shipped. Units ranged in size and weight. Smaller units were set by hand. Several of the lintel units over the windows weighed in excess of 500 kg and had to be set using a combination of Lewis pins, chain falls and extreme care.

6 CONCLUSION

While good preservation philosophy stresses repairing, restoring and conserving orignal building fabric whenever possible, in some instances these approaches may be impractical. While Lake Superior sandstone is a beautiful building material, it does not offer good long term performance. Depending on the condition of the material and when treatment programs are initiated, complete replacement can be avoided.

T 15

ABSTRACT

By means of a questionnaire a study was carried out to investigate the perception of small scale damage and repairs of natural stone used in buildings. Participants were asked to evaluate damage to natural stone shown on pictures. They were also asked to give their opinion on interventions needed to preserve or restore the material. Significant differences can be found between specialists and non-specialists in conservation.

Respondents consider some cases as "damage" situations, even though no intervention is deemed as necessary, as if damage was a sort of natural weathering, thus to be expected and accepted. In other cases, also defined as "'damage" situations, interventions are considered necessary. This seems to imply the use of a different criterion to define "damage", maybe including the expected risks related to its development. This study contributes to the definition of damage, and to a better understanding of the criteria used by different people to decide on the need of interventions.

1 INTRODUCTION

Decisions about the conservation of monuments often depend on different technical considerations, such as the acute need of preservation, material properties or arguments regarding the artistic value of the object. It includes sometimes a reconstruction, and in practice, non-technical arguments relating to public appreciation, tourist concerns, or even political purposes [e.g., Von der Dunk 2006]. Assuming that these considerations are often made by persons with different interpretative frameworks, depending on their education and professional experience, a clear definition of damage is absolutely necessary as a starting point for any decision on interventions. The definition of damage should be objective and commonly accepted. Several glossaries combined with damage atlases have been developed over the years, involving a wide range of specialists in conservation [e.g., Van Hees & Naldini 1995, Franke et al. 1998, Van Balen et al. 1999, Fitzner & Heinrichs 2002, Naldini et al. 2006; see also the *ICOMOS International Scientific Committee for Stone*, http://www.lrmh.culture.fr/-icomos/icomos/consult/index.htm]. Still the definition of damage is not unambiguous, but rather subjective, which partly explains the different approaches shown in monument conservation.

Situations (i.e., damaged buildings) that are technically identical are often handled in different ways, depending on the building concerned and the people involved in the conservation process. Apparently, the technical arguments are not decisive. Probably, decisions are also based on non-technical arguments like intuition, aesthetics and perception. Further, it is not clear whether, from the same perspective of intuition, aesthetics and perception, the results of the intervention (repairs, cleaning) are considered to be an improvement, especially by non-specialists. Though they play a major role in everyday decision making on conservation, non-technical arguments such as perception in relation to replacement or preservation have not been widely researched. This study is aimed at assessing which factors are involved in deciding whether deteriorated building parts should be preserved, restored, reconstructed or replaced.

In this study, pictures of small scale damage (i.e., damage to individual stones or small sections of a wall) have been submitted to the participants for evaluation, because it is expected that in these cases non-technical arguments would determine their decisions far more than in the case of large scale damage (i.e., entire façades). When facing large scale damage, technical surveys are commonly carried out and decisions based on perception are supposedly minimized.

2 METHODOLOGY

2.1 Questionnaire

The methodology of this study was inspired by research of Andrew [2002] on the perception of weathered stone façades, and earlier studies on perception by Van Wegen [1970] De Jonge [1971] and Steffen [1983].

A questionnaire was composed of 20 images of natural stone; both weathered/damaged and repaired (Fig. 1). Each of the images was accompanied with 11 statements to be answered on a 7-point scale ranging from “totally agree” to “totally disagree”. The research was related to the Dutch conservation world, therefore, the questionnaire was in Dutch. The questionnaires were sent to people known to be interested in and/or working in the field of conservation of natural stone, architects, geologists and students attending courses on building conservation. To have the layman’s opinion, the questionnaire was also sent to family and friends who do not have a professional relation to conservation of natural stone. The questionnaires were distributed in colour-printed form. All the images had a printed size of 80 mm height. The returned questionnaires have been processed using standard spreadsheet software, where the 7-point scale is entered as 1-2-3-4-5-6-7 (1 being totally agree and 7 being totally disagree).

Figure 1. A-T. The twenty images that have been used in the questionaire.

2.2 Statements

Several historic examples show the diversity of arguments used to underline a conservation approach [e.g., Quist & Van Hees 2006]. Based on an overview of the most recurrent arguments, 11 statements have been used to capture the perception of small scale damage and repair of natural stone:

1. The stone shows damage.
2. The stone is attractive.
3. The stone needs maintenance.
4. The stone shows natural weathering.
5. The stone is well looked after.
6. The stone needs to be repaired.
7. The stone is in good condition.
8. The stone is ugly.
9. The stone needs to be cleaned.
10. The stone looks neglected.
11. The stone needs to be replaced.

2.3 Response

Out of 230 questionnaires, 102 usable questionnaires have been returned, a response of 44%. Respondents had to choose a profession out of a list; it was allowed to choose more than one profession. It is remarkable that almost all architects working in the field of conservation chose both the profession of "specialist" and "architect". The distribution is as follows: Student: 12 (10%); Specialist in the field of conservation: 49 (39%); Architect: 26 (21%); Geologist: 13 (10%); Other: 25 (20%). Due to a low response in most of the predefined populations, only the "specialists" and "the others, not being specialist" can be used as a different population within the analyses. The architects-population seems usable, but 17 out of 26 respondents are also part of the specialists-population. The remaining 9 respondents can not be used as a separate population.

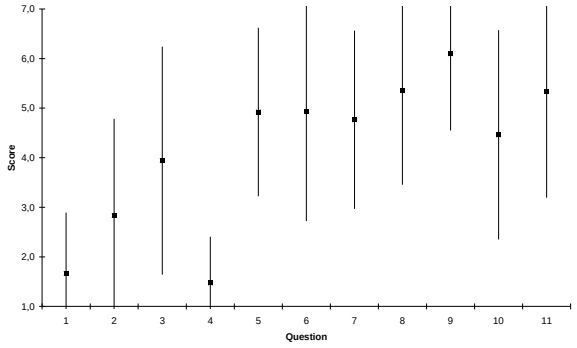

Figure 2. $\bar{x}$ and σ of all the statements regarding image 9 (Fig. 1-I).

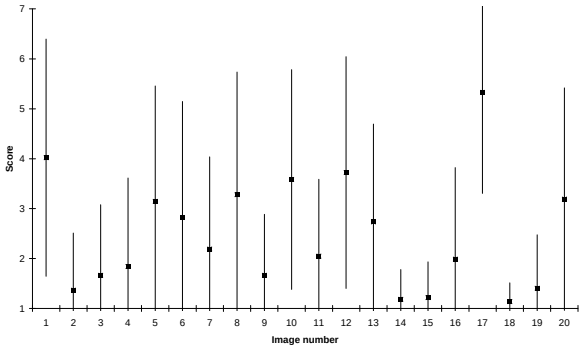

Figure 3. $\bar{x}$ and σ of all the first statements (damage) regarding all images (Fig. 1 A-T).

3. INTERPRETATION

3.1 Mean Average and Standard Deviation

For every question on the questionnaire, the mean average ($\bar{x}$) and the standard deviation (σ) were calculated. Figure 2 shows a graphical representation of $\bar{x}$ and σ of all statements regarding the ninth image. Figure 3 shows a graphical representation of $\bar{x}$ and σ of the first statement (damage) regarding all images (see Fig.1 A-T). In both cases all the respondents were taken into account. Figure

2 and 3 serve as an example to illustrate the high statistical dispersion. All the other $\bar{x}$ and σ show the same tendency. In general, the dispersion is lowest for image 18, and highest for image 5; images 2, 7, 8, 16 and 20 also show a very high statistical dispersion.

There are 2 possible explanations for this high statistical dispersion:
1. The total population is not homogeneous. The perception of the specialist population significantly differs from the non-specialist population.
2. The statements used in the questionnaire do not distinguish enough.

3.1.1 The Total Population Is Not Homogenous

To check whether there is a significant difference in perception for the specialist-population and the non-specialist-population, the student's homoscedastic t-test, with a two tailed distribution was carried out. With this test, 220 data ranges (20 images with 11 statements each) were processed (see table 1). For 85 out of the 220 data ranges can be concluded that $\bar{x}$ differs significantly (p=5%). This proves that, in relation to a lot of statements and images, there is a different perception of small scale damage and repair of natural stone for both populations.

Six out of twenty images show significantly different mean averages for both populations. These images are 3, 5, 11, 12, 16 and 20, of which four images concern repaired natural stone. Looking at the statements, four (statement 2, 8, 9 and 10) appear to differ significantly for over 10 images. The specialists tend to judge the images more positively in relation to the statements "attractive", "ugly" and "neglected". The opinion of the specialists in relation to "cleaning" differs for 18 out of 20 images significantly.

Table 1. p-values to check whether differs significantly for both populations.

20	1	0	0	66	0	0	0	0	0	0	1

3.1.2 Explaining High Standard Deviations

Further analyses of the frequency distributions of scores on statements with high standard deviations show that there are two types leading to the same high σ, namely:
1. The scores are almost evenly distributed to all seven items on the 7-point scale. The histogram shows an almost horizontal linear trend. This concerns statements 2, 5, 7, 8 and 10.
2. There is a high concentration of scores on either the "agree-side" and the "disagree-side". The histogram shows a parabolic trend. This concerns statements 1, 3, 6, 9 and 11.

This division can be assigned to types of statements. The evenly distributed scores all concern the more "soft", personal statements and the polarized scores all concern the more "expert, technical, objective" statements. These phenomena can be found in all three populations (total, specialists, and non-specialists). Two opposite opinions exist with regard to damage, maintenance, repair, cleaning and replacement.

3.2 Correlation

Both the specialist-population and the non-specialist-population show four pairs of statements indicating linear regression: $-0.6 < r\ (PMCC) > 0.6$, see table 2. In addition, two more correlations can be found in the non-specialist-population.

Table 2. Statements that show linear regression.

Population specialists	Population non-specialists
The stone is attractive and the stone is ugly (r = -0.82)	The stone is attractive and the stone is ugly (r = -0.77)
The stone needs maintenance and the stone needs to be repaired (r = 0.68)	The stone needs maintenance and the stone needs to be repaired (r = 0.72)
The stone is well looked after and the stone is in good condition (r = 0.64)	The stone is well looked after and the stone is in good condition (r = 0.67)
The stone is well looked after and the stone looks neglected (r = -0.65)	The stone is well looked after and the stone looks neglected (r = -0.67)
	The stone is in good condition and the stone looks neglected (r = -0.63)
	The stone is in good condition and the stone needs to be replaced (r = -0.63)

The strong negative regression between "attractive" and "ugly" indicate that these statements are considered to mean the opposite. The same counts for "well looked after" and "neglected". The linear regression between "maintenance needed" and "to be repaired" shows that in most of the cases when talking about maintenance, people want to intervene by repairing the natural stone.

After a first analysis of the results, some images have been grouped to investigate whether linear regressing according to comparable cases of damage can be demonstrated:

1. Sandy limestone on several scales (images 1, 9 & 13)
2. Repair (images 5, 7, 8, 11 & 20)
3. Larger scale, "wide-angle" (images 1, 10, 13 & 17)
4. Obvious loss of material (images 2, 3, 15 & 19)
5. Scaling (images 3, 9, 16, 18)
6. Sandstone degradation (images 2, 16)

Despite the assumed similarity between these groups of images, no correlation can be found.

4 DISCUSSION AND CONCLUSIONS

If all respondents are evaluated as one group, some interesting observations can be made on a number of situations regarding the question whether a situation is considered to be damage (statement 1) and if so, whether or not intervention (statements 6, 9 and 11) is necessary (Fig. 4). In some cases, the situation shown by the images is considered as damage, but accepted, without any intervention deemed to be necessary. This holds for images 6 (pronounced layering due to weathering), 9 (exfoliation), 13 (wide angle view of blocks with exfoliation) and 19 (spalling). Perhaps, these cases are considered as a kind of natural weathering. In contrast, regarding images 2 (sanding), 14 (joint), 15 (strong exfoliation) and 18 (strong powdering and exfoliation), the situation is also associated with

"damage" (statement 1), but most respondents consider intervention to be necessary. An explanation for the different inclination (whether to intervene or not) between both series of images may be the observed impact or expected future development of the damage. Another interesting situation is provided by image 10, an example of biological growth on tuff stone masonry. About 50% of the respondents consider this situation as damage. Also, about 60% states that an intervention is necessary. Obviously, those who consider biological growth to be damage, always deem that repair is necessary.

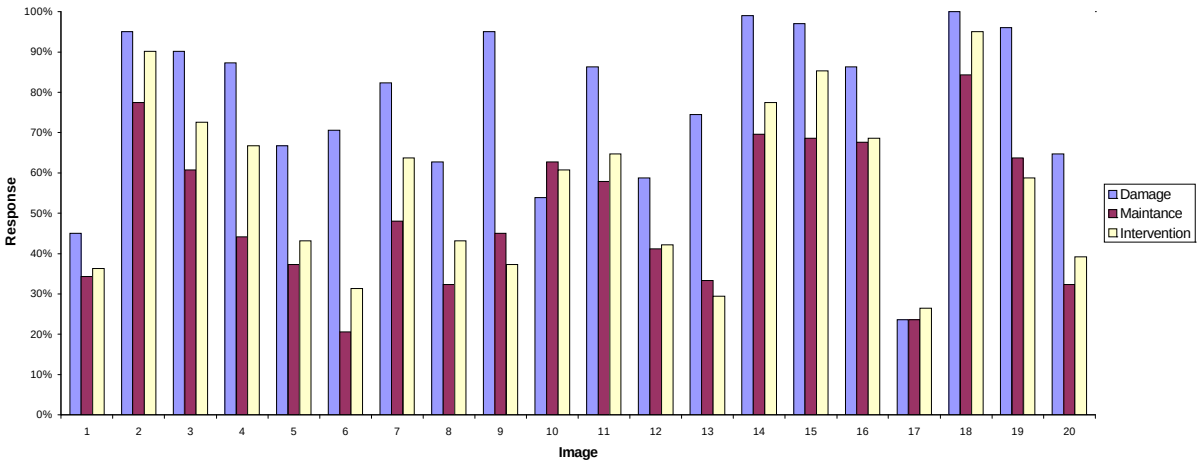

Figure 4. Comparison of the response on the issues of damage (statement 1), maintenance (statement 3) and intervention (statements 6, 9 and 11) of all respondents together.

It is impossible to point out the exact differences between predefined groups of people due to a low response within most of the groups and the high σ. Despite this, it is possible to observe some tendencies, especially in relation to statement 1 (damage). In general (Fig. 5): Students tend to give low scores (i.e., tend to agree); Geologists tend to give high scores (i.e., tend to disagree) especially image 6, 8 and 10; Response of the conservation specialists and architects on the images 5, 12 and 20 tend to diverge from the others.

The response by the students may possibly be explained by a lack of knowledge and experience, which makes them consider all kinds of degradation as "damage". The response from geologists clearly shows that (small scale) damage to natural stone is not an objective term. It is defined depending on the background and interpretative framework of different specialists. This is illustrated by the fact that geologists do not consider material degradation due to natural processes (i.e., weathering) as damage, and, consequently as reason for intervention. Apparently, the fact that internal characteristics of the stone, such as layering or presence of fossils, become more pronounced and better visible due to weathering processes (as in image 3), may even be appreciated. The stone is considered to express itself to a larger extent, and to gain charm by ageing. To some extent, this concept is comparable with the noble patina of age and (referring to paintings) *time as a painter* [Gombrich, 1988] sometimes invoked in art theory. On the contrary, conservation specialists and architects tend to associate the same result with damage, probably because it changes the original conception of a façade, and tends to erase the working of the stone by stone masons and artists. The definition of damage depends on the education and professional experience of the person involved, rather than on objective criteria, which influences how decisions about intervention are made.

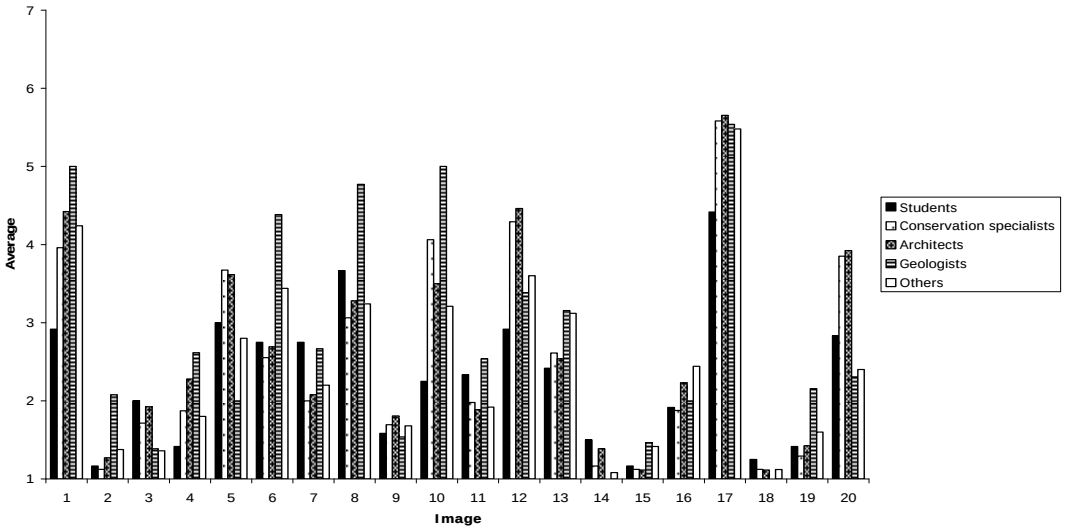

Figure 5. Average score on statement 1 (damage), regarding images 1-20.

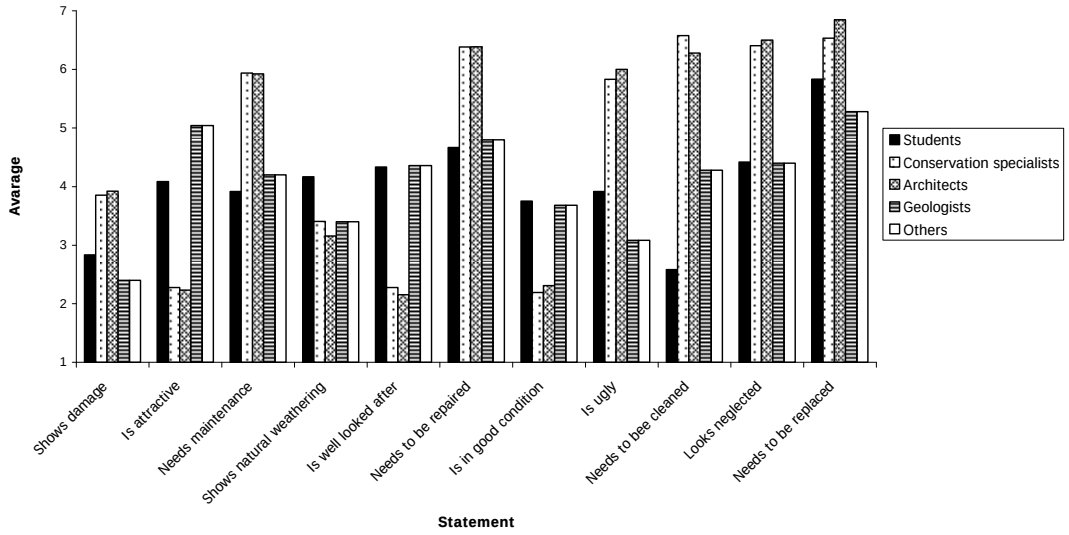

Figure 6. Average score on the statements, regarding image 20.

Decisions about interventions are not only based on the direct need of conservation in order to preserve material and building, but are also made to enhance a building, street or neighbourhood in a way 'the general public', 'visitors' or 'tourists', supposedly appreciate. A clean façade or neat blocks of stone are often regarded as ways to get this appreciation. The results allow some interesting reflections on this point.

Images 11 and 20 show situations in which a repair is visible. However, if all respondents are grouped together (Fig. 5), most of them (c. 85 %) consider the repair shown in image 11 to be damage. Many of those 85 % even consider intervention to be necessary. The situation shown in image 20 - a close-up of a recently executed sandstone repair - is clearly seen as the more successful one (Fig. 4). However, conservation specialists and architects apparently feel different about what is a successful repair from the general public. Architects and monument specialists highly appreciate the repair, in contrast with the other respondents (Fig. 6).

In general, conservation specialists and architects seem to have a greater appreciation of repairs than the general public. The latter still tend to consider a repaired stone "damaged". The specialists recognize the situation from their professional experience, and assume that this was the only option to

preserve the block of stone. Contrary, the non-specialists do not judge the actual repair, but "the disturbed, not naturally looking, not original situation". Opinions of "creators", judging the repairs positively, and "observers", judging the repairs negatively, consequently diverge. This implies that, when appreciation by the general public is one of the motives for intervention, initiators of this intervention (such as owners of a building, authorities, etc) may not obtain the desired result.

With regard to cleaning, the situation is the opposite. Whereas non-specialist in general do not appreciate the repairs, they tend to opt for cleaning as an intervention. In contrast, specialists are (very) negative to cleaning, whilst they appreciate the repairs. Specialists are probably aware of the technical implications of cleaning, and the damage that may result from it. In this case, new methods enabling damage-free cleaning might combine public appreciation with professional care.

Biofilm Effect and Microbiological Deterioration on the Material Surface

Sedat Kurugöl [1]
Dilek Dilhan Hatipoğlu [2]

T 15

ABSTRACT

Under natural circumstances, microorganisms preferably tend to continually show progress on a surface. Generally, other building materials like wood and plastics as well as most metals, except the ones that are toxic, natural stones, concrete cannot resist this progress of bacterial colonies in convenient environments and circumstances. Formation of this microbial organization on the material surface and the intensity of the colonization do not depend on random circumstances, but become obvious as the result of various factors gathering together. Microbiological activities can be also considered as an indicator and a reflection on the material of the variety and the transformation of ecological circumstances. On the other hand, they are critically important also with regard of durability, because of the deterioration mechanisms due to the physicochemical effects they generate in time on the material surface underneath the biofilm they have formed. In this study, by explicating the formation and progress stages of biofilms, the effects of these activities on various building materials like metal, stone and concrete are discussed.

1 INTRODUCTION

Biofilms are naturally growing bacterial activities and bacterial coatings by clinging and adhering of various microorganisms to generally stable and humid surfaces. They constitute several negative physicochemical effects on the surface of the material in terms of durability by chemical mechanisms they develop with the influence of the ambient. Biofilim is an activity on the surface of the material. All technological and physicochemical effects like adhesion, abrasion, friction, corrosion may grow up depending on surface qualities of materials. Therefore, in this sense surfaces are always reactive and behave in accordance with all effects they suffer. One of the interactions on material surface is the surface film formed in consequence of microbiological activities, which is called 'biofilm'. Microbiological activities within an ecosystem show themselves as biofilm formations on the surface of material. These activities, ultimately, cause surficial deteriorations and decompositions on the material due to surface properties and environmental circumstances.

In natural environments, microorganisms cling to various organic or inorganic surfaces and provide the required vital energy by utilizing the surrounding environment to pursue their lives and generations. Generally, biofilm is described as "a sum of microorganisms formed by gathering and getting organized in a matrix of organic molecules which cling to a surface" [Chevrou&Rodiere 2004]. The existence of biofilms seems to be the source of also industrial and economic problems besides serious and important issues in every field. Biofilms, as well as being emphasized in various scientific fields like industry, medicine, biology, chemistry, microbiology, geology, etc., are confronted as a remarkable phenomenon in terms of physicochemical effects they generate on the surface of building materials and the damage they give seem to be high beyond the suppositions.

Biofilm grows up on the surface of the material as a result of its relationship with the environment and almost all materials are covered with a biofilm layer in their non-sterile natural environments. Biofilm bacteria can be colonized in all humid surfaces whether organic or inorganic [Bergeli 2005]. Depending upon the environments they develop, 1 mm^3 of a biofilm may contain a huge amount of microorganisms and there may be various bacteria, fungi and algae within a biofilm [Haras 2005]. In aquerous, humid and stuffy environments, these microorganisms use compounds of oxygen, carbon, nitrogen and sulfur in the soil for growing up and providing energy by benefitting from them. Biofilm microorganisms also give rise to growing up of biofilm layers by generating various organic molecules (EPS: Extracellular Polymeric Substances) as a result of nutrition. The EPS matrix is composed of organic molecules like polysaccharide and protein and they can take up 75-95 % of a matured biofilm capacity [Haras 2005, Suci *et al*. 1994]. 80-95 % of a biofilm and 85-98 % of an EPS matrix consist of organic items. Additionally, in biofilm, there can be various inorganic items (humic substances, debris, clay, silica, gypsum, etc.) [Flemming 1998]. Biofilm shows itself when four components come together. These factors are : 1- Generally a bit aggressive environment and its characteristics. 2- A material affected by the environment and its surface characteristics. 3- Various types of microorganisms whose existence had been ignored or not considered [Chevrou & Rodiere 2004, Bergeli 2005, Suci *et al*. 1994, Flemming 1998, Féron 2005]. 4- Time (Figure 1).

In this structure, there may be different types of bacteria, fungi, microalgae and moulds together and they may cause a biofilm to grow up. These bacteria, which have various types depending on their ways of nutrition, are organisms that have very tiny constructed elementary morphology that can be merely seen under a microscope, they can stay alive in every environment like air, liquid, soil, and can grow up up to the various circumstances of the environment like oxygen, temperature, pH, hydrostatic pressure and salinity [Magot 1998]. And the primal terms of biofilms to grow up are: 1-A nutrition source 2-An energy source 3-Water and damp 4-An adequate temperature 5-An adequate pH 6-An adequate amount of oxygen and [Chevrou&Rodiere 2004] 7-Surface characteristics of the material. For a biofilm to form and grow up, primarily physicochemically, microorganisms have to hang on to the surface and be accepted by the surface. Formation of a biofilm formation with bacterium on a solid surface in adequate and aggresive environment seems like a complex case where are lots of parameters. A biofilm formation ready to increase in numbers occurs in four steps that follows one another [Féron 2005].

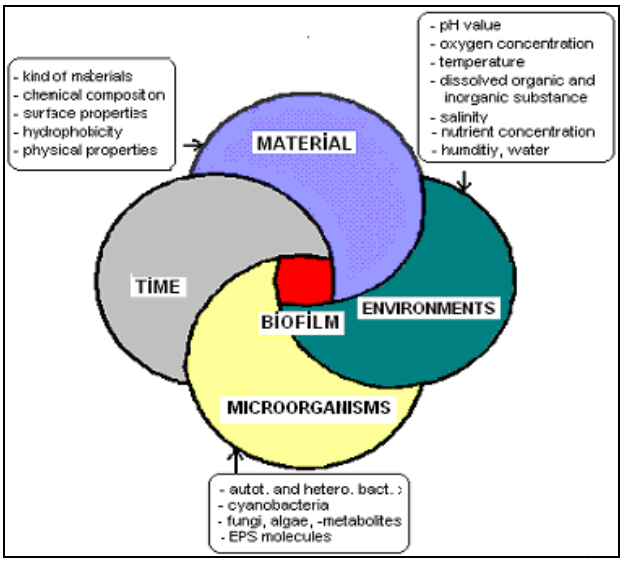

Figure 1. The factors that determine the formation of a biofilm.

1. Transport : It is a matter of microorgansims being moved to a surface with many different ways.
2. Absorption: It is an instant matter, it causes the surface to have physico-chemical transformation.
3. Adhesion: The theories about the adhesion mechanism besides being interpreted in various ways according to different scientific disciplines, generally occurs depending on a two-stepped activity. At the first step, a reversible phase that holds the bacteria on surface and can be easily washed away and gone is formed, and at the second step which follows this, stiff and solid matrix (like scratching&brushing) that causes the irreversible adhesion of the bacterium and requires a huge energy to take these back is formed.
4. Colonization: This activity may take a few months or a few hours depending on the terms the microorganism is in and this colonization ends up with a formation of a biofilm. In a formation of a biofilm, not only the effect of bacterium and damp but also at the same time the organic items that has been created by the organisms on the surface (EPS) play a role (Figure 2,3). Colonization may take place in different times depending upon the type of material and the environment. For instance, it is formed in a few hours in sea water on stainless steel (inoxydable AISI 304), few days on AISI 316 steel [Lemaitre *et al.*1990], seven days in a fluid water on a mild steel [Donlan *et al*. 1990], few months in fresh water [Feugeas *et al.* 1997]. On the surface of the material, there might not be a coordinated and uniformed spread of the biofilm. Microorganisms that created biofilms can show themselves in various types in this structure. This colonization can occur on the whole surface or in one part of the surface based on the relationship between the surface characteristics of the material & bacteria structures [Haras 2005].

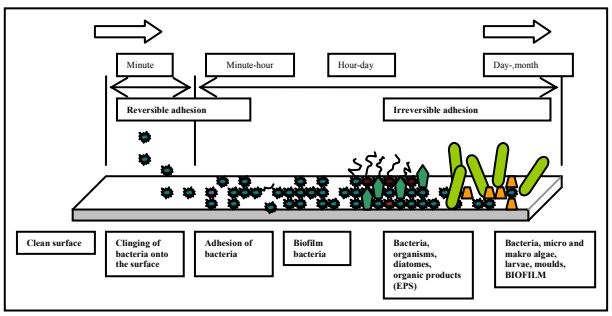

Figure 2. Presentation of a biofilm formation image on a surface as schematic.

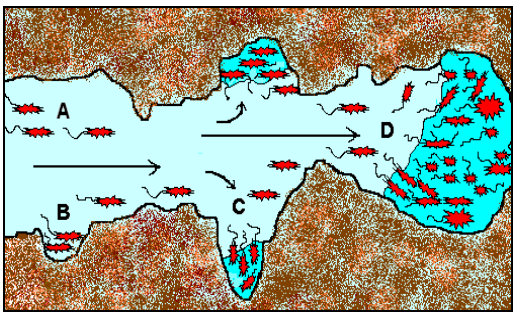

Figure 3. Presentation of steps of the biofilm formation in a covern as schematic.A-Actions of water and the bacteria(absorbation), B-Bacteria's holding to the surface(adhesion), C-Creation of the EPS molecules, D-Colonization. Bacteria fill in the

Substantial environments created by organic items is counted as the reason of the variety of microorganisms that can be seen in biofilms. Accordingly, corruption of the environment and various organic items they have are effective like a formative factor in the formation of a biofilm and correspondingly the microcolonization and biofilm formations on the surface raises.

2 EFFECT OF BIOFILM ON THE MATERIAL

Biofilms seem to have a capability of growing up in suitable cases on every kind of structure material like metal, concrete, stone, wood and plastic. Biofilm activities which are on various materials are discussed in the subtitles.

2.1 Microbiological Effect on Concrete

Concrete which is a structure material and widely used worldwide can be deteriorated because of the biofilm on the surface created by various autotroph and hetotroph bacteria, cyanobacteria, alga and fungus [Saad & Gaylarde 2004]. Main problems of the abrassion of concrete below the biofilm layer with the effect of bacterium show itself in drain water and canalization systems generally made by this material because of the reason that there is hydrogen sulfur (H_2S) in the environment.

Underground waters that contain sulphate and chloride ions, sea water, waters that contain free CO_2 or H^+ ions which mix up with industrial contaminations and dirty waters may therefore cause harmful reactions [Yeğinboğalı 1999]. This situation, although observed in many countries, was first analyzed in ABD and Germany. The effect of sulfuric acid on concrete had been known time out of mind. In addition to this, the mechanism of the transformation of H_2S to H_2SO_4 was not a well known thing. Afterwards, the investigations made have revealed that this thing originates from bacterium. To determine the existence and types of microorganisms, with the investigations made on concrete, mortar and limestones [Graef *et al.* 2004, Muynck *et al.* 2005], the existence of the *T.bacillus* bacterium on concrete elements have been proved, lichen formations have been seen, and it has been appointed that gypsum stone cristals are formed with the effect of sulfuric acid released by the *T.bacillus* bacterium and (Fig.4) therefore the ettringit cristals have grown up on concrete.

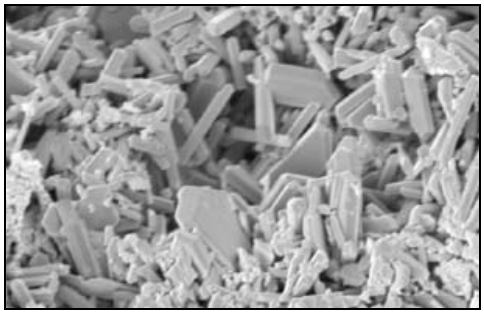

Figure 4. Gypsum cristals in concrete due to H_2SO_4 created by Thiobacillus [Welton *et al.* 1998].

In these environments, offensive odor, toxicity, corrosion of metals and the deteriorations seen on the concrete in the course of time are the prominent indicators. Generally, it has the characteristic feature of dampish concrete that damaged by the effects with microbiologic source and has a whitish appearance. It is covered by a sticky and thin layer of film. The pH value on the surface is approximately 1. This case mostly shows itself in not much aerated environments that contain acid and bacteria. Sulfur oxidizing microorganisms that become effective in these kinds of environments are gathered under three categories [Tache 1998]: 1- Colorless Chimiolithotrophes (*Thiobacillus, T.spira, T.bacterium, T.microspira, T.vulum, Macromonas, Sulfolobus* etc). These bacteria grow up as autotroph. They use the CO_2 in the environment for their synthesis. 2- Colorful Photosynthetic bacteria (reddish color). These are anaerobic bacteria which can make oxidation in an oxygen-free environment with light and reduce sulphate. And their basic type is known as *Desulfovibrio, D.fomonas,*

D.fococcus, D.fobacter and *D.fobalbus.* 3- Heterotroph microorganisms which are capable of oxidizing sulfur compounds without taking energy. In another example [Belie *et al*. 1997] dept of deterioration and microcracks have been detected. Here it has been found that the acids created by bacteria affects the material much, and especially in the exterior surface of the concrete, the connection phase between cement and aggregate has been deteriorated enormously. In another study, [Silva 1994, Silva 1997] it has been shown that the microbiological activities on the concrete grow up in not only water systems but also every environment. Studies have been made by using six different investigation technique to analyze these activities on the concrete samples taken from the three buildings that are in different climates, (among the buildings of 7 or 30 years old and exposed to the temparature between -5, + 35C^{o}). As a result, the deterioration of the concrete by organisms occurs even in different climates which can be regarded as normal, and in concrete surfaces, in addition to the same type microorganisms characterized morphologically, we may happen to meet non-characterized various types (*Diatom algea, Actinomycete, Cladosporium, Protozoa* etc). On the other hand, on the surface of concrete and cement, other than sea water and drain water,even in natural fresh water, it has been seen that various microorganisms, by growing up, can create biofilms that may cause cement to deteriorate [Roux *et al*. 2005]. Biodeterioration is caused mainly by 1-bacteria; 2- fungi; 3- algae and lichens and; and 4- organisms that erode an drill the concrete [Gaylarde *et al.* 2003]. Among those that cause concrete biodeterioration some of the most important are: 1- cyanobacteria; 2- nitrobacteria; 3- sulfur-reducing bacteria; and 4- sulfur-oxidizing bacteria. Their main characteristics and influence on concrete are presented in Table 1 [Bastidas-Artega *et al.*2008].

Table 1. Effect of bacteria on reinforced concrete.

Bacteria type	*Lifestyle*	*Temperature*	*pH*	*Consequence on concrete*
Cyanobacteria	Autotrophic, aerobe or anaerobe	-60 to 85 ^{o}C	wide range pH	Generate tensile stress leading to an increment in the size of cracks.
Nitrobacteria	Heterotrophic and anaerobe	18 – 25 ^{o}C	< 7,5	Nitrifying bacteria (*nitrosomona and nitrobacter*) produce calcium nitrate by solubilising some of cement components.
Sulfur-reducing bacteria	Heterotrophic and anaerobe	25 – 44 ^{o}C	5.5< 9	Produce H_2S that is used for the *sulfur-oxidizing bacteria* to produce sulfuric acid. This prosess is commonly called *concrete corrosion*.
Sulfur-oxidizing bacteria	Heterotrophic and anaerobe	25 – 44 ^{o}C	2< 9	Produce sulfuric acid, acetic acid, sulfates, sulfur, sulfites and polythionates that affect the concrete chemically.

According to the similar studies on this issue, various microorganisms use both concrete and stones as substrats and shows that they cause activities to deteriorate the concrete by creating acids.According to the investigations [Tache 1998] with the effect of this activitiy,there is a loss of material which has 2-3 mm thickness on the concrete surface. H_2S created in an anaerobic environment by *Desulfovibrio* type of bacteria, H_2SO_4 created in an aerobic environment by *Thiobacillus* type of bacteria shows themselves on the concrete as a source of microbiological deterioration. On the concrete, the simplified mechanism of sulfuric acid effect is like this: Cement paste, attacked by this acid created, causes calcium hydroxide [$Ca(OH)_2$] to dissolve. Sulphate, by reacting with calcium ionics, forms gypsum (hydrate calcium sulfate) and as a result they create silica gel.

$$Ca(OH)_2 + H_2SO_4 \rightarrow CaSO_4.2H_2O \text{ (gypsum)} \quad (1)$$

$CaSO_4.2H_2O$, later on, can react with the tricalcium alluminate (C_3A) in cement and gives way to the formation of ettringite ($3CaO.Al_2O_3.3Ca_2O_4.32H_2O$) causing concrete to swell and burst, and then may cause an increase in permeability [Aviam *et al.* 2004]. These activities go on like this by following each other and as time goes by, give way to durability problems like reinforcement corrosion besides decompositions in concrete.

2.2 Microbiological Effect on Metal

Biofilm effect on metal confronts us as microbiological corrosion (*MIC*). Biological corruption of metal materials, biochemical corrosion, biocorrosion, microbial corrosion, bacterial corrosion, corrosions created by microorganisms, or MIC/CIM, all these terms expresses the same reality and expresses the active and crucial role of various microorganisms, bacteria, fungi in corrosion [Féron 2005]. Biocorrosion is the dissolution of a metal or a blend electrochemically. These reactions occur in many different steps with the mutual interaction of metal and biological structure on the surface. [White *et al.* 1990]. First step of biocorrosion begins with the biofilm formations which grow up by necessity on the surface of the metal [Magot 1998]. In addition to this, it must be stated that a biofilm layer is not always a reason for corrosion. And there may not be always a relationship between biolayer and biocorrosion. [Bach *et al.* 1990]. Bacteria that cause corrosion have different metabolic features. They have an ability to oxidize irony ionics and sulfur and reduce oxygen, sulphate, tiosulphat and iron. Environment and the physicochemical features of the environment have also indicative roles in growing of biocorrosion activities. The physico-chemical compositions like temperature, pH value, oxygen contents, organic production they have, moisture content affect the growings of the microbiological formations. In formation of a biofilm, surface roughness of the metal is not seen as a formative factor, and in waxed and polished surfaces (like polishing), compared with raw and rough surfaces, sensitivity towards the formation of MIC reduces [White *et al.* 1990]. But however engraving of the surface of metal raises this sensitivity (e.g. as if brushing).

Bacteria that seem very aggressive steel and its blends encounter are sulphurogen type bacteria. These (Flemming 1998, Bach *et al.* 2005]; make up two important groups under the name of 'sulfur reducer'(BSR) and 'thiosulfide reducer'(BTR). BSRs generally use sulfur as electron receiver, so many substrats on the surface or from carbon sources as electron transmitter, acids (lactic, fumarate, acetate) hydrogen, from ethanols (methanol, ethanol, propanol), saturated hydrocarbon big molecular oil acids, simple aromatic compounds (phenol, benzene) and sucrose (fructose) [Chevrou *et al*. 2004, Haras 2005]. H_2S that appears during the reduction of sulfur transforms the iron in the environment to the FeS. Deterioration of the metal is generally the vallecula (or redd) type of corrosion. In case the metal which faces corrosion is an iron, sulfur reduction occurs in following reactions [Doruk 1982].

Anodic occurrence	$4Fe \rightarrow 4Fe^{2+} + 8^{e-}$	(2)
Kadotic occurrence	$8H_2O \rightarrow 8H^+ + 8OH^-$	(3)
	$8H^+ + CaSO_4 \rightarrow 4H_2O + CaS^+ - 8^{e-}$	(4)
	$CaS + 2H_2CO_3 \rightarrow Ca(HCO_3)_2 + H_2S$	(5)
Total amount occurrence	$4Fe+2H_2O+CaSO_4+2H_2CO_3+2H_2CO_3 \rightarrow 3Fe(OH)_2+FeS+Ca(HCO_3)_2$	(6)

Biofilm colony formations formed on the surface of the metal by microorganisms and diffused to several parts create different aerated part figures on the surface. So the place between these parts and the colonies are oxided differently and for this reason the center of the colonies is suddenly oxided as a result of contact to metal. This different oxidizing at the two parts of the metal causes potential electric discrepancy and ultimately a corrosion drift [Haras 2005, Féron 1998]. This formation is in the image of corrosion that is created by different airing. (Figure 3, 4). The MIC formation can grow up on several types of steel.

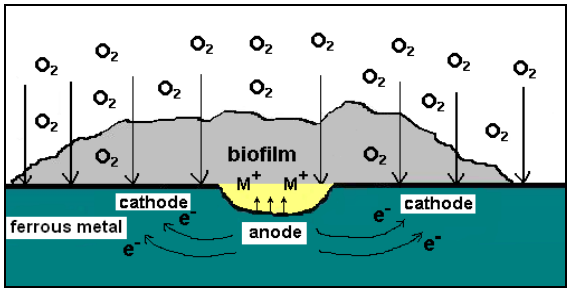

Figure 3. Little or much oxygenic biofilm part.

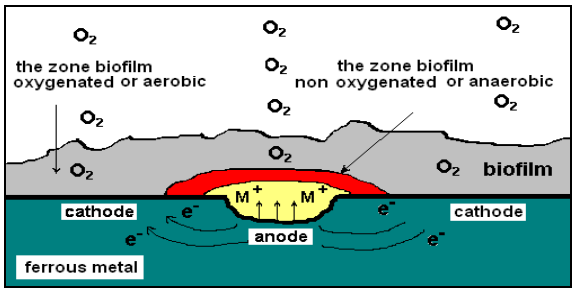

Figure 4. Biofilm in anaerobic parts.

2.3 Microbiological Effect on Stone Material

As stone has the quality of a traditional material in the way of its usage in historical process, it is the mostly analyzed material because of biological deterioration as much as various disintegration mechanisms. Out of the parts of the stone that is exposed to the effect of water, especially in the parts on which earth humid is effective, and which is very near to the soil, it is known that bacteria and fungi colonizations become activated. There is a relationship between disintegration mechanisms biofilm caused and stone types and climatic conditions. In addition to this, in all types of climatic conditions, on various stones bacterial activities can be mentioned. For example, Kumar and Kumar [1999] have analyzed microbiological formations on different stone types in various tropical environments of the world, their types, characteristics and accordingly their types of deterioration. In the environments where temperature decrease to -25 ^{o}C (Erzurum), it is seen that on surfaces of several monuments, microorganisms, which make stones deteriorate, grow up under the biofilm layer due to air pollution. [Nuhoğlu *et a*l. 2005].

Researchers have shown that bacteria on stone surfaces produce corrosive organic acids when exposed to pollutants, resulting in significant stone degradation. The scientific understanding of these processes remains limited because of the major variables involved. It is difficult to assess the relative importance of microbial processes in microbial-induced stone degradation. Chemoautotrophic sulfur oxidizing bacteria attack stones under aerobic conditions by producing inorganic sulfuric acid. Sulfuric acid reacts with the constituents of the stone to form sulphate crusts, precipitated within the pores of the stone, which upon recrystallization exert tremendous stress on the pore walls due to increase in volume, thereby causing damage to the stone [Khobragadeı *et al*. 2006]. The effect and composition of various biofilms growing up in carbonate stone monuments have some features in common and it is possible to see lichens on the stone surfaces of all the historical monuments. Cynobacteria, fungi, algae and heterotrophic bacteria are the typically seen microorganisms in these biofilms. It is observed that the acid effect of the grainy and laminal decays and cracks on the stones appear in the parts where these microorganisms are colonized.

Cyanobacteria create variously coloured microbial films on stone surfaces and facilitate adherence of airborne particles of dust, pollen, oil and coal ash, giving rise to hard crust of patinas18. Respiration and photosynthetic reactions of cyanobacteria also produce acids as by-products causing etching of mineral components and dissolution of binding minerals [Khobragadeı, *et al*., 2006]. These activities effect the stones aesthetically, chemically and physically [Rois *et al.* 2005], cause especially in calcareous Cynobacteria stones, decays by creating patinas with their biochemical activities. [Crispim & Gaylarde 2005, Albertona 2004]. Besides algas, protozoas, fungus, bacteria (cyanobacteria), limestones, they can be colonized on other types of rocks. [Ortega-Morales 2006]. Algae cause deterioration primarily by staining the stone surfaces resulting from different coloured pigments of the algae. Algae also produce organic acids which increase solubility of the stone in water, and alter the physico-chemical properties of stone [Griffin, *et al*. 1991].

The colonization of *Tihobasills* and nitrifying bacteria grows up to the existence of sulfur and nitrogen compounds. These are sulfur and nitrogen oxidizing and heterotrophic bacteria and show themselves

with the color change. The activities of nitrogen bacteria carbonate rocks is explained with the following balance and accordingly we draw a conclusion that external decay is predicated on nitrification. As a result of these activities, decays ending up with the dissolving of minerals and their transportation from the surface.

$$2CaCO_3 + (NH_4)_2 + 4O_2 \rightarrow Ca(NO_3)_2 + CaSO_4 + 2CO_2 + 4H_2O \quad (7)$$

3 CONCLUSION

Biofilm forms, in various processes, in one sense a type of corrosion, a type of biological deterioration for most materials. In this study, several researches related with the subject performed on materials like concrete, metal and stones are summarized. Besides the corrosion and decomposition mechanisms in these materials, biofilms also constitute various physico-chemical effects like splitting of molecular bonds in some polymers, decay in wood, surface erosion, spots and loss in the optical characteristics in glass and may cause significant problems in durability of the material. Measures which might be taken against biofilms may include physical, chemical and biological studies. In this respect, material type together with the composition of the biofilm form the characteristic criteria in common prevention and preservation studies. Hence, the methods to be chosen and protective materials should be assessed in this context. In general, studies of preventing and struggling against the biofilm formation on the surface of the material consist of two-phase practices which are a) to prevent the colonization on the surface (in the reversible step of the biofilm) and b) to remove them from the place they settled (in the irreversible step). The methods to be chosen have to be decided on only after the required analysis.

T 15

ABSTRACT

Coupled water and nitrate transport in sandstone frequently used in historical buildings on the Czech territory is investigated in the conditions of one-sided water and KNO_3 solution uptake. In the experimental work, rod-shaped samples are used for the determination of moisture and nitrate concentration profiles in simulated 1-D water and nitrate solution transport. The moisture content is determined by gravimetric method, the nitrate concentration is measured using the pH/ION 340i device with utilization of ion selective electrode. Experimentally determined KNO_3 concentration profiles and moisture profiles are used for identification of nitrate diffusion coefficient and moisture diffusivity on the basis of inverse analysis using the diffusion-advection model. The moisture diffusivity in dependence on moisture content is calculated in three different ways. First, the moisture diffusivity is calculated from moisture profiles measured for the penetration of distilled water into a specimen. Then, the moisture diffusivity vs. moisture content function is calculated from moisture profiles measured for the penetration of KNO_3 solution. Finally, the third moisture diffusivity vs. moisture function is obtained by the inverse analysis of nitrate concentration profiles under assumption that no nitrate diffusion takes place in the liquid phase. The results of inverse analysis show that the possible neglect of nitrate diffusion in the liquid phase is apparently wrong because the moisture diffusivity calculated from nitrate concentration profiles under this assumption is two to three orders of magnitude higher than moisture diffusivity calculated from moisture profiles.

1 INTRODUCTION

A part of building damages assigned to the negative moisture effects would not arise if only pure water would be present. Water represents very often only transport medium for other harmful pollutants that take part in the process of surface degradation of building materials. Water transport in porous materials makes possible salt transport or accumulation as well. Salt accumulation in specific places of building structures can lead in consequence to their failure or destruction.

Salts are from the chemical point of view binary or multi-component compounds consisting of simple or complex cations and anions. Only specific group of salts represents real danger in building practice or restoration. In light of danger for facades, paints, mortars, stones, bricks and other building materials, the salt solubility is the most important criterion. In corrosive processes only those salts take part, which are well soluble in water, whereas the influence of insoluble salts is more or less negligible.

The most frequent salts that cause damages of building materials and structures are sulphates, chlorides and nitrates and in some particular cases also water-soluble carbonates. The most important harmful salts that occur in building materials including their solubility are given in Table 1.

Table 1. The most frequent harmful salts that occur in building materials.

Salt	*Solubility* [g/L of solution]
Sulphates	
$CaSO_4 . 2H_2O$	2.4
$MgSO_4 . 7H_2O$	1172
$Na_2SO_4 . 10H_2O$	583
Na_2SO_4	481*
K_2SO_4	111
Chlorides	
$CaCl_2 . 6H_2O$	5359
$CaCl_2 . 2H_2O$	1281
$MgCl_2 . 6H_2O$	3051
NaCl	360
KCl	340
Nitrates	
$Mg(NO_3)_2 . 6H_2O$	2805
$Ca(NO_3)_2 . 4H_2O$	4305
$NaNO_3$	880
KNO_3	316
NH_4NO_3	1920

The salts sources can be divided into four main groups; salts primarily contained in building materials, salts transported into the structures by means of moisture rising from subsurface or moisture transport from different part of structure, salts originated in chemical corrosion of building materials induced by polluted atmosphere and salts originated from biological sources.

The destructive effect of water-soluble salts is the consequence of two main processes – crystallization and salt hydration in porous materials. In case of salts solution penetration into the porous structure of building materials, at the water evaporation the salts concentration in the solution is rising. The critical moment for salt crystallization is so called salt crystallization threshold that represents state, when the salt concentration in the solution exceeds the solubility of specific salt in water. Salt crystals can gradually fulfill the porous space and the crystallization pressures are exerted on the porous space. In dependence on temperature, supersaturation rate and pores dimensions, the destruction of materials can occur.

The second degradation process evoked by water-soluble salts is related to the salts that enable to bind defined amount of water molecules in their crystal lattice. The formation of hydration products is characteristic by changes of salt volume that are accompanied by hydration pressures. Also in this case, the harmful effect on the durability of building materials can be observed.

The extent of possible salt damage gives sound arguments for its thorough investigations; thus damage assessment of building materials and structures due to the effect of salts is very actual topic for researchers and building practice. In literature, two basic possibilities how to evaluate the danger of salts contained in building materials can be found. The first possibility is to take specimens from damaged structures and analyze them in laboratory. This provides information on water content and on the type and amount of ions in material which is very useful for assessment of the current state and for discovering the possible reasons for the presence of the particular ions. However, it is very difficult to make reliable predictions of further damage on the basis of these data. This requires years or even decades of on site measurements, aside from the fact that the extent of such analyses is logically restricted by the amount of material which can be taken from a historical building.

Another method of prediction of water and salt movement and salt crystallization in building structures represents mathematical and computational modeling. In this way, the time development of water and salt concentration fields can be obtained which is crucial for a proper assessment of possible future damage. However, the accuracy of simulated water and salt concentration fields critically depends on the availability of all input parameters.

There are two types of these parameters which have to be known in advance. The first are initial and boundary conditions. Initial conditions can be determined using on site analysis of water and salt concentration fields in the walls. Boundary conditions are of two types. The first of them are meteorological data for temperatures, relative humidities, rainfall and solar radiation, possibly also concentration of acid-forming gases in the atmosphere. The second type of boundary conditions involves water content and salt concentration in the underground soil close to the studied building. These data can be obtained again by on site analysis.

The second type of input parameters are water and salt transport and storage parameters of the materials of the wall which appear in water and salt mass balance equations. For the studied problem of coupled water and salt transport, these parameters include moisture diffusivity and water vapor diffusion resistance factor as water transport parameters, sorption isotherm and water retention curve as water storage parameters, ion binding isotherm as salt storage parameter and salt dispersion coefficient as salt transport parameter. These parameters can be determined by common laboratory methods.

In this paper, determination of moisture diffusivity and nitrate diffusion coefficient of sandstone in dependence on moisture and salt concentration is done on the basis of inverse analysis of experimentally determined moisture and salt concentration profiles.

2 MECHANISMS OF MOISTURE AND SALT TRANSPORT AND DETERMINATION OF TRANSPORT PARAMETERS

Determination of material parameters describing the mechanism of coupled salt and moisture transport is based on the assumed mode of this transport. In this work, the moisture dependent moisture diffusivity is calculated in three different ways on the basis of inverse analysis of experimentally obtained moisture and salt concentration profiles. First, the moisture diffusivity is calculated from moisture profiles measured for penetration of distilled water into the dry specimen. Then, the moisture diffusivity vs. moisture content function is calculated from moisture profiles measured for the penetration of KNO_3 solution. Finally, the third moisture diffusivity vs. moisture function is obtained by the inverse analysis of nitrate concentration profiles under assumption that no nitrate diffusion takes place in the liquid phase.

The diffusion mechanism of moisture transport where the dependence of moisture diffusivity κ [m^2s^{-1}] on moisture concentration w [m^3/m^3] was taken into account was assumed in the first two cases. For the inverse analysis of experimentally determined moisture profiles $w(x, t)$ Matano method [Matano, 1933] was employed. Its application leads to the following solution for moisture diffusivity.

$$\kappa(w_0) = \frac{1}{2t_0\left(\frac{dw}{dz}\right)_{z=z_0}} \int_{z_0}^{\infty} z \frac{dw}{dz} dz \ . \tag{1}$$

where t_0 =*const.* is a given time where the moisture field $w(z,t_0)$ is known and z is the space variable (for details see Drchalová *et al.* [2002]).

For description of coupled salt and moisture transport, diffusion-advection model proposed by Bear and Bachmat [Bear & Bachmat, 1990], [Pel *et al.*, 2000] was used. This model employs the system of parabolic equations describing salt and moisture transport. System of equations can be subjected to an inverse analysis in a similar way as for one parabolic equation, provided the initial and boundary conditions are simple enough, and the material parameters D and κ can be identified as functions of water content and salt concentration. The simplest possibility of such an inverse analysis is again an extension of the Boltzmann-Matano treatment under the same assumptions of constant initial conditions and Dirichlet boundary conditions on both ends of the specimen for both moisture content and salt concentration where one of the Dirichlet boundary conditions is equal to the initial condition. After applying Boltzmann transformation and performing some straightforward algebraic operations, we arrive at the following formula for the determination of salt diffusion coefficient.

$$D(z_0) = -\frac{C_f(z_0)\kappa(z_0)\left(\frac{dw}{dz}\right)_{z_0}}{w(z_0)\left(\frac{dC_f}{dz}\right)_{z_0}} + \frac{\int_{z_0}^{\infty} z\left(\frac{d(wC_f)}{dz} + \frac{dC_b}{dC_f}\frac{dC_f}{dz}\right)dz}{2t_0 \cdot w(z_0)\cdot\left(\frac{dC_f}{dz}\right)_{z_0}}, \tag{2}$$

where z is the space variable, t_0 the time corresponding to the chosen moisture and concentration profiles $w = w(z,t_0)$, $C_f = C_f(z,t_0)$, the chosen values of moisture and concentration are $w_0 = w(z_0, t_0)$, $C_{f0} = C_f(z_0, t_0)$, the corresponding moisture diffusivity and salt diffusion coefficient $\kappa(z_0) = \kappa(w_0, C_{f0})$, $D(z_0) = D(w_0, C_{f0})$ and $C_b = f(C_f)$ is the ion binding isotherm.

Using diffusion-advection model, the third moisture diffusivity function was also calculated neglecting the nitrate diffusion in the liquid phase ($D = 0$). The relation for moisture diffusivity calculation using this procedure is given as

$$\kappa(z_0) = \frac{\int_{z_0}^{\infty} z\left(\frac{d(wC_f)}{dz} + \frac{dC_b}{dC_f}\frac{dC_f}{dz}\right)dz}{2t_0 \cdot C_f(z_0) \cdot \left(\frac{dw}{dz}\right)_{z_0}}. \quad (3)$$

3 EXPERIMENTAL

Many historical buildings in the Czech Republic were built using sandstone. The sandstone studied in this paper originated from Mšené-lázně quarry and was originally used for ornamental parts of architecture. It is psamitic equigranular rock, about 95% of which is made up of suboval quartz clasts. Other mineral grains are present only as accessories (tourmaline, epidote, muscovite and zircone). Quartz grains reach up to 0.1 mm in diameter, but those of muscovite are larger, up to 0.3 mm. The matrix is formed by clay minerals (mainly kaolinite). In Table 2, the basic parameters of the studied material are given, ρ_b is the bulk density, ρ_{mat} matrix density and ψ total open porosity.

Table 2. Basic material properties of the studied sandstone.

ρ_b [kg m^{-3}]	ρ_{mat} [kg m^{-3}]	ψ [m^3 m^{-3}]
1807	2627	0.31

The rod shaped samples with the dimensions of 20 x 40 x 160 mm were used for the determination of moisture and nitrate concentration profiles in simulated 1-D water and nitrate solution transport. The dry, on lateral sides vapour-proof insulated samples were exposed by their 40 x 20 mm face to the penetrating KNO_3 solution (concentration 101.1 kg/m^3 of solution). Duration of the experiment was 30, 60 and 90 minutes for three different groups of samples. After this time, the samples were cut into 8 pieces and in each piece water content and nitrate concentration were measured. Moisture content was determined by the gravimetric method using weighing the moist and dried specimens. In the determination of nitrate concentration, the particular samples were after drying first ground by a vibration mill so that grains smaller than 0.063 mm were obtained. Then the ground samples were overflowed by 80 °C warm distilled water and leached. The nitrate contents in particular leaches were determined using an ion selective electrode.

For the determination of ion binding isotherm, Tang and Nilsson modified absorption method was chosen. This modification consisted in using the specimens of more realistic dimensions (40 x 40 x 10 mm) instead of crushed specimens [Jiřičková & Černý, 2006]. On the basis of the measured ion binding isotherm of KNO_3, $C_b = f(C_f)$, the profiles of bound and free nitrates were determined.

4 RESULTS AND DISCCUSION

The experimentally determined moisture and nitrate concentration profiles are presented in Figs. 1-3. For the computational inverse analysis it was necessary to smooth the measured data to obtain continuous functions. The linear filtration method was used for that purpose (see Figs. 1-3).

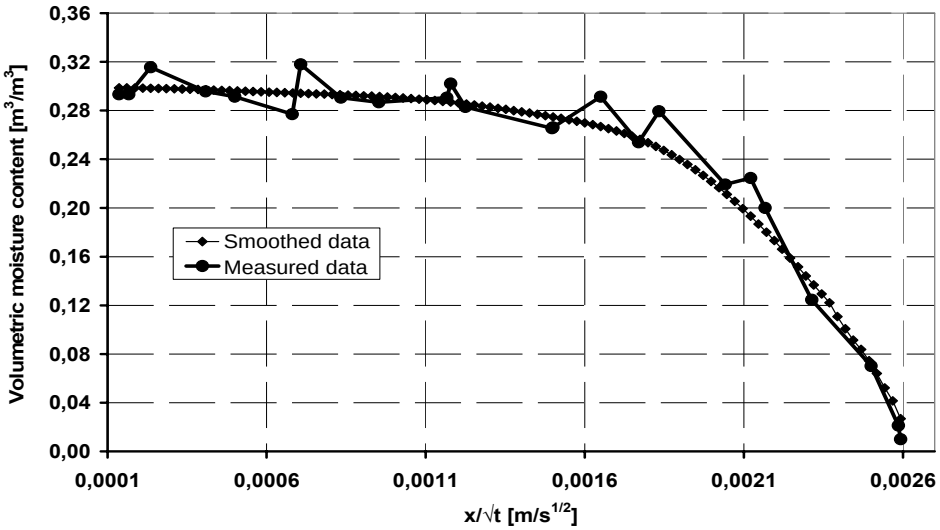

Figure 1. Volumetric moisture content for penetration of distilled water.

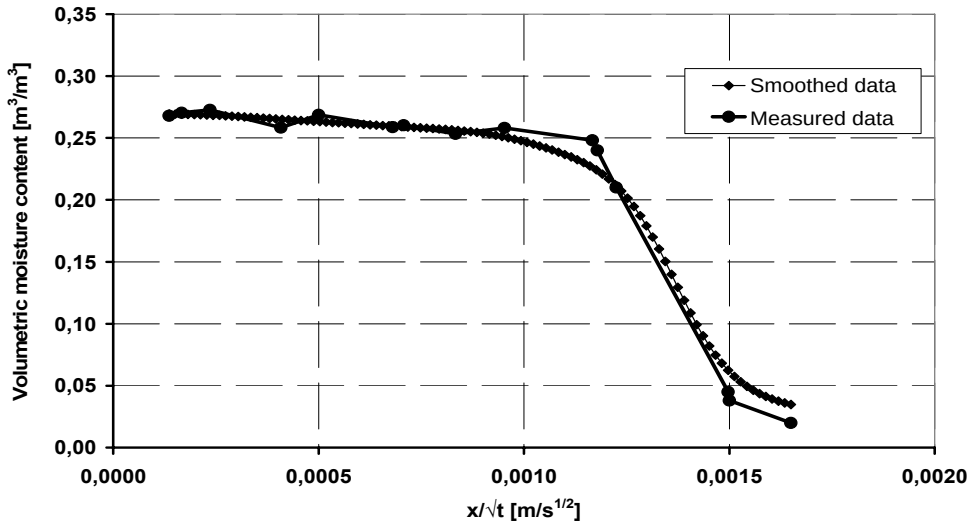

Figure 2. Volumetric moisture content for penetration of KNO_3 solution.

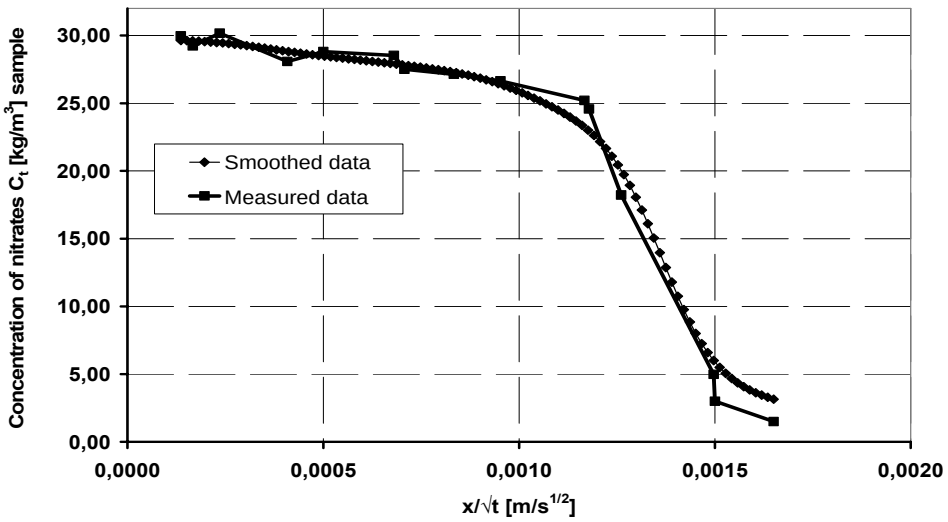

Figure 3. Total nitrates concentration.

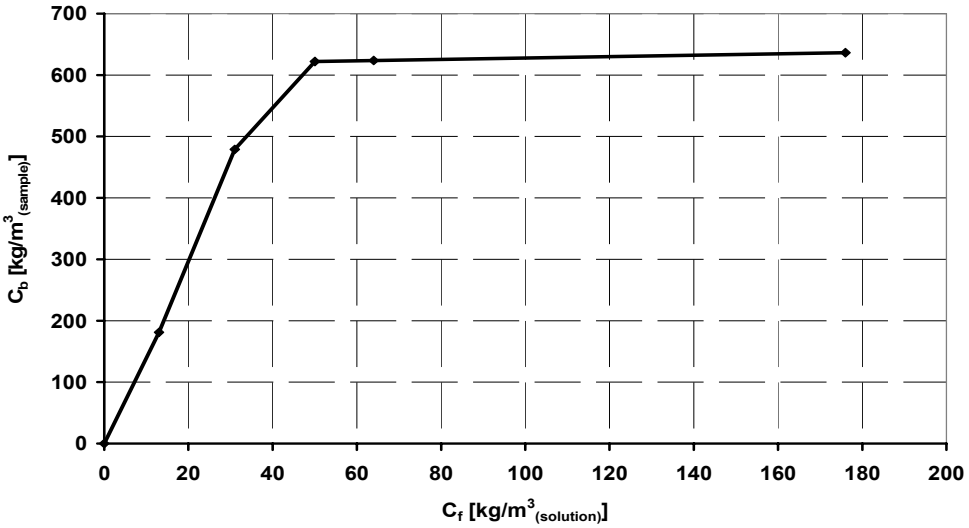

Figure 4. Binding isotherm of KNO_3 for the studied sandstone.

The nitrate binding isotherm measured by modified Tang and Nilsson adsorption method is shown in Fig. 4. The obtained binding isotherm gives evidence about the very high nitrate binding capacity of the studied material. The results of moisture diffusivity calculations are presented in Fig. 5. The moisture diffusivity calculated for penetration of distilled water is systematically higher than the moisture diffusivity obtained for KNO_3 water-solution. This is probably the consequence of the higher viscosity of KNO_3 solution compared to viscosity of distilled water. The results of inverse analysis also show that the possible neglect of nitrate diffusion in the liquid phase is apparently wrong, because the moisture diffusivity calculated from nitrate concentration profiles under this assumption is two to three orders of magnitude higher than moisture diffusivity calculated from moisture profiles. The dependence of nitrate diffusion coefficient on concentration is shown in Fig. 6. From the quantitative point of view, the calculated nitrate diffusion coefficient is quite high, about three orders of magnitude higher than the diffusion coefficients of most ions in free water. Therefore, the common diffusion mechanism is probably not the only driving force for nitrate transport within the liquid phase and some other driving forces are taking place here. This acceleration of nitrate transport can be attributed most probably to surface diffusion on pore walls and/or to osmotic effects.

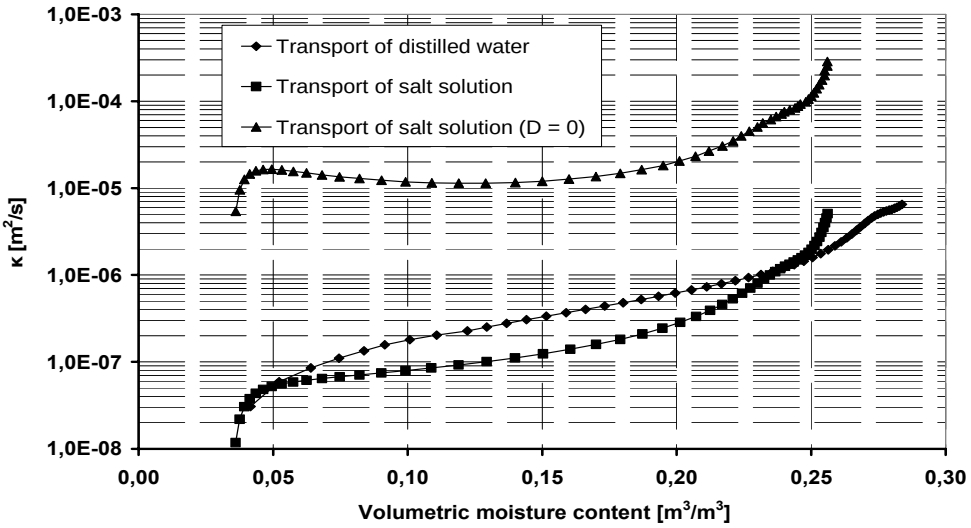

Figure 5. Moisture diffusivity of sandstone determined in three different ways.

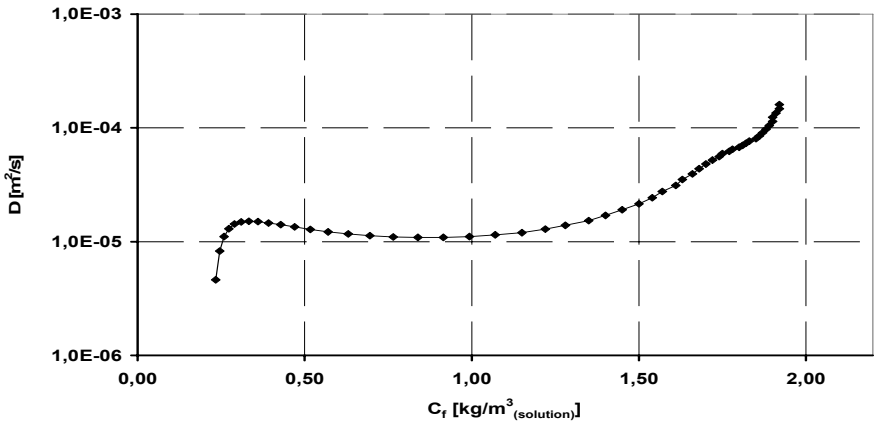

Figure 6. Nitrate diffusion coefficient of sandstone.

5. CONCLUSIONS

The main contribution of the work presented in this paper consists in the determination of two basic parameters describing the moisture and nitrate transport capability of the studied sandstone which make possible to perform damage assessments. The obtained results revealed very fast salt transport within the liquid phase affecting the total nitrate concentration in the material in a very significant way. From the point of view of exact explanation of mechanisms of coupled water and nitrate transport in porous materials, the presented experiments and calculations revealed the necessity to implement some other effects (e.g., surface diffusion and osmosis) into the diffusion-advection model.

ABSTRACT

Laboratory experiments on rock samples have shown electric signal emissions when the samples are subjected to temporal stress variation. These electric signals are attributed to the generation and propagation of microcracks that guide the sample to mechanical failure.

In this work such electric emissions will be demonstrated for marble samples subjected to stress at a rate 0.3MPa/s approximately. The emissions become intense when the relative compressional stress becomes approximately 70% of the ultimate stress while it reaches its maximum value for relative stress value 0.95. Consequently the emission diminishes. Based on the sample stress-strain diagrams the electric emissions are directly related to the deviation of the linearity in the stress- strain diagram. The emitted electric current is correlated to the deformation of the sample through the measured strain. These emissions are attributed to the movement of dislocations and cracks that cause electric polarization and consequently charge flow. The damage in the bulk of the sample increases with stress while there is a stress level beyond which damage increases rapidly as new cracks form and connect to the growing existing cracks until a failure plane is formed and the sample collapses.

1 INTRODUCTION

Laboratory investigations that show the existence of electric signal emissions during a full cycle of rock deformation have received considerable attention in recent years. These electric emissions have been attributed in the past at several potential sources like the quartz existence [Nitsan, 1977; Ogawa *et al.,* 1985; Eccles *et al.,* 2005], fluid movement causing electrokinetic effect [Eccles *et al.,* 2005; Ishido & Mizutani, 1981; Yoshida *et al.,* 1998], point defects [Varotsos & Alexopoulos, 1986] and electron emissions [Brady & Rowell, 1986; Enomoto & Hashimoto, 1990].

At the same time acoustic emissions (AE) have been studied when applying stress to rocks and it was shown that they are highly indicative of rock deformation and failure processes [Lavrov, 2005; Lockner *et al.,* 1991; Sammonds *et al.,* 1992].

When dealing with quartz free rocks with extremely low internal moisture and low porosity the piezoelectric and the electrokinetic effects are not considered as strong underlying physical mechanisms to support the existence of electric signal emissions. A model that is applicable for this case was proposed by Slifkin [Slifkin, 1993] and was further developed by [Vallianatos & Tzanis, 1999; Tzanis & Vallianatos, 2002] and explains electric signal emissions due to the dislocation and other defect movements that cause local polarization. This model is known as Moving Charged Dislocations (MCD) model.

Papers of experimental laboratory recordings and analyses of electric signals emitted under temporally varying uniaxial compressional stress upon rock samples like marble and amphibolite have been conducted [Anastasiadis *et al.,* 2004; Stavrakas *et al.,* 2004; Triantis *et al.,* 2007; Anastasiadis *et al.,* 2007a,b]. The electric current emitted during such temporal stress variation leading to a catastrophic process and to sample fracture has been rendered under the term “Pressure Stimulated Current” (PSC).

The technique applied in order to show up and record the above described signals is rendered under the term «PSC technique».

The Pressure Stimulated Currents are characterized by very low peak values (1pA up to 100pA) and they reveal from the background noise level when the applied stress on the sample leads to the non-linear deformation region (out of the limits of Hooke’s law) and specifically when the sample is led to the Crack Propagation Zone (CPZ). Intense PSC emissions are observed slightly before the fracture of the sample.

According to the MCD model the observed transient electric variation is related to the non-stationary accumulation of deformation. The expected emission of Pressure Stimulated Current (PSC), is proportional to the strain rate [Vallianatos *et al.,* 2004]. When a PSC emission psc(t) is recorded during a process of a continuously increasing axial compressional stress it should obey the following law:

$$\mathrm{psc}(t) \propto \frac{d\varepsilon(t)}{dt} \tag{1}$$

where ε(t) is the temporal variation of the strain during the axial compressional stress variation σ(t). According to the Eq. 1 the total charge Q, released during that process is given as:

$$Q(t) = \int_0^t \mathrm{psc}(t)\,dt \propto \varepsilon(t) \tag{2}$$

During this work marble samples were subjected to constantly increasing compressional stress from early stress levels up to fracture. The stress rate was 0.3MPa/s. The PSC emissions were recorded

during all the experimental procedure. The emitted PSC is discussed with respect to the deformation and the applied compressional stress.

2 SAMPLES AND EXPERIMENTAL TECHNIQUE

In this section marble, which is the material under examination, is described. Rock materials and especially marble have been used in the past in constructions and therefore results concerning their strength may serve in many restoration works that are in progress as for example on the Parthenon temple of the Acropolis of Athens as well as on other civil engineering applications.

Marble is a geomaterial of known physical and chemical properties. The marble samples under examination were collected from Mt. Penteli (Dionysos) and are mainly composed of calcite (98%) and other minerals i.e. 0.5% of muscovite, 0.3% of sericite, 0.1% of chlorite, it also contains 0.2% of quartz (Kourkoulis et al. 1999). Its specific density is 2730 kg/m^3, its apparent density is 2717 kg/m^3 and its porosity is very low, varying from 0.3% for pristine marble to 0.7% for marble that has suffered natural weathering and has been exposed to corrosive agents [Kleftakis *et al.*, 2000].

The used samples were prismatic and the stress was applied in parallel axis to the long edge. The dimensions of the used specimens were 35mm x 35mm x 60mm and their fracture limit was 47MPa approximatelly.

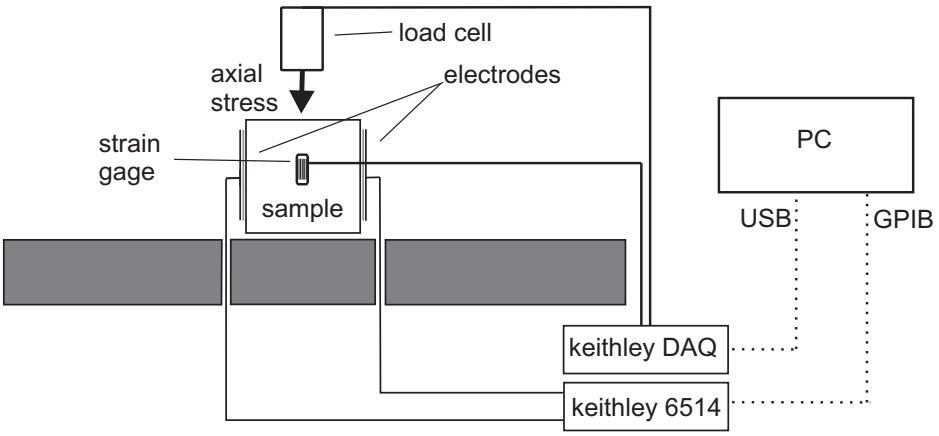

Figure 1. A schematic representation of the experimental set-up to conduct PSC experiments.

Figure 1 shows the schematic representation of the experimental PSC-techniques. The experiment was conducted in a Faraday shield to prevent from electric noise from affecting the measurements. The shield protects the mechanical parts that transfer the stress on the sample (i.e hydraulic stressing cylinder Enerpac-RC106, plates, sample underlay holder), the stress and strain sensors and the electrodes that measure the PSC.

The sample was placed on a steel anvil and thin Teflon plates were placed between the anvil and the stressing plates to provide electric insulation. The electrodes were attached to the marble sample, using conductive paste. Two gold plated electrodes were attached on the sample where the conductive paste was applied in a direction perpendicular to the axis of the applied axial compressive stress.

The stress sensor (load cell) is placed on the axis of stress and the strain sensor is placed in the free edges of the sample in a direction perpendicular to the stress (see Fig. 1).
Properly shielded Keithley cables that minimize electric noise lead through interfaces the PSC to the programmable electrometer placed outside the shield. PSC measurements were conducted using the programmable electrometer Keithley 6514. The communication of the Keithley electrometer and the PC that stored the measurements was achieved through a GPIB interface.

The stress was measured through a stress sensor ADW 15 that converts the applied stress to voltage. The strain was measured using Kyowa strain gauges attached on the Microlink-770, 120Ω resistance bridge. The stress and the strain were directly recorded on the PC through a 8 differential channel, high sampling rate, and 500x maximum amplification, Keithley A/D converter. All the data were stored in a computer hard disk through the described interfaces at a sampling rate 3samples/s.

3 EXPERIMENTAL RESULTS – DISCUSSION

The applied compressional uniaxial stress was constantly increasing on the sample at a rate of 0.3MPa/s from very low stress levels up to fracture. Figure 2 (curve a) presents the temporal development of the emitted PSC. It becomes obvious that the PSC starts to show an excitation only after time t=220s. It is significant to notice at the curve b of the same figure that time t-220s corresponds to a strain value slightly higher than 0.004. This strain value corresponds to the stress-strain curve (Fig3. curve a) at the point were stress and strain are no more linearly related. It is known [Lavrov, 2005] that this value corresponds to the crack formation and propagation region, regarding the sample's mechanical behaviour. Since PSC emissions are mainly attributed to crack formation and propagation it is expected that when these mechanisms are activated they dominate the sample bulk and PSC excitation is expected to be observed.

Another significant observation is that despite the fact that the stress increases linearly the PSC values after time t=270s approximately seem to grow fast following a corresponding change of the deformation. This is the point that the yielded strain changes much faster than the applied stress. In terms of cracking and damage mechanisms in general it can be stressed that this is the region where dynamic processes take place, macrocracks are created, the fracture plane is formed and the irreversible failure process initiates.

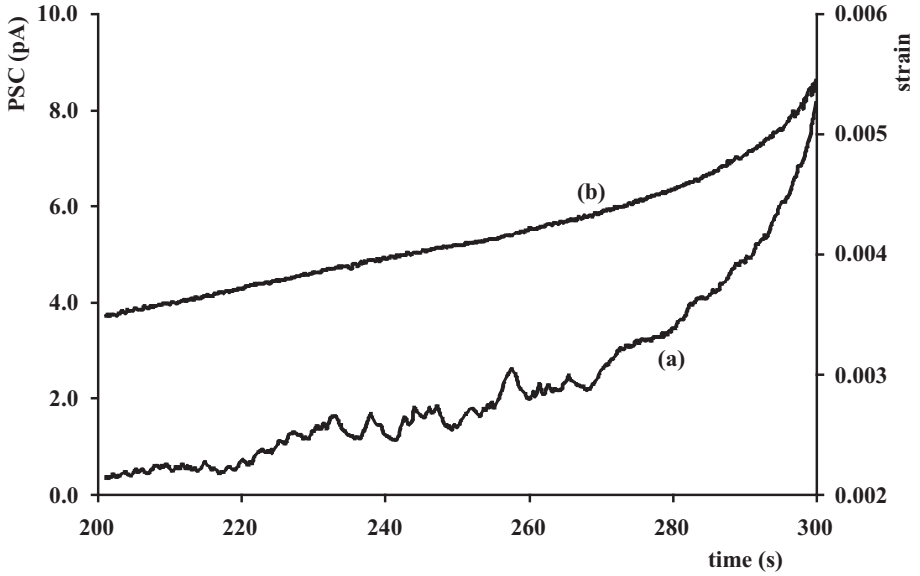

Figure 2. The temporal development of the emitted PSC (curve a) and the temporal development of the deformation while applying constantly increasing stress (curve b).

Studying the totaly released charge with respect to deformation some significant results can be drawn. Figure 3, curve a, clearly shows that the stress and the strain are linearly related up to a stress value of the order of 40MPa approximatelly. Beyond that point the stress and the strain are no more linearly related to each other and the strain starts to grow faster than the applied stress. At a value of stress 47MPa approximately the failure of the sample occurs. Regarding the total released charge with

respect to the stress-strain curve of the marble samples it can be stressed that no significant charge is released when the stress and the strain are linearly related. For a strain value of the order of 0.004 it can be seen on the curve that the total released charge Q is of the order of 20pC. When the stress increases further and stress and strain are no more linearly related the released charge increases linearly with the yielded strain. This process goes up to the vicinity of fracture for stress levels of the order of 46MPa approximately which corresponds to the 98% of the ultimate compressional strength.

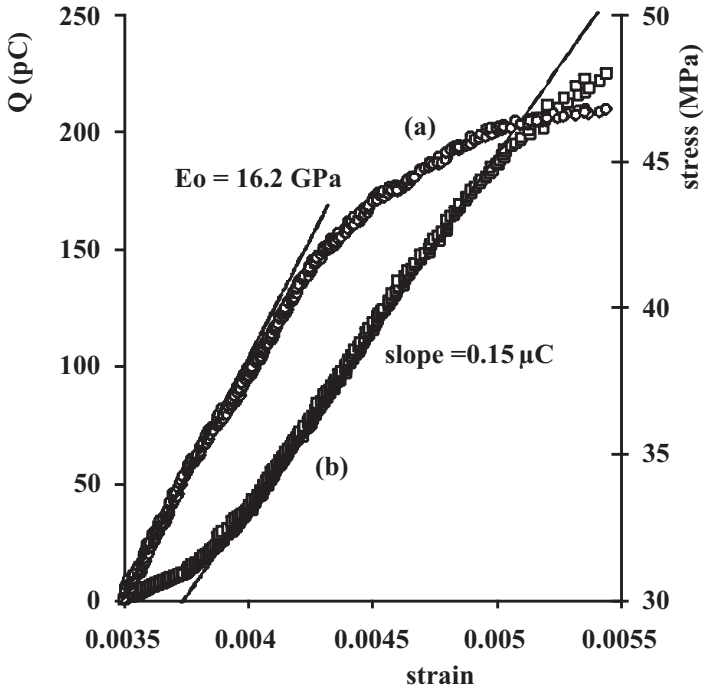

Figure 3. A representative stress strain curve of the used marble samples (curve a) in the same diagram with the totaly released charge with respect to the strain (curve b).

4 CONCLUDING REMARKS

This work demonstrates that during a stressing process of marble samples the total released charge is linearly related to the deformation change in a good approximation. This linearity is valid from the point that both stress and strain are no more linearly related (see the stress-strain curve at about 60% of the ultimate compressional stress strength) up to the near fracture range (98% of the ultimate compressional stress strength of the sample).

When the released charge and the strain are no more linearly related this indicates the upcoming event of fracture.

After all these the PSC technique and specifically by the study of the totally released charge was proved to be a valuable tool in laboratory conditions that can detect the mechanical status of marble samples. The underlying mechanisms of the generation of the PSC are based on the Moving Charged Dislocation Model.

Freeze Thaw Susceptibility of Natural Stone – Characterization of the Mechanical Strength and Microstructure During Frost Cycling

T. Yates [1]
A. Mauko [2]

T 15

ABSTRACT

Frost resistance of natural stones is complex phenomena. Different intrinsic properties (e.g. porosity and mineral composition) as well as extrinsic properties (e.g. presence of salts, temperature variation, humidity) influence frost resistance of stone. In some countries frost is consider as being one of the most potent causes of decay, although attribution of deterioration features of in-built stone only to one factor is ambiguous.

The test method for determination of susceptibility of natural stone to frost deterioration is standardised with CEN standard EN 12371. Additional requirements for testing are given in appropriate harmonised standards for natural stone products, e.g. EN 1469 for cladding slabs. Although standard EN 12371 has been used for some years now, it has been established that a robust correlation of test results to actual condition is difficult to make.

The main objective of the research presented in this paper was to give insight into frost deterioration of two selected marbles and two limestones during 104 cycles of standardised test. Relationships between intrinsic properties of stone (porosity and mineral composition) and frost resistance, which was determined by mechanical characterization of stone (flexural strength and USV measurement) after 12, 24, 56 and 104 frost cycles, are given. The results of research can be used as input information for modelling the life span and risk assessment of natural stone façade when subjected to frequent freezing.

1 INTRODUCTION

During its life span natural stone product is exposed to various degradation processes. Their damage effects can be additive, antagonistic or synergetic [Wessman 1997]. Among many acting mechanism the actual cause for stone deterioration ['Fig. 1'] is sometimes difficult to define. Nevertheless, freeze-thaw cycles are generally considered as one of the main decay factor of natural stone, especially in northern and central European countries.

Although generally assessed as important parameter, detailed mechanisms of stone frost deterioration are still not fully understood. Freeze-thaw durability depends greatly upon stone's intrinsic and extrinsic parameters. Porosity, the moisture content and presence of dissolved salts highly influence performance of stone while exposed to frost action [Lindqvist *et al.* 2007].

Current practice of assessing the effect of freeze-thaw cycles on natural stone product's characteristics (flexural strength, dowel hole strength, compressive strength) is based on CEN standard EN 12371. After certain number of cycles of freezing in air and thawing in water [e.g. 48 cycles for stone pavements – EN 1341 and 1342, or 12 cycles for stone cladding – EN 1469], the frost resistance is determined as the change of mean strength or as the number of cycles necessary to initiate cracks or rupture. However, such concept is difficult to apply to in-built performance of stone products, since some products show cracks and spalling after a while, although they have passed the frost test, while others not passing the test exhibit good performance during their life span in building [Ingham 2005].

In this study, susceptibility to freeze and thawing was determined for four selected natural stones, two marbles and two limestones. With flexural strength and USV measurements after 12, 24, 56 and 104 cycles, different performance for four selected stone was determined. Additionally, materials were characterised by measurements of open porosity and apparent volume.

In this study, hypothesis about deterioration rate differences between studied samples is examined. Following this hypothesis, prediction of life span of natural stone products exposed to natural cycling of freezing and thawing must be based on detailed studies, since different behaviour can be established even among same rock types.

Figure 1. Here, deterioration of calcitic marble in the form of intense cracking is visible. The actual cause for deterioration is difficult to define; probably it is due to simultaneous action of freezing and thawing and thermal degradation, or even mechanical loading.

2 MATERIALS AND METHODS

Four samples have been chosen for determination of frost resistance; two marbles (one dolomitic, one calcitic) and two limestones. In [Table 1] a list of samples is presented. Samples were tested according to CEN standards or other methods, e.g. EN 12371 – Determination of frost resistance, EN 12372 – Determination of flexural strength, EN 14579 – Determination of sound speed propagation, EN 1936 – Open porosity and apparent volume, OM – Optical microscopy, SEM – Scanning electron microscopy, Hg – Mercury porosimetry, EN 13755 – Water absorption at atmospheric pressure, EN 13364 – Determination of dowel hole strength. Only part of results (mechanical strength, apparent volume and porosity) is presented in this paper.

Table 1. List of samples tested in the frame of frost resistance study.

Sample no.	*Petrographic name*	*Number of specimens*	*Dimension of specimens [mm]*	*Method according to standard*
1	Dolomitic marble	63	30x50x180	EN 12371, EN 12372, EN 14579*
		57	30x30x30	EN 1936, OM, SEM, Hg

		10**	200x200x30	EN 13364

* Deviations from standard's requirements regarding size of specimens

Freeze-thaw cycling was carried out according to test procedure described in EN 12371:2001. Five batches of specimens with denotations *A – E* were sawed from cladding panels of 20 and 30 mm thickness. On specimens from batch *A*, initial properties of fresh samples [flexural strength, speed of sound propagation and open porosity] were determined according to corresponding standards [EN 12372, EN 14579, EN 1936]. Specimens from batches *B*, *C*, *D* and *E* were then exposed to freeze-thaw cycling. After every 12th cycle apparent volume and visual examination were carried out. After 12, 24, 56 and 104 cycles, specimens of corresponding batches were taken out from frost chamber, dried at 70 ^{o}C in ventilated oven to constant mass, after which USV, flexural strength and open porosity, were again determined.

3 RESULTS AND DISCUSSION

3.1 Visual Examination

Four samples exhibit different characteristics during frost exposure. The most decaying material is white calcitic marble (sample no. 2), in the case of which signs of deterioration had been observed even before exposure. Poor cohesion between mineral grains in sample no. 2 is marked by degranulation or "sugaring".

During frost exposure this material becomes progressively deteriorated. After no more than 12 cycles changes in colour can be observed and thin hair-like cracks start to form, although none of the specimen had completely disintegrated during 104 cycles. During exposure other samples didn't change significantly, with exception of slight rounding of edges. Cohesion between stylolites in sample no. 3 is good even after the end of exposure.

3.2 Mechanical Strength

Results of initial flexural strength measurements and measurements of flexural strength after 12, 24 and 56 cycles, are given in [Table 2] and 'Fig. 2 and 3'.

The lowest flexural strength can be observed in the case of sample no. 2, while the highest flexural strength has micritic limestone with stylolits, sample no. 3 ['Fig. 2'].

On 'Fig. 3' different characters of flexural strength decrease, or in the case of #3 slight increase, can be observed.

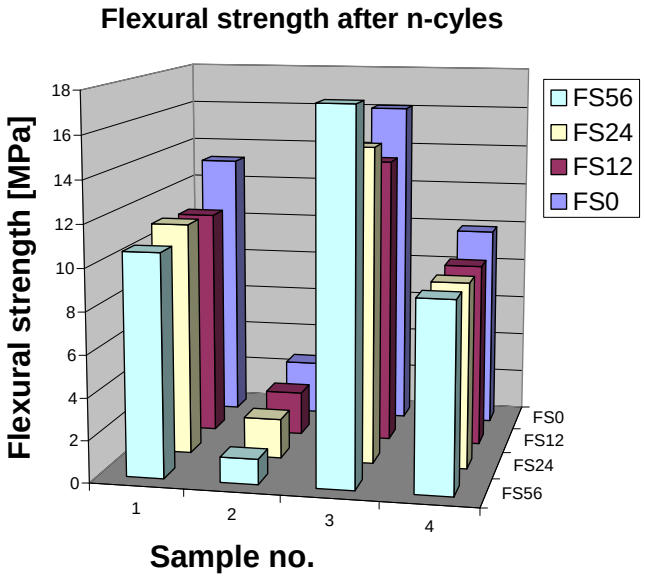

Figure 2. Flexural strength of samples before exposure (*FS0*) and after 12 (*FS12*), 24 (*FS24*) and 56 (*FS56*) *c*ycles.

Table 2. Decrease/increase of flexural strength before exposure [Rtf_0] and during 12, 24 and 56 cycles [Rtf_{12}, Rtf_{24}, Rtf_{56}, respectively].

Sample		*Rtf_{nave}*	*$Stdev_0$*	*Δ [%]*
1	Rtf_0	13,2	1,8	0
	Rtf_{12}	11	0,5	-16,7
	Rtf_{24}	11,2	0,9	-15,2
	Rtf_{56}	10,6	0,8	-19,7
2	Rtf_0	2,6	0,6	0,0
	Rtf_{12}	2,1	0,5	-19,2
	Rtf_{24}	1,9	0,4	-26,9
	Rtf_{56}	1,2	0,3	-53,8
3	Rtf_0	16,1	2,6	0,0
	Rtf_{12}	13,9	1,5	-13,7

	Rtf_{12}	8,9	3,2	-10,1
	Rtf_{24}	8,9	1,2	-10,1
	Rtf_{56}	9,0	0,8	-9,1

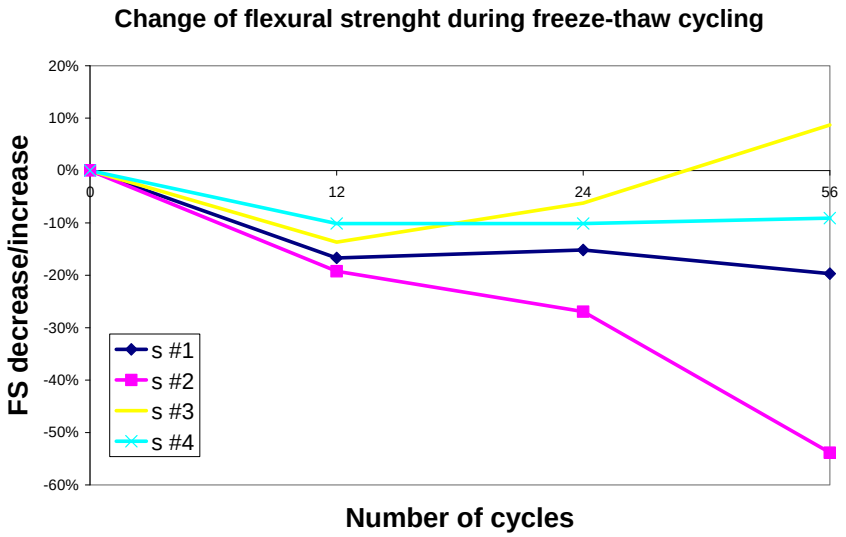

Figure 3. Change of average flexural strength (in percentage) during 56 cycles.

3.3. Ultrasonic Velocity

Average speeds of sound propagation and rates of decrease [increase] during exposure are listed in [Table 3]. In general, USV degradation curve ['Fig. 4'] follows the flexural strength degradation curve ['Fig. 3]. Again, velocity of sound propagation decrease with the highest rate in the case of sample 2, while sample 3 shows constant increase in speed propagation.

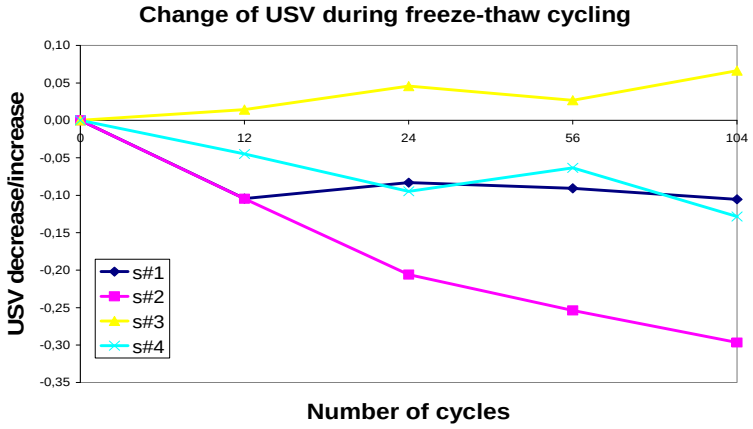

Figure 4. Change of USV during 104 cycles.

Table 3. Change of USV after 12, 24, 56 and 104 cycles.

Sample		USV_{0ave} [km/s]	$Stdev_0$ [km/s]	USV_{nave} [km/s]	$Stdev_n$ [km/s]	Δ [%]
1	v_{12}	5,94	0,18	5,32	0,36	-10,4
	v_{24}	6,02	0,29	5,52	0,19	-8,3
	v_{56}	5,95	0,29	5,41	0,25	-9,1
	v_{104}	6,07	0,21	5,43	0,18	-10,5
2	v_{12}	2,87	0,51	2,57	0,43	-10,5
	v_{24}	3,06	0,55	2,43	0,37	-20,6
	v_{56}	2,60	0,23	1,94	0,19	-25,4
	v_{104}	3,17	0,34	2,23	0,18	-29,7
3	v_{12}	6,97	0,65	7,07	0,69	1,4
	v_{24}	7,00	0,4	7,32	0,45	4,6
	v_{56}	7,07	0,36	7,26	0,46	2,7
	v_{104}	7,08	0,6	7,55	0,57	6,6
4	v_{12}	5,63	0,41	5,61	0,37	-0,4
	v_{24}	6,02	0,41	5,75	0,24	-4,5
	v_{56}	5,91	0,51	5,35	0,48	-9,5
	v_{104}	5,99	0,45	5,61	0,45	-6,3

3.4 Apparent Volume

No significant change in apparent volume can be seen during freezing and thawing, although with other methods deterioration trend could be observed. Following this, despite of different broad range regarding frost resistance of studied materials [material with high rate of deterioration, material with no deterioration], method of measurement apparent volume after every 12 cycles is too robust to determine susceptibility of stone to frost action.

On 'Fig. 5' apparent volume of sample no. 2 after 12, 42 and 104 cycles is presented.

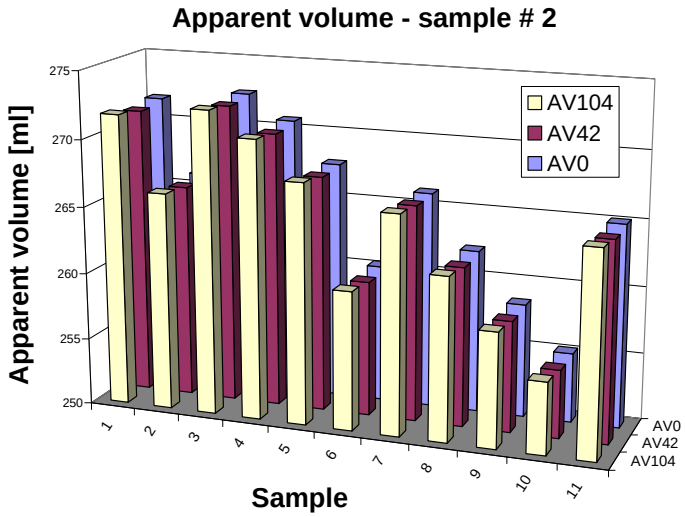

Figure 5. Apparent volume of sample no. 2 after 0, 42 and 104 cycles.

3.5 Open Porosity

In the state of art only open porosity for marbles has been determined [Table 4]. No change in porosity is observed in the case of dolomitic marble, which also shows good performance after exposure and a relatively moderate decrease of USV and flexural strength. A slight increase of open porosity was measured in the case of calcitic marble.

Table 4. Open porosity of sample no. 1 and 2 before exposure and after 104 cycles.

Sample	*Average open porosity before exposure*	*Average open porosity after 104 cycles*
Sample 1	0.5	0.5
Sample 2	0.6	0.7

5. CONCLUSIONS

Frost susceptibility of four samples of two different marbles and limestones has been studied. It has been established that there is significant difference in deterioration rate due to freeze thaw cycling even among samples of the same rock group. While three of the studied samples show general decrease in flexural strength and USV, compact micritic limestone shows distinctive increase of mechanical properties.

While in the case of flexural strength this could be explained on the first glance by heterogeneity of natural stone, steady increase of USV shows this is not so. The detailed mechanism of improvement of

mechanical properties of some samples during frost exposure can not be explained in this stage. Further explanation of the mechanism could be given after detailed study of nature of porous and rock microstructure.

Visual Effects of Building Stone Texture

Jun Tsuchiya [1]
Shoji Sunaga [2]

T 15

ABSTRACT

Durability of buildings is an important issue of social demand. For this demand it is necessary to maintain not only structural durability but also visual performance, which pertains to the pleasant appearance of building materials. However, currently there is no common evaluation method for the visual performance of building materials, so it is still difficult to find a general standard for selecting finishing materials. Due to its durability and appearance, many stones has used as finishing materials. On the other hand, little research has been done on the visual performance of building stone finishing.

In this research, the effect of surface properties on the visual evaluation of building stone finishing was investigated.

One of the important characteristic appearances of stones is a feeling of depth,which gives high quality impression by a deep color. Factors affecting the visual depth of natural stone surface were analyzed by performing a sensory test using natural stone specimens which varied in stone type, surface finishing method and surface pattern. And appearance of glossy and glitter surface especially analyzed by performing a sensory test using 7 level polished black stone specimens.

Physical values of luminance, and surface color were measured and the relationship between them and the results of the sensory tests were considered. It was shown that the visual evaluation of stone specimens is affected by various factors, visual gloss and the feeling of depth are related to the physical value of the surface luminance and dark color. There was no definite relationships between luminance and other evaluation items such as flavor , comfort and calmness.

1 INTRODUCTION

Durability of buildings is an important issue of social demand. For this demand it is necessary to maintain not only structural durability but also visual performance, which pertains to the pleasant appearance of building materials. This is a performance relates to the aging effect for the visual materials deeply.However, currently there is no common evaluation method for the visual performance of building materials, so it is still difficult to find a general standard for selecting finishing materials. Due to its durability, the use of stone has increased as finishing material in recent years. On the other hand, little research has been done on the visual performance of building stone finishing. It is thought that the stone has the aging characteristic.

Kitamura and Isoda (1998) evaluated the appearance of building materials by visual sensation and tactile sensation. Nakayama (1998) examined the deterioration and discoloration of natural stones used for building. However, there does not seem to be a full examination of stone finishing only. In addition to the many kinds of stone types, building stone has some traditional surface finishing, and the visual impression changes with the finish. Moreover, there are other factors which affect the impression of stone, such as colors, patterns and surface forms. These factors influence each other. The purpose of this study is to extract the features and determine the factors affecting the visual evaluation like the feeling of depth of various stones.

2 SENSORY TEST ON THE IMPRESSION OF STONE

2.1 Outline

In order to grasp the factors which influence the impression of a stone, a sensory test was performed on specimens of natural stone of various types and surface finishing. For comparison, surface properties such as surface colors were measured. The relationship between these surface properties and the evaluated sensory values were analyzed.

2.2 Procedure of Sensory Test

2.2.1 Preliminary Sensory Test (Test 1)

Stone specimens of size 90×150×10 mm were cut out of actual stone. Thirteen kinds of stone types generally used as stone finishes for the interior or exterior of buildings in Japan were selected. The surface finishing of these stones was changed (Table 1). The sensory test was performed on 13 stone specimens by 33 subjects, all of whom were students and teachers with normal eyesight (19men & 14women who were about 20 ~ 50years old). The laboratory was arranged such that the stone specimens were illuminated with 700 lx fluorescent light (5000 K). The test was conducted under the controlled lighting condition. The subjects were asked to evaluate the feeling of depth and similar words to depth. The results were quantified.

2.2.2 Sensory Test of Granite (Test 2)

Stone specimens of size 90×90×10 mm were cut out of actual stone. The surface finishing of these stones was changed (Table 2). The sensory test was performed on 7 stone specimens by 22 subjects, all of whom were students and graduate students with normal eyesight (11men & 11women who were about 20 ~ 30years old). The laboratory was arranged as well as test1. The test was conducted under the controlled lighting condition. The subjects were asked to evaluate 10 items (Table 3) which extracted from test1, and results were quantified.

2.3 Measurement Surface Properties

Surface color was measured by spectoral photometer (MINOLTA CS-1000A) in test1 and luminance factor was measureed by multi spectoral imaging method. Figure 1 shows the result of the luminance factor of the granite specimens in Test 2.

3 RESULTS AND CONSIDERRATIONS

3.1 The Evaluation of The Feeling of Depth of Various Kind of Stone

Figure 2 shows the result of the evaluation of the stone specimens.This is the avereage of the evaluation of the feeling of depth (Test 1). The polished finish A, E, I were estimated to be deep. For granite E, whose surface has glitter minerals, there was a high feeling of depth. The feeling of depth of specimens D, E were the lowest of all specimens. The value of a* was high in these specimens. Figure 3 shows the results of the multi dimensional scaling of specimens (MDS). MDS is a set of related statistical techniques often used in data visualization for exploring similarities or dissimilarities in data. It is a special case of ordination. An MDS algorithm starts with a matrix of object-object similarities, and then a location for each object is assigned in a low-dimensional space that is suitable for graphing.

The tendency of the feeling of depth depend on surface finishes, surface color. The polished finish granite specimens were high feeling of depth, however the different tendency in colored and colorless specimens. Especially uneven surface color specimens were high feeling of depth.

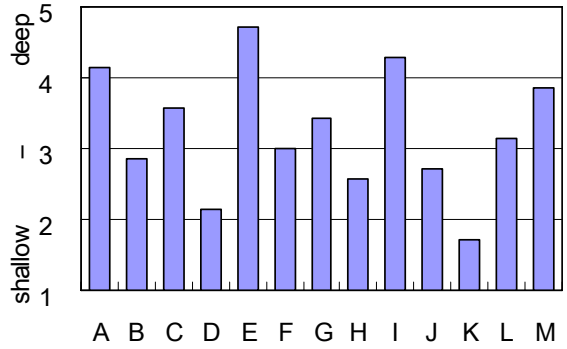

Figure 2. Evaluation of the stones (Test1).

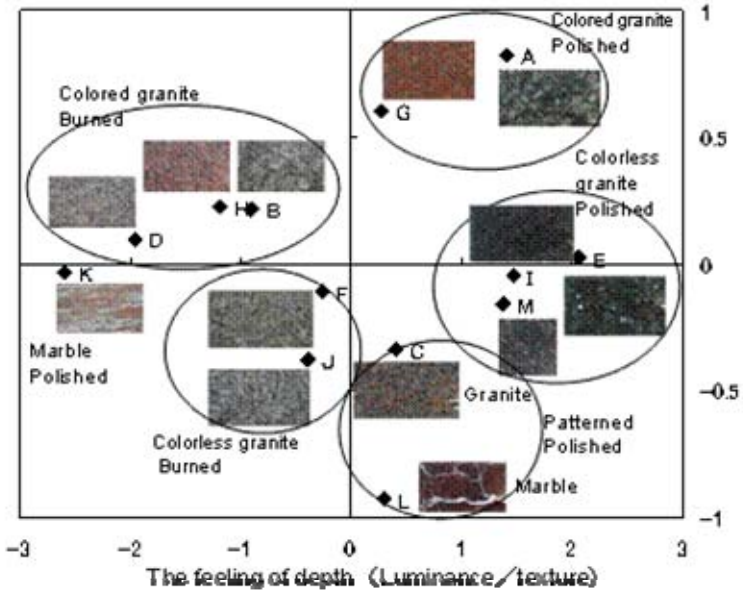

Figure 3. The Result of Multi Dimensional Scaling.

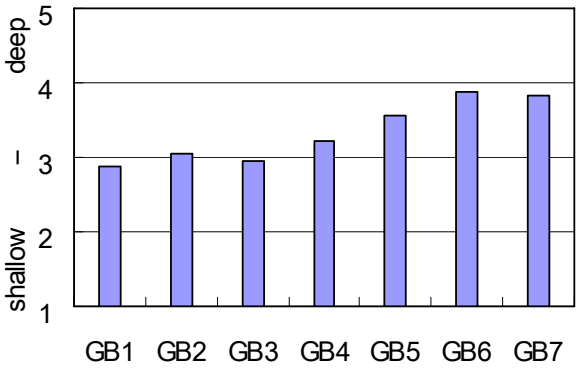

Figure 4. Evaluation of the stones（Test 2).

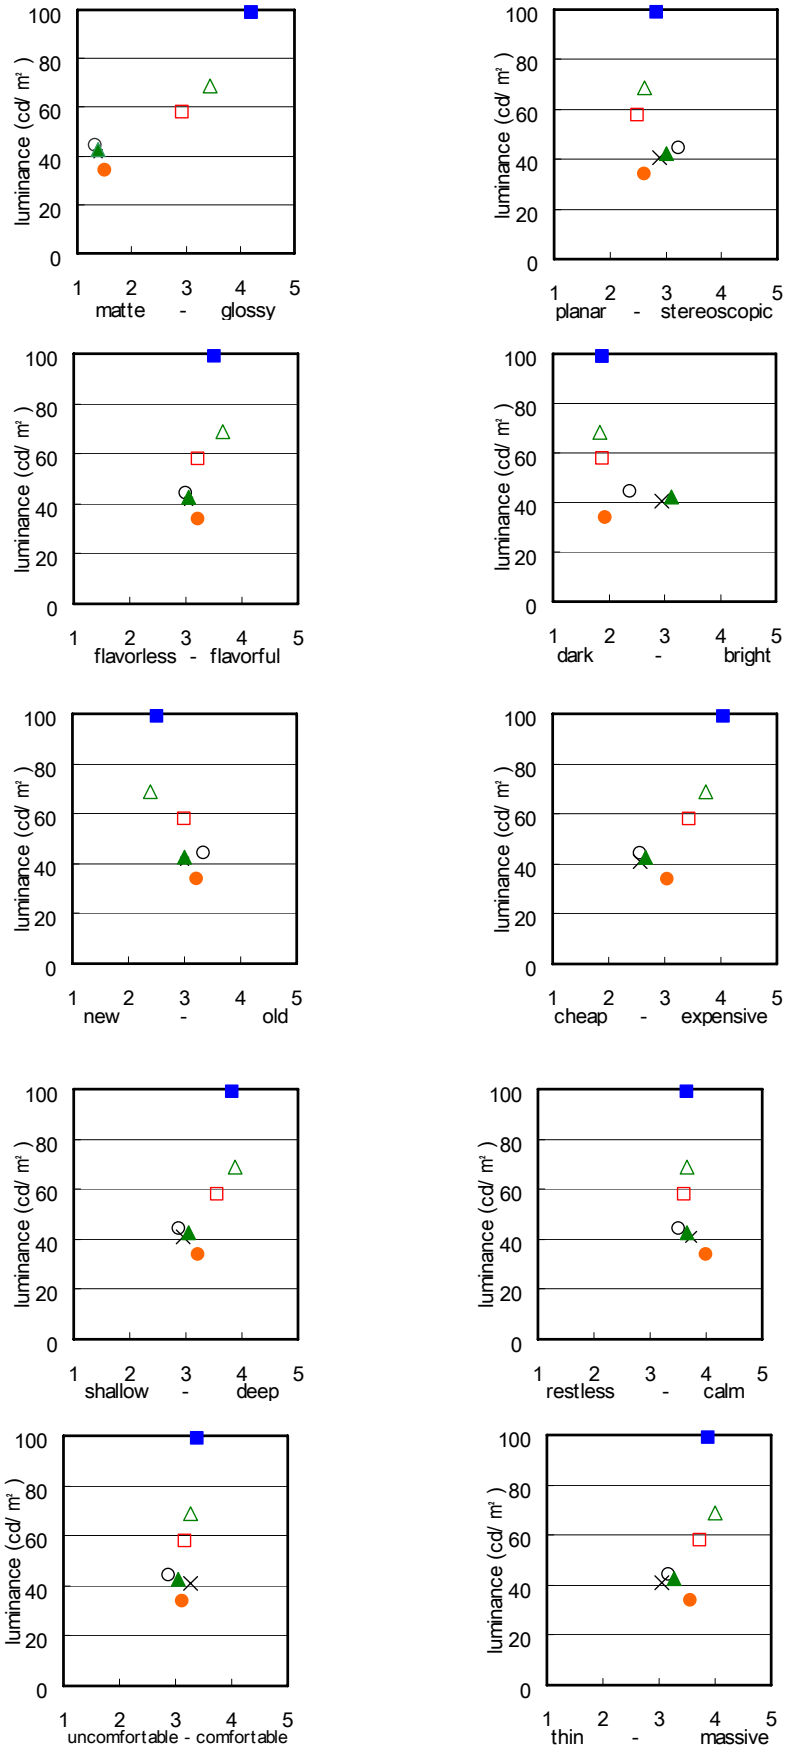

Figure 5. Relationship between luminance and the each evaluation items.

3.2 The Evaluation of 7 Surface Finishing Granite

Figure 4 shows the average of the evaluations of feeling of depth (Test 2).These 7specimens changes surface gloss by grindstone gradually. The rough surface finish changed stone whitish, then it was affecting the evaluation as well as surface gloss.

Although the order from least to most rough was G1B, G2B, G3B specimens, there was little difference of the feeling of depth because the effect of whitish and high L* surface in those three specimens.

For GB6, the evaluation was the highest of all specimens. The value of luminance and L*a*b* of this specimen were lower than GB7. It indicated that the optimum conditions of surface finishes in the feeling of depth.

Figure 5 shows the relationship between luminance and the each evaluation items. The evaluations of gloss and feeling of depth showed a correlation with luminance. There were no definite relationships between luminance and other evaluation items.

4 CONCLUSIONS

The conclusions of this study are as follows.
(1) The polished finish granite was high feeling of depth.
(2) Uneven surface color affected the evaluation of feeling of depth.
(3) The evaluations items of gloss and feeling of depth showed a correlation with luminance.
(4) There was no definite relationships between luminance and other evaluation items.

Outdoor Wall Painting Semi-Natural Test

Alberto Giacardi [1]
Luigi Morra [2]

T 16

ABSTRACT

This research is the result of experimentation of two Authors. It proposes a study on durability of two kinds of wall painting. The target of the study is to value degradation of wall painting superficial film for exteriors. Hence, it is crucial to:

- collect adequate information on geographic area;
- establish sample shape (hollow flat block already selected at laboratory);
- decide the means necessary to hold up samples;
- determine the superficial treatment to be used [two kinds of painting have been chosen: Metilsilossanico (CVP 60) and Vinilversatico (CVP 45)];
- define the superficial film application steps;
- explain the method applied as well as the results achieved.

On these premises, the Authors have deepened aspects of the problem (according to the instruction contained in ISO 2810:2004, UNI EN ISO 7783-1:2001 and EN 1062-3:1998 standards), leading to the following outcomes:

- measurement of permeability to water vapour and liquid water transmission of samples prepared and exposed outside (vs. the witness specimens preserved in laboratory);
- definition of different behaviours of wall painting film during two years of exterior exposition.

The final goal is to demonstrate which kind of lesions are more frequent on wall painting film, which sort of water and vapour transmission may be observed during the coming years and which type of superficial treatment is better to adopt (naturally, between the two issues here above mentioned).

1 INTRODUCTION

Research activity on degradation of superficial film of wall painting for exteriors follows the guidelines proposed by fundamental ISO 15686-2:2001 standard and related UNI 11156:2006.

Eight samples have been tested. Six of them have been exposed to climate agents and air pollution in Vercelli (2nd Faculty of Engineering) and stressed from May 2005. The others have been stored and preserved in Turin at Department of Building Science and Technology.

2 MODALITY OF TEST

2.1 Framework

Every single framework, on which wall painting was applied, has been personally constructed by the Authors in all its details (design, realisation, selection of components used for plasterwork, maturation, ground support, ...).

For the selection of components used to prepare plasterwork layer for wall painting (see Table 1), the results of a research brought out by Polytechnic of Milan and Professional University School of Italian Switzerland [Maggi 2001] have been greatly significant.
Plasterwork necessary to apply painting (thickness about 15mm), has been reinforced with a netting of anti-crack fiberglass.

Table 1. Granule distribution of sand for finish plasterwork, for a total quantity of 6 kg.

Filler <*0.075* mm	*from 0.075 to 0.15* mm	*from 0.15 to 0.3* mm	*from 0.3 to 0.6* mm	*from 0.6 to 1.18* mm	*from 1.18 to 2.36* mm	*from 2.36 to 4.75* mm	*Total*
3%	12%	13%	13%	19%	27%	13%	100%
180g	720g	780g	780g	1,140g	1,620g	780g	6,000g

2.2 Sample Dimension

The choice of sample format depends on measures of hollow flat block available (dimension: 40x24x2.5cm) and on possibility of making element movement easier. Final format of samples (mortar included) is 47.5x28x4.5cm with a band (28x10cm) having a thickness increased to 5.5cm (Fig. 1).

Figure 1. Sample in its final configuration.

2.3 Support For Exterior Exposition of Samples

Two fir frameworks of appropriate dimensions have been designed and produced in order to support samples in exteriors. They have been equipped with bracings and protected by impregnation for open-air conditions (Fig. 2). Top edge has been covered with an aluminium facing and inclination of sample surfaces has been carried out in compliance with the guidelines proposed by the ISO standard 2810:2004 («Paints and varnishes - Natural weathering of coatings - Exposure and assessment»). Inclination value is about 45° on horizontal plan. Framework has been oriented to south.

The research has pointed out that, in comparison with traditional solution (vertical painting on massive wall), worsening of surface integrity is linked not only to inclination but also to the low mass of support. Superficial temperatures are, from time to time, either particularly high or extremely low. In the last case, it's possible to realize the presence of a periodic ring of condensation during the morning. This reaction proves the presence of a heat exchange due to a nocturnal re–radiation without that "inertia" or "thermic capability" shown by heavy and massive structures.

Figure 2. Frameworks placed outside in Vercelli.

2.4 Monitoring of Meteorology Condition of Exposition

In order to collect data on nature of real prodding, for the whole trial period, the monitoring of meteorology conditions has been kept. Thanks to ARPA station located in Ruggerina (2.4 km westward from Vercelli exposition site), it has been possible to keep information up to date.

Table 2. Historical data (1994-2002) regarding city of Vercelli.

Months	*Daily Average Temp. Max* (°C)	*Daily Average Temp. Min* (°C)	*Average Humidity* (%)		*Average Rainfall* (mm)
			Max	*Min*	
January	6.9	-1.9	99.9	28.1	58.4
February	10.9	-1	99.1	17.6	42.6
March	16.5	2.4	99.8	14.7	40.2
April	18.9	7.3	100	15	71.8
May	23.8	13	99.6	25.6	106.5
June	27.7	15.5	99.8	23	64.1
July	29.9	17	99.8	27.3	55
August	29.2	16.5	99.4	30.9	67.5
September	23.8	11.1	98.9	25.4	84.7
October	18.8	7.9	98.9	27	71.7
November	11.6	2.9	99	27.9	103.1
December	7.2	-0.1	99.8	37.6	45.5

2.5 Choice of Painting Cycle to Apply

Two kinds of painting have been chosen: Metilsilossanico (CVP 60)* and Vinilversatico (CVP 45). Both of them have been acquired by companies Caparol and Melzi. The cycle of Metilsilossanico is a recent compound having - according to manufacturer - a great resistance to environmental pollution, while the Vinilversatico has already been tested before and the result of that research shows that it is not so resistant to severe environmental pollution.

2.6 Application of MetilsIlossanico Cycle

Drafting process of product on samples implies (before exposition):

1) wetting of screen test with sponge;
2) overcoat of AMPHISILAN TIEFGRUND LF followed by natural dry out for 55';
3) first paintbrush drafting (no dilution) of AMPHISILAN VOLTON UND ABTÖNFARBE - "oxidrot" color, with 1 h and 40' room temperature drying;
4) second paintbrush of AMPHISILAN VOLTON UND ABTÖNFARBE - "oxidrot" color;
5) 27 days of concrete maturation.

On the basis of consumption of painting, it has been possible to notice that thickness of coating has been certified on an average measure of 220 µm (more or less constant for four sample realized). This result is comparable to the one visible with optical microscope (Fig. 3). In this case the value of reference sample is about 230 µm.

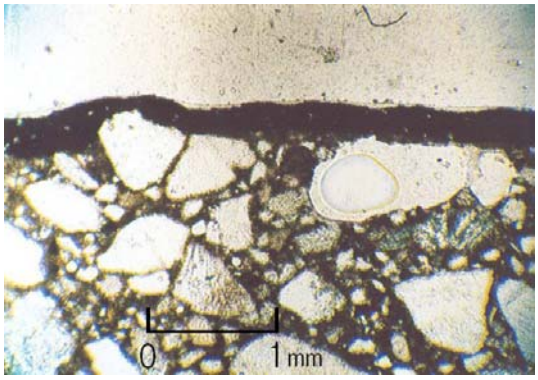

Figure 3. Thin film section of Metilsilossanico cycle.

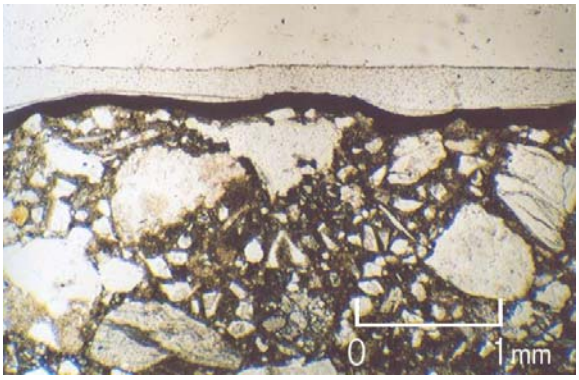

Figure 4. Thin film section of Vinilversatico cycle.

2.7 Application of Vinilversatico Cycle

Procedure has involved:

1) paintbrush undercoat of oxide red color (14 % dilution compared with subsequent painting coats) and natural drying period of 16 h;
2) first paintbrush coat with a drying time of 8 h (room temperature);
3) second and last resin paintbrush.

Depending on consumption of painting, thickness of coating has been rated on an average measure of 100 µm (variable for four sample realized). This result is in step with the thin film section: 120 µm (while the reference value for control group is about 110 µm - see Fig. 4).

**Notation "CVP" means value of volumetric powder concentration measured in %.*

2.8 Look of Protected Surfaces

The following images (Figs. 5 and 6) refer to the surface aspect of sample kept intact in our laboratory.

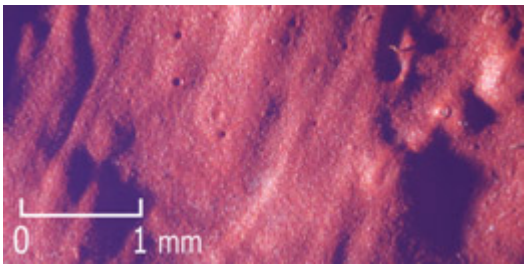

Figure 6. Close-up photo of Vinilversatico cycle.

3 MEASUREMENTS

3.1 Measurement of Permeability to Water Vapour

Test has been carried out following procedure proposed by UNI EN ISO 7783-1:2001 standard [«Paints and varnishes - Coating materials and coating systems for exterior masonry and concrete - Determination and classification of water-vapour transmission rate (permeability)»]. Preparation of laboratory specimens has implied:

1) cut of rectangular portions (4.5 x 10 cm);
2) subsequent dehydration of these sections;
3) arrangement of aluminium boxes to be used as capsules (as mentioned by UNI EN ISO standard to point 7.1);
4) introduction, before complete sealing of sample inside capsule, of saturated solution made with ammonium dihydrogen phosphate (as scheduled at point 7.2 of the standard);
5) measurement of mass loss through weighing during well-known time steps.

UNI EN ISO standard mentioned above, foresees that test ends when change of mass for atmosphere exposition time unit becomes a constant.

Achieved results (Fig. 7) show that original Metilsilossanico cycle has a transmission level of water vapour equal to 13.25 g/m^2·d. Numeric value determination comes from formula reported in Fig. 9.

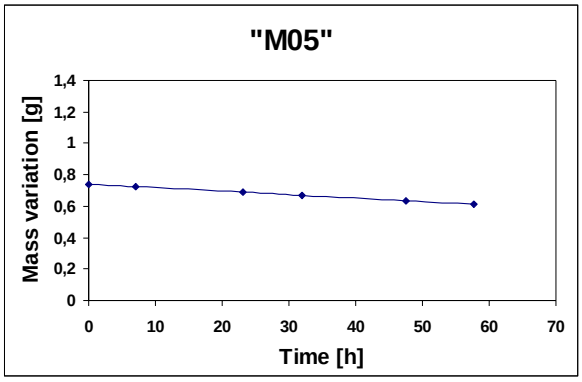

Figure 7. Transmission of water vapour for Metilsilossanico cycle.

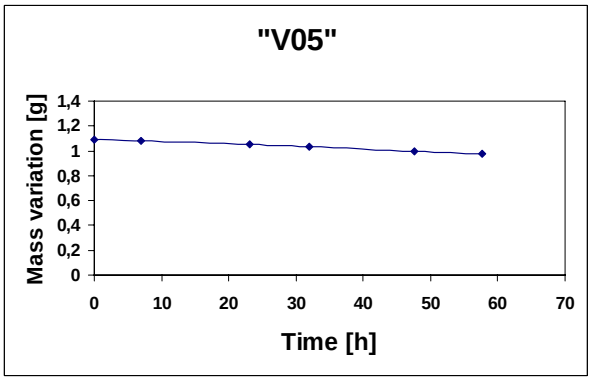

Figure 8. Transmission of water vapour for Vinilversatico cycle.

On the other hand (see Fig. 8), Vinilversatico cycle (concerning screen tests stored in laboratory) has a transmission level of water vapour equal to 10.52 g/m^2·d (numeric value determination comes from formula reported in Fig. 9).

$$WVT \left[\frac{g}{m^2 \cdot d}\right] = \frac{240 \cdot Dm}{A}$$

read as follows:

$$Dm \left[\frac{mg}{h}\right] = \frac{(m_1 - m_2)}{(t_2 - t_1)}$$

m_{1-2} : mass at selected points (on straight line)
t_{1-2} : time at selected points (on straight line)
A : sample surface area

Figure 9. Calculation formula of water vapour transmission (WVT).

$$LWT \left[\frac{kg}{m^2 \cdot h^{0.5}}\right] = \frac{Dm}{A \cdot Dt^{0.5}}$$

read as follows:

$$Dm \left[g\right] = (m_2 - m_1)$$

m_{1-2} : mass at selected points (on straight line)
A : sample surface area

$$Dt^{0.5} \left[h^{0.5}\right] = (t_2^{0.5} - t_1^{0.5})$$

t_{1-2} : time at selected points (on straight line)

Figure 10. Calculation formula of liquid water transmission (LWT).
