Chloride ingress: $\boldsymbol{B} = C_{cr}$ is a critical concentration of dissolved Cl^- leading to steel depassivation and $\boldsymbol{A} = C_a$ is a concentration of Cl^- at the reinforcement at time t_D.
Concrete cracking due to corrosion: $\boldsymbol{B} = \sigma_{cr}$ is a critical tensile stress that initiates a crack in concrete (on the interface with a reinforcing bar) and $\boldsymbol{A} = \sigma$ is a tensile stress in concrete or $\boldsymbol{B} = w_{cr}$ is a critical crack width on the concrete surface and $\boldsymbol{A} = w_a$ is a crack width on the concrete surface generated by reinforcement corrosion.
A decrease of the effective reinforcement cross-section due to corrosion: $\boldsymbol{B} = A_t$ is the reinforcement cross-sectional area at time t_D and $\boldsymbol{A} = A_{min}$ is the minimum acceptable reinforcement cross-sectional area with regard to either serviceability limit state (SLS) or ultimate limit state (ULS).

As stated in the basic design code EN 1990 [2002], the recommended value of the reliability index for SLS (irreversible state) is 1.5, which is relevant to a 50-year design service life. It should be noted that the values of $0.8 < \beta_d \le 1.6$ for the DLS are currently under discussion (e.g. the recommendation of the fib Model Code reads $\beta_d = 1.3$). The level of reliability in the context of durability should be left to the client's decision together with the target service life - as indicated in both future documents ISO/WD 13823 and fib-Model Code.

3 ANALYTICAL MODELS

Several models were selected on the basis of the authors´ literature survey and are briefly mentioned within the next paragraphs. Most of the models were primarily published as deterministic ones; for our purposes all of them were randomized and included in the probabilistic software FReET [Novák et al. 2003], creating a special degradation module FReET-D [Teplý et al. 2007] – see section 4.1.

3.1 Initiation Period

The mathematical models of processes relevant for the initiation periode concern the concrete carbonation and chloride ions ingress.

(i) Carbonation models introduced herein are based on the diffusion of CO_2 in the pore system of concrete and have been discussed in [Teplý et al. 2005, 2008]. Both, the carbonation of concretes from

Portland Cement (OPC) and from blended cements (where the suplementary cementing materials – SCMs – are used) have been incorporated; more details about the latter case see in [Chromá et al. 2007], including the discussion of *k*-value concept. Model from *fib* Model Code [2006] is also included.

(ii) Chloride ingress models are also encompassed in FReET-D software module starting with the models utilizing the widely used Crank's solution to Fick's 2nd law for diffusion of chlorides through concrete, taking into account the fact that the transport of chlorides in concrete is mainly diffusion controlled, and the convection zone is relatively small [Hunkeler 2005].

The simplest models usually involve a diffusion coefficient D of chloride through concrete as a time and space independent input parameter. It is according to Tang & Gulikers [2007] too conservative due to the fact that D is naturally decreasing in time resulting from chloride binding. Therefore the value of D may be calculated e.g. on the basis of the formula proposed by Thomas & Bamforth [1999]. They have derived a formula for the diffusion coefficient as a function of time for (a) a control mix made of OPC only, (b) concretes with 30 % of fly ash and (c) with 70 % of slag as a partial replacement for OPC. Unfortunately, this mathematical simplification where parameter D is simply substitued by time-dependent $D(t)$ without adequate clarifying the mathematical basis of diffusion may not be quite correct [Tang & Gulikers 2007]. In such case the apparent diffusion coefficient is underestimated and it will cause errors in durability design and redesign of reinforced concrete structures. Also the mathematical expression adopted by *fib* Model Code [2006] does not fulfill the correct differential equation. The proper mathematical derivation of time-dependent diffusion coefficient was published by Nilsson & Carcasses [2004] and comparison of possible errors caused by some oversimplified mathematical expressions were presented by Tang & Gulikers [2007].

Although those models based on simple Fick's 2nd law are used by engineers in practical applications due to their relatively simple mathematical expressions, however models based on the actual physical or chemical processes would be more adequate. They are often used only for research purposes owing to necessities of more sophisticated calculations and only some models were simplified into a more engineer-friendly form [Papadakis et al. 1996, Tang 2007].

3.2 Propagation Period

The key factor for the modeling of steel corrosion as a time dependent process is the corrosion rate which is usually expressed through current density, i_{corr}. This variable is strongly affected by ambient conditions such as humidity and temperature, moisture and oxygen availability at steel level, the degree of concrete carbonation and amount of chlorides; thus depending on the diffusion characteristics of concrete. The presented models are sorted into three basic groups (i) - (iii) according to their output information and are also implemented in FReET-D.

(i) The loss of reinforcement in time may be expressed by formulas proposed by Andrade et al. [1996] and Gonzales et al. [1995] for uniform and pitting type of corrosion, respectively.Those formulas are based on current density and parameter R_{corr} that expresses the type of corrosion. The residual reinforcement cross section in the case of pits can be predicted by the simplification into a hemispherical form as proposed by Val & Melchers [1998].

(ii) Time to cracks initiation in concrete: Complex models that describe the entire process of stress and crack development in concrete due to corrosion are rather rare; more extensively published are models predicting only the time of cracking initiation in concrete. The model for calculation of the time to crack initiation in concrete cover proposed by Morinaga [1988] is an empirical equation based on experimental data. This model takes into account only the initial bar diameter, concrete cover thickness and rate of corrosion. It does not include any mechanical parameters of concrete. Bažant [1979] has proposed a physical-mathematical model for calculation of initiation time to corrosion cracking taking into account concrete cover depth, reinforcing bar diameter and spacing, mechanical

properties of concrete, etc. Concrete is considered to be a homogeneous elastic material shaped as a thick-wall cylinder. This model also solves the time of steel depassivation due to critical chloride concentration. Bažant´s model [1979] was extended by Liu & Weyers [1998] who proposed a model for time of crack initiation based on a comparison of the minimum stress required to cause cracking (which equals to the tensile strength of concrete cover) with the expansive pressure in concrete developed over time due to the growth of corrosion products. Another improvement was proposed by Maaddawy & Soudki [2007]. The authors have developed a relationship between steel mass loss and the internal radial pressure caused by rust growth. The time to corrosion cracking is estimated on the basis of Faraday´s law.

(iii) Stresses and cracks development in concrete: Bhargava et al. [2005] have developed a model describing the entire cracking process after crack initiation. Five modifications of the model are proposed to reproduce various experimental trends. Li et al. [2006] have also proposed a model describing the whole cracking process in concrete due to corrosion with the possibility of calculating the width of a crack on a concrete surface.

4 NUMERICAL EXAMPLE

In the following some of the above mentioned models are used to illustrate possible practical applications. Firstly, a software tool developed by the authors for the probabilistic assessment of different DLSs is introduced.

4.1 Software Tool

The multipurpose probabilistic software FReET, for general statistical, sensitivity and reliability analysis of engineering problems, has been used for randomization of the analytical models [Novák et al. 2003]. It enables the feasible and user friendly utilization of stochastic approaches (a combination of analytical models and simulation techniques) to form the specialized software FReET-D for assessing the potential degradation of newly designed as well as existing concrete structures [Teplý et al. 2007]. Implemented degradation models may serve directly for the durability assessment of structures in the form of a simple limit state (Eq. 1), i.e. the assessment of service life and the level of relevant reliability measure. The user may create different limit conditions. For the statistical analysis of the following examples the Latin Hypercube Sampling method was applied. For the output quantities the best fit of probabilistic distribution function (PDF) was found using the Kolmogorov Smirnov goodness-of-fit test.

4.2 Loss of Reinforcement Due to Corrosion Initiated by Chloride Ingress

Let us assume the critical loss of the reinforcement area to be 10 % (such a loss may e.g. lead to the exceeding of the reliability level for the ULS or SLS – depending on the structure and loading configuration). For the calculation of steel loss in time a deterministic model proposed by Andrade et al. [1996] was applied. Time to corrosion initiation t_i was calculated on the basis of model proposed in [Papadakis et al. 1996]: t_i = LN (47.4; 11.5) years. The full description of all input parameters is given in Tables 1 and 2. The decrease in rebar diameter over time is plotted in Fig. 1 The mean values of t_i and $t_{d,crit}$ = the time of a critical drop in rebar diameter are marked in this figure.

Table 1. Input parameters for the calculation of time to reinforcement depassivation.

Reflection of	*Variable*	*Unit*	*Mean value*	*COV*	*PDF*
Models	Uncertainty factor of model	-	1	0.15	Lognormal (2par)
Environment	CO_2 content in the atmosphere	mg/m^3	820	0.12	Normal
	Relative humidity	%	70	0.07	Beta (a = 0, b = 100)
Concrete mix	Unit content of OPC cement	kg/m^3	313	0.03	Normal
	Unit content of water	kg/m^3	185	0.03	Normal
	Unit content of aggregate (0-4 mm)	kg/m^3	847	0.03	Normal
	Unit content of aggregate (4-8 mm)	kg/m^3	386	0.03	Normal
	Unit content of aggregate (8-16 mm)	kg/m^3	625	0.03	Normal
	Specific gravity of cement	kg/m^3	3100	0.02	Normal
	Specific gravity of aggregate (0-4 mm)	kg/m^3	2590	0.02	Normal
	Specific gravity of aggregate (4-8 mm)	kg/m^3	2540	0.02	Normal
	Specific gravity of aggregate (8-16 mm)	kg/m^3	2660	0.02	Normal
Other	Concrete cover	mm	25 - 75	-	Deterministic
	Concentration of Cl^- on nearest concrete surface	mol/m^3	50	-	Deterministic
	Saturation concentration of Cl^- in solid phase	mol/m^3	140	-	Deterministic
	Threshold concentration of Cl^- in liquid phase	mol/m^3	13.4	-	Deterministic
	Diffusion coefficient of Cl^- in infinite solution	m^2/s	$1.6 \cdot 10^{-9}$	-	Deterministic

Table 2. Input parameters for calculation of loss of reinforcement due to corrosion.

Input parameter	*Unit*	*Mean value*	*COV*	*PDF*
Initial bar diameter	mm	30	0.025	Lognormal (2 par)
Time to corrosion initiation	years	47.4	0.244	Lognormal (2 par)
Current density	$\mu A/cm^2$	1	0.2	Normal
Coefficient of corrosion type	-	2	-	Deterministic
Uncertainty factor of model	-	1	0.15	Lognormal (2 par)

The best-fitted PDFs for output net rebar diameters are LN (2 par) for 0, 10 and 20 years, Student t for 30 years, Laplace for 40 and 50 years, LN (2 par) for 60, 70, 80, 90 and 100 years, LN (3 par) for 110 and 120 years and LN (2 par) for 130, 140 and 150 years. Chosen histograms of output parameter together with fitted PDFs are depicted in Fig. 2 showing the complexity of a statistical description of the problem solved. Note that lognormal PDFs appear for time intervals of 0-20 and 60-150 years. In the first interval the steel is not yet depassivated, while in the second time interval the steel is already depassivated in the majority of stochastic realizations. Therefore, the standard deviation (std) of output net rebar diameter in the time interval of 0 to 20 years is given by std of the input initial bar diameter

while the std in the time interval of 60-150 years is affected by all input variables and is much greater. In the intermediate part (i.e. 40-100 years) the standard deviation gradually increases (see Fig. 1).

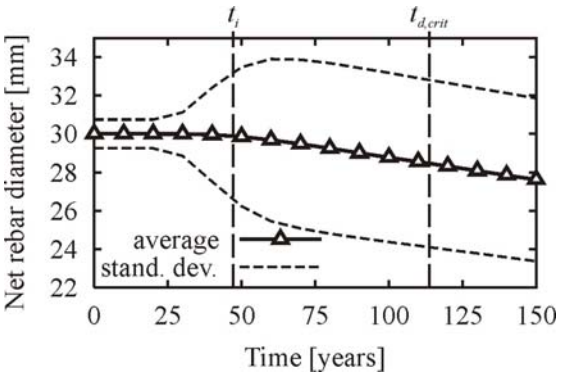

Figure1. Net rebar diameter (± standard deviation) vs. time.

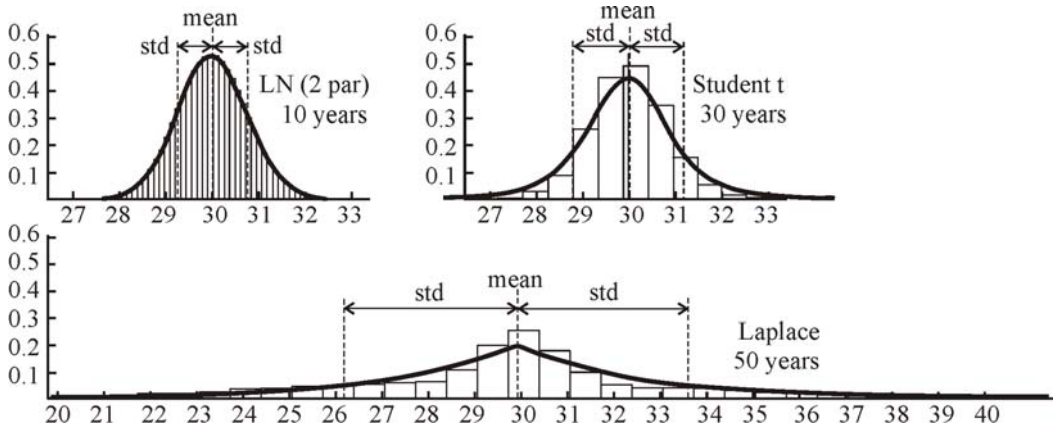

Figure 2. Histograms of output net rebar diameter plotted in figure1 (decreased due to corrosion) together with the best-fitted PDFs in chosen time steps.

5 FINAL REMARKS

The probabilistic durability design approach is discussed in this paper, focused on the initiation and propagation period. Appropriate limit states are explained and suitable models are briefly described. Finally, a numerical example is shown.

Concurrently, the presented approach lacks certain considerations, e.g.: (i) the spatial randomness of material and/or environmental characteristics are not considered (random fields could be a remedy), (ii) the spatial distribution of deterioration is not distinguished while assessing limit states, and (iii) combination with mechanical stress is not taken into account. The authors' ongoing research is focused in this direction partially; the effect of chloride concentration on reinforcement corrosion is also currently being studied utilizing the celullar automata technique.

Development of a Simulation Tool for Insulated Glass Durability

Russell Pylkki [1]
Michael Doll [2]

T 43

ABSTRACT

Efforts to increase the energy performance of windows has been an ongoing effort that has seen fenestration progress from windows with storm windows to sealed double pane insulated glass (IG) to IGs with glass coatings which moderate the light and heat transfer through the glass. As time has progressed, the cost of glass failure has increased significantly. The United States Department of Energy is concerned that a lack of durability could lead to slow adoption.

In order to address the advancements that are needed to meet current and future building envelope energy performance goals, a project to deliver the foundation for a comprehensive IG durability simulation tool was undertaken. This need is based upon the lack of IG field failure data and the lengthy field observation time necessary for data collection. Ultimately, the simulation program is intended to be used by designers throughout the current and future fenestration industry supply chain. Its use is intended to advance IG durability as expectations grow and designs evolve around the impact a window has on energy conservation..

Included in the simulation model presentation are elements and / or methods to address IG materials, design, process, quality, induced stress (environmental and other factors), validation, etc. In addition, acquired data is presented in support of project and model assumptions.

1 INTRODUCTION

The Window Industry Technology Roadmap, sponsored the U. S. Department of Energy's Office of Building, State and Community Programs, identified durability of windows as a barrier to their advancement. This is of concern because of the pivotal role that insulating glass (IG) is expected to play in meeting the US Department of Energy (DOE) performance goals for current and future building envelopes. Although data is lacking regarding IG unit durability, there is a growing perception of costly IG unit failure rates that creates a barrier to new technology implementation and associated costs.

To address this concern, the DOE funded a project, "An Insulating Glass Knowledge Base," [Hage *et al.*, 2002; Doll, M. L. *et al.*, 2005] that included the development of a software model to evaluate the durability of IG units. This paper discusses the development of a software program that was to provide a mechanism by which durability characteristics of IGUs could be captured in a useful and practical manner.

2 APPROACH

2.1 FMEA/Fault Trees

General research efforts addressing IG unit durability have been and continue to be focused at the understanding IG unit seal systems and their materials. Although, as an example, permeation of moisture vapor and gasses through the sealant materials is an important aspect of IG unit durability, this project was defined and brings focus to identifying and evaluating all modes of root cause IG unit failure. This process requires that each IG unit be considered as a unique system with respect to its design, materials and assembly process. A Failure Modes and Effects Analysis (FMEA) was completed to document the possible root cause failure modes of the IG system. The FMEA was then used to develop an Event Tree Diagram, shown below for a box spacer in Fig. 1.

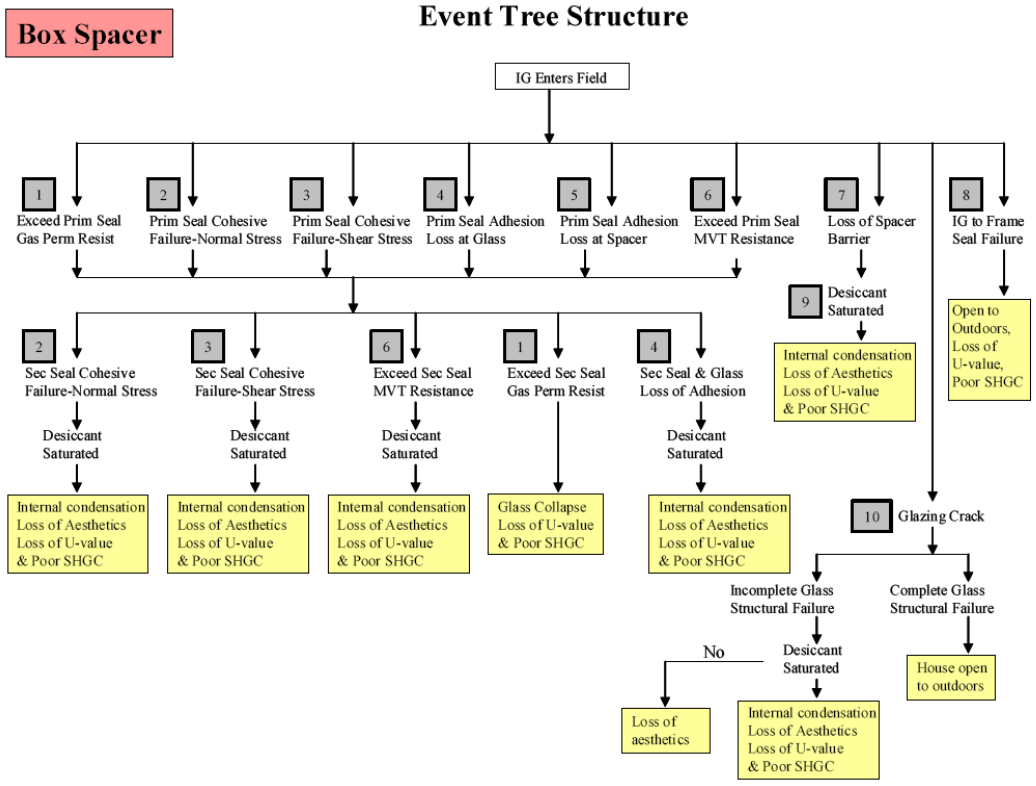

Figure 1. Example of an Event Tree for an IGU with a box spacer.

Understanding of failure mechanisms was also an input reference for the event trees. Specifically, understanding of the sequential chain of events leading to a system failure was captured from failure mechanism knowledge. The event tree differs from the FMEA in that it captures with more detail the sequence of events which must occur for a given system failure to be realized. This more thorough graphical representation of the failure chain allows greater qualitative understanding of the cause-failure effect chain. Such event trees were used the development of the model and were used to determine the model's failure criteria.

3 SIMULATION DESIGN

3.1 Simulation Schematic

A representation of an IG unit (box spacer) and the forces that act upon it are shown below in Figure 2. Stressors that act upon the IG unit include temperature, pressure (barometric and wind), solar radiation, which differ between the exterior and the interior environments, and gravity. The IG unit has multiple glass surface temperatures, gas pressure, gas composition and gas temperature.

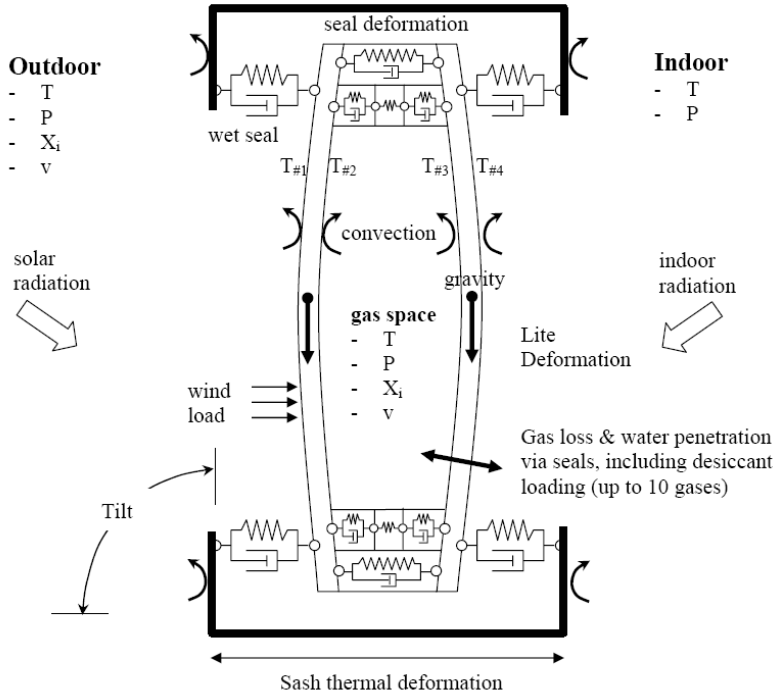

Figure 2. Schematic of the representation of in the model of and IG (Box Spacer) and indication of the physical effects modeled on an IG unit (T = temperature, P = pressure, X = gas composition, v = velocity

As a function of time, the durability design tool simulates the behavior of an IG unit exposed to realistic climate conditions. As the environment acts upon the IG unit, stresses and strains in the IG unit are calculated together with temperature distributions, gas permeation effects (i.e. gas loss and desiccant moisture loading), and dew point temperature in the IG unit air space, and changes in the heat transfer through the IG unit. The effects of the environmental exposure on the IG unit are compared against the strength of the window assembly to determine the durability of the design.

3.2 Simulation Components

In order to carry out the simulation, the IG unit's response to the environmental stressors is separated into three models (thermal, permeation, and stress) which are described briefly as follows.

3.2.1 Thermal Model

The thermal model, using meteorological data 1) calculates the incident angle of the sun on the window; 2) determines the optical properties of the glass at that angle; 3) calculates the optical properties of the IG unit; 4) calculates a center-of-glass temperature (using the average lite separation and IG gas fill) and 5) calculates a one dimensional temperature distribution in the sash.

3.2.2 Permeation Model

The permeation model calculates the movement of gasses (including water) with time through the IG unit's polymer seals and the loading of the desiccant with water. The model is also designed to work with sealant systems where the sealant is formulated with desiccant. This allows both a box spacer and a 'thermoplastic spacer' type designs to be modeled.

3.2.3 Stress Model

The stress model calculated the physical stresses that act upon the IG unit with time. These stresses include the movement of the IG unit components relative to each other that can take place due to the effects of thermal expansion or contraction, bending of the glass lites due to differences in pressure between the atmosphere and the IG unit gas space and wind loads.

3.3 Coupled Model Calculations

The coupling of the structural model with the thermal model and the model for gas permeation is the program is shown in the calculation sequence shown below in Fig. 3. At each time increment, the temperature model is solved (based on the most recent solutions for the permeation and structural models. The second model considered in Fig. 3 is the permeation model, in which the most recently determined temperature and structural data are used. The last model is the structural response, which uses the most recent solutions for the temperature and gas permeation. Since a sequence of calculations may not result in a balanced solution, convergence is tested. When

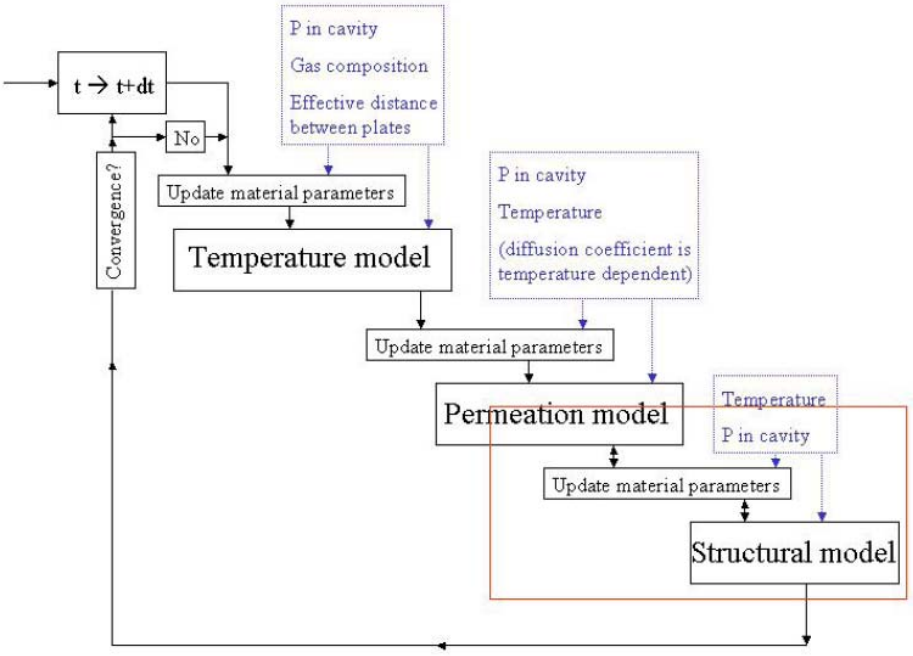

Figure 3. Sequence of coupled model calculations

3.4. Durability Tool – User Interface

The user interface is used to control the simulation. The user 'assembles' an IG unit to be tested, defining all aspects of its design: dimensions, glass thickness and coatings, spacer system, sealant materials and dimensions. Material properties for glass, spacer materials, and sealants are selected from their respective data bases. A standard deviation of material properties can be defined for use in Monte Carlo simulations. The International Glazing Data Base is used for the glass optical properties. Meteorological data (TMY2 format) are used to define the outdoor environmental conditions for the simulation. The user also defines the indoor environment. A total of 44 failure criteria can be selected and the user also sets the failure threshold. The interface program is also used to control the simulations parameters, launch the simulation and evaluate its results. An example of the input for sealants dimensions for a box spacer system is shown below in Fig 4.

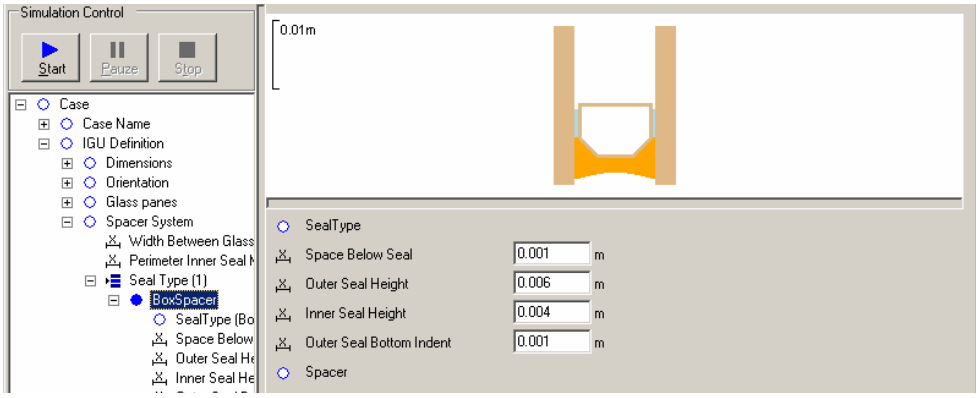

Figure 4. Seal dimension input screen (partial view)

When simulation is completed, the results are shown in a summary screen. In this example (Fig. 5), a simulation consisting of 50 Monte Carlo runs was made. The pie chart identifies the distribution of failure modes, while the details of the simulation are displayed below. The left axis shows the number of runs that were performed in the simulation while the time to failure is shown on the right axis. The frequency of failure modes are shown in a histogram format. The average time to failure and standard deviation are shown as a whisker plot for each failure mode encountered.

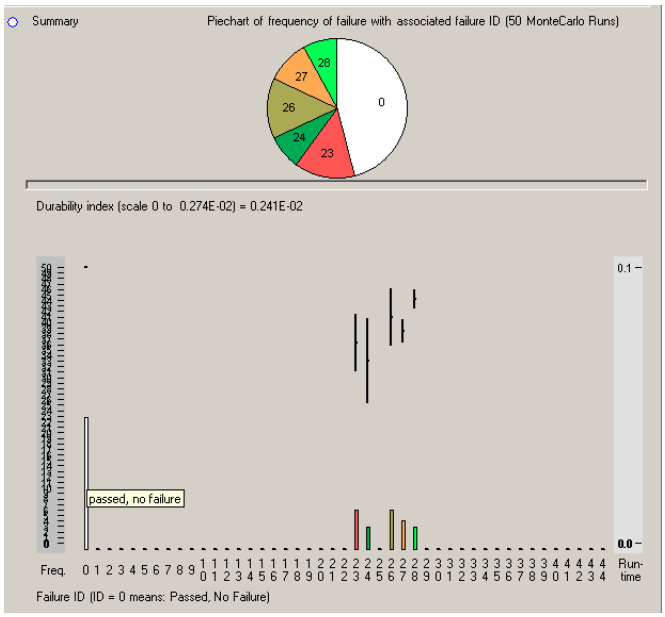

Figure 5. Results Summary Screen (parial view)

4 Simulation Tool Validation

Validation of the simulation tool will be an important aspect of continuing the tool development process. We know that the model is built upon an understanding of the physical forces that are acting upon an IG unit and the IG unit's response to those stressors. Assumptions were made with respect to the boundary conditions for the model. For example, the current release of the durability model leverages code from other modeling tools (WINDOW, THERM, etc.) widely used in the US in support of energy certification. Yet, to evaluate root cause failure, the durability model must extend analysis beyond the current tools and include, for example, direct and indirect radiant solar adsorption on the seal components. Thus, the program must model all the components during all environmental cycles and expected applications. As an example, the current tools output validated temperature gradients from a simulated winter night. The seal temperature which might be expected from these simulations differs greatly from the seal temperatures which will be achieved during a sunny late winter day.

Figure 6 presents the temperature along the bottom seal materials of an IG unit of a brown south-facing window, showing that the seal materials reach temperatures of *ca*. 50 °C. The glass surfaces on the same day were 32 °C, nearly 20 °C cooler than the temperature of the lower seal. Accurate estimation of temperatures is important in estimating the service life on an IG unit because the permeation properties of the sealants change with temperature and stresses that can be induced by thermal expansion of the IG unit's components. This effect of this temperature error on permeation can be compensated by providing the simulation tool with a file of seal temperatures as a function of time to use with the simulation.

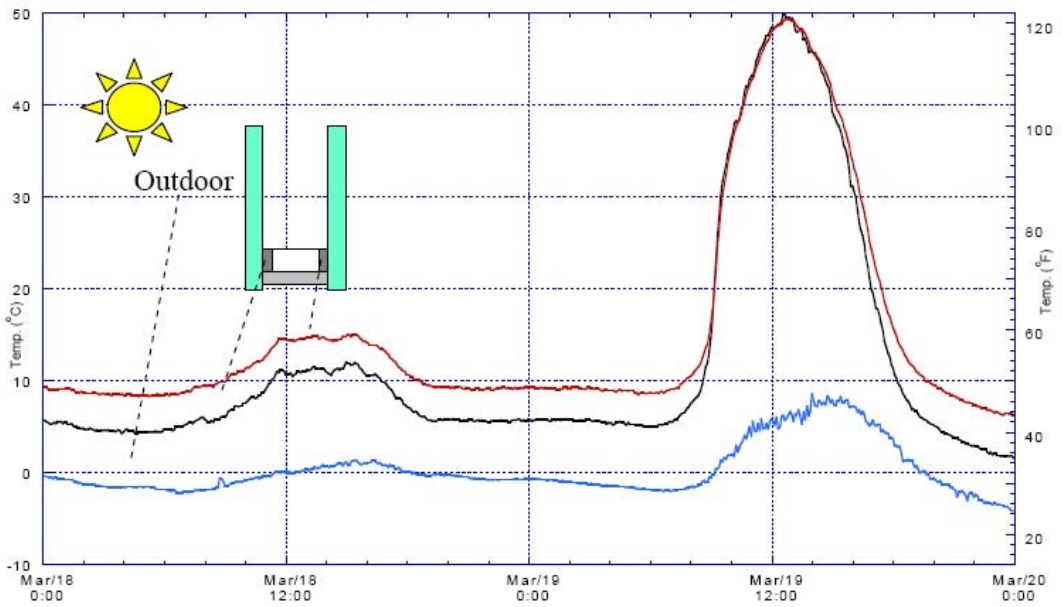

Figure 6. Effect of a cloudy vs. sunny day on the seal temperature of an IGU. The IGU is in a brown, south-facing window. The exterior temperature near the window is also shown.

5 SUMMARY

We have presented an overview of the development of a simulation tool for determination of IG unit durability. The development began with a Failure Mode and Effect Analysis of IG units and led to the definition of an Event Tree Structure for the IG unit's failure. This was used in the development of the simulation tool, which consists of coupled thermal, permeation and structural models of the IG unit's response to a user defined environment.

This simulation tool is envisioned to ultimately be a predictive model, utilizing Monte Carlo methods to statistically choose and compare stress and strength distributions of the IG unit. The current release is the foundation of that vision.

Critical Considerations on the Assessment of the Durability (Serviceability) Limit State of Reinforced Concrete Structures

Rui Miguel Ferreira [1]
Joost Gulikers [2]

T 43

ABSTRACT

Until recently, reinforced concrete structures were not designed specifically for durability but this issue was incorporated indirectly in the prevailing codes without any type of mathematical or scientific verification. Traditionally, design for durability has been based on a deem-to-satisfy approach. However, this approach has been shown, in some situations, not to guarantee the required concrete quality necessary to achieve the specified service life. The lack of reliable information on the durability of the concrete makes it difficult to evaluate its quality and performance. The deem-to-satisfy approach does not quantify the durability of the concrete, and therefore also not the performance. Consequently, for a specific exposure environment, without prior knowledge of performance, design solutions can not be optimized for durability and costs.

However, and largely thanks to European projects like *Lifecon* and *DuraCrete*, a different approach has been developed based on that commonly used for structural design in which limit state (LS) equations define the acceptance or the rejection of design solutions. LS can be assessed deterministically, semi-probabilistically (use of factors that can reduce resistance and increase loads, alter time periods, etc.) and probabilistically. The probabilistic approach can allow for optimization but requires much more information, which is not always available. The LS equations are sometimes rewritten so as to focus either on the resistance of the material, the accumulation of damage, or even the development of the degradation process over time. A different formulation of the same LS equation can be adversely influenced by the type of variables and their sensitivities.

The objective of this paper is to critically analyze the assessment of the LS with probabilistic and semi-probabilistic approaches. The probabilistic assessment is based on the Monte Carlo simulation method. A critical overview of the assessment of the durability limit states shall be presented. A thorough comprehension of the underlining conditions for the use of these approaches is vital for the correct durability design of reinforced concrete structures.

1 INTRODUCTION

Until recently, reinforced concrete structures were not specifically designed for durability, but this aspect was incorporated indirectly in the prevailing codes without any type of mathematical or scientific verification. Traditionally, design for durability has been based on a deem-to-satisfy approach. The lack of reliable information on the durability properties of the concrete makes it difficult to evaluate its quality and performance. Such a deem-to-satisfy approach does not quantify the durability of the concrete, and therefore, also not it's performance. However, a different approach has been developed based on a LS equation that defines the acceptance or the rejection of design solutions. Limit states can be assessed deterministically, semi-probabilistically and probabilistically. The probabilistic approach can allow for optimization but requires much more information, which is not always available.

There are different ways of defining a serviceability limit state (SLS) according to the degree of deterioration, such as corrosion initiation, cracking, spalling, etc. For all these limit states, however, it is very difficult to define the associated criteria. Since corrosion initiation is considered a critical and well defined point of the degradation process, it is the most commonly used SLS.

The objective of this paper is to analyze critically the assessment of the limit states with a probabilistic approach based on the Monte Carlo simulation method. A critical overview of the assessment of the durability limit states shall be presented. A thorough comprehension of the underlining conditions for the use of these approaches is vital for the correct durability design of RCS.

2 CONSIDERATIONS ON THE VERIFICATION OF THE SLS

2.1 Definition of Probability of Failure and Degree of Reliability

The SLS defines the conditions beyond which a specified service requirements for a structure (or component) are no longer met for a certain degree of reliability (DR). The probability of failure (PF) is defined as the probability that a structure (or component) no longer satisfy the design performance requirements (i.e. SLS), where as the reliability index is defined as the fractile of a normalised normal probability function corresponding to the ability of the structure (or component) to perform its requirements without failure during a specific interval of time.The PF and DR are not easily understood by both the consultant and owner as it provides no information on the actual condition of the structure in terms of damage. It appears that an unambiguous definition of probability cannot be given and consequently the DR is based on arbitrary grounds [Gulikers 2007]. The DR is usualy indicated by the reliability index, β.

For the SLS of corrosion initiation, the physical phenomenon is a relatively well defined moment. What remains to be defined is the acceptable value of PF and the required value of the reliability index. Does the PF represent a physical degree of deterioration of the structure, or is it only a mathematical/ statistical value agreed on as being acceptable? For the SLS of corrosion initiation, the PF can be described as the mathematical likelihood that corrosion has been initiated. There is no indication as to the extent of corrosion initiation, however, it is usually assumed that the higher the PF the wider spread the phenomenon. Therefore, a 10 % or 90 % PF only indicates the likelihood that corrosion has been initiated, but not the extent or the severity of the corrosion. An extreme situation would be a PF of 0%. This level would logically correspond to a situation with complete absence of steel reinforcement corrosion. Another extreme situation is the PF of 100 %. It is a mathematical guarantee that corrosion has initiated, in some part of the structure, but it does not indicate that 100 % of the structure has initiated corrosion, i.e., all the reinforcement. According to LNEC E-465 [2005] the acceptable level of PF for the SLS of corrosion initiation, varies from approximately 2 % up to 12 %. However, in Germany probability levels up to 30% are suggested in order to arrive at reasonable cover depths.

How should the DR be quantified? Should it represent an economical optimum? The DR should depend on the type of structure, accessibility, the consequences of degradation and failure, maintenance, among other factors. In certain publications, the reliability index depends on the Reliability Classe (RC) of the structure, which in turn is associated with the Consequence Class (CC) of structural failure. In general, for SLS, a reliability index ranging from 1.3 to 1.8 is considered appropriate. These β-values correspond to probabilities of approximately 10 % and 3 %, respectively. Service life calculations have demonstrated that in most cases the adoption of β = 1.7 to 1.8 will result in an excessive cover depth, and for that reason β = 1.3 will generally be advocated. In the fib Model Code for Service Life Design, β = 1.3 is presented as a "recommended minimum value" for exposure class XS independent of the RC of the structure [Gulikers 2007]. According to the LNEC E-465 [2005], the reliability index varies according to the RC from 1.2 to 2.0 for the RC1 and RC3 class, respectively. These β-values correspond to probabilities of approximately 12 % and 2 %, respectively. It is apparent that there is no consensus as to what should be the appropriate values for the reliability index. As it remains unclear what is the acceptable value of PF (what physical phenomena is represents), and therefore what the appropriate DR or acceptable reliability index, then it seems unlikely that probabilistic calculations for the corrosion initiation can be conclusive. This issue has to be urgently addressed, and in the extreme, by convention it should be defined what the interpretation should be and what values are to be considered.

3 CHLORIDE INGRESS MODELING: ASSUMPTIONS AND PARAMETER ANALYSIS

With respect to chloride ingress service life calculations for reinforced concrete structures are commonly based on the mathematical solution to Fick's second law of diffusion, expressed by:

$$C(x,t) = C_i + (C_s - C_i)\cdot\left(1 - \mathrm{erf}\left[\frac{x}{2\sqrt{D_a \cdot t}}\right]\right) \qquad [1]$$

in which C_s - surface chloride content (%m/m cement); C_i - initial chloride content (%m/m cement); D_a - apparent diffusion coefficient (m^2/s); t - duration of exposure to chloride (s); erf - error function.

In practice, both the surface chloride content, C_s, and the apparent diffusion coefficient, D_a, are derived from chloride profiles measured on cores retrieved from existing concrete structures. Most often, the surface layer is discarded as in this region the chloride profile shows a distinct deviation from the profile as suggested by Eq. (1). Consequently, the value of C_s reflects a more or less fictitious chloride content which is quantified by extrapolation of the chloride profile at greater depths. Based on the results obtained over a longer period it has been concluded that the apparent diffusion coefficient gradually decreases over time according to the empirical relationship:

$$D_a = D_{a,o}\cdot\left(\frac{t_0}{t}\right)^a \qquad [2]$$

in which a - ageing factor (-); $D_{a,o}$ - apparent chloride diffusion coefficient at reference age t_0 (m^2/s); t_0 - reference concrete age (s); t - actual concrete age (s).

However, in order to allow for service life calculations of new concrete structures in the design stage the use of measured apparent diffusion coefficients derived from existing structures is considered less appropriate. Consequently, in DuraCrete [1999] and later in the fib Model Code [2006] mathematical expressions for D_a have been introduced which take into account the concrete quality aimed at. This has been accomplished by using a migration coefficient, $D_{RCM,0}$, determined on the target concrete by a laboratory test at age t_0 (usually 28 days), which is thereupon translated into a practical level, i.e. the $D_{a,o}$ level, by multiplication with one or more correction factors.

In contrast to DuraCrete, in the fib Model Code only a temperature factor, k_e, is employed whereas curing, type of cement and environmental exposure conditions are not considered to be of any relevance anymore. In order to account for chloride transport by capillary suction in the surface layer, in the fib Model Code a substitute exposure surface is suggested at a depth Δx from the exposed concrete surface. Consequently, chloride contents can only be calculated for $x > \Delta x$.

Taking into account the presence of a convection zone yields the overall expression employed in the fib Model Code:

$$C(x,t) = C_i + \left(C_{s,\Delta x} - C_i\right)\left(1 - erf\left[\frac{x - \Delta x}{2\sqrt{D_{a,o} \cdot t}}\right]\right) \quad [3]$$

in which $C_{s,\Delta x}$ - chloride content at substitute exposure surface (%m/m cement)

$$D_{a,o} = k_e \cdot D_{RCM,0}\left(\frac{t_0}{t}\right)^a \quad [4]$$

and

$$k_e = \exp\left(b_e\left[\frac{1}{T_{ref}} - \frac{1}{T_{real}}\right]\right) \quad [5]$$

in which k_e - environmental transfer variable (-); b_e - regression variable (K); T_{ref} - standard test temperature (K); T_{real} - temperature of the structural element or the ambient air (K).

In fact, Eq. (3) does not describe the underlying transport processes but rather gives an estimate of the resulting chloride profile after a considerable period of exposure time. In addition, Eq.(3) is applicable for 1-D situations only and thus is less suitable for columns and beams, especially in the regions near the edges. These situations would require a 2- or even a 3-D approach.

It should be noted that this expression includes a number of implicit assumptions. Amongst others, these involve the start of exposure to chloride at t = 0, i.e. immediately after casting, the continuous presence and fixed level of the exposure conditions as evidenced by a constant value of $C_{s,\Delta x}$, the overall dependence of D_a on time and temperature only, and the gradual decrease of the diffusion coefficient over time until infinity according to Eq.(4).

3.1 Considerations on the Age Factor and Critical Chloride Parameters

One of the most practical concerns in durability design is the pronounced influence of the age factor on the outcome whether this is expressed in terms of service life, t_{sl}, thickness of concrete cover, or migration coefficient. The empirically derived age factor *a* expresses the time-dependent development of the chloride diffusion coefffciencient over time according to Eq.(2). In practice, the value of *a* may range from 0.3 to 0.7, dependent on the type of cement and environmental humidity conditions. The influence of *a* is illustrated in Fig. 1 regarding thickness of concrete cover and migration coefficient, for a reference situation of t_{sl} = 100yr, C_s = 3.0%, C_i = 0.1%, C_{crit} = 0.6%, Δx = 0.0mm, whereas in Fig. 2 the effect of *a* on calculated service life is demonstrated (deterministic approach). An increase of the age factor from 0.5 to 0.6 would result in an increase of predicted service life by one order of magnitude, i.e. from 100 to 1000 years (c = 45mm). It can be concluded that in most situations the age factor is far more dominating than any other model parameter. Consequently, considerable care should be exercised in it's quantification. In the literature a wide range of values for *a* is suggested depending of the type of cement and exposure conditions. In order to allow for a reliable quantification of *a* a significant amount of chloride profiles obtained from concrete structures with the same type of cement and exposed to comparable conditions over a prolonged period of time, i.e. more than 50 years, should

be available. Regarding the time-dependency it should be noted that results obtained from laboratory tests may demonstrate a completely different time-dependency. For concretes produced with CEMIII/B an age factor of 0.36 has been derived for $D_{RCM,0}$, whereas the age factor based on chloride profiles of real structures suggested a value in excess of 0.60 [Gulikers, 2006].

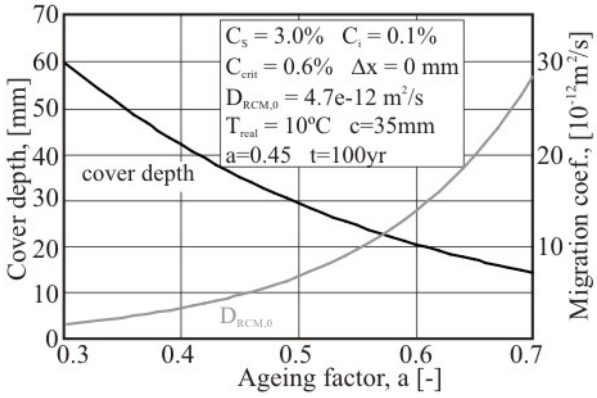

Figure 1. Influence of ageing factor on cover depth and migration coefficient.

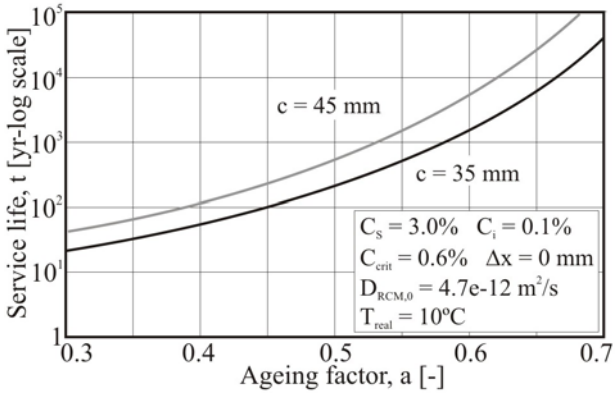

Figure 2. Influence of the ageing factor on predicted service life.

A matter of considerable debate also concerns the so-called critical chloride content. Firstly, a clear and practical definition of C_{crit} should be employed in order to be used in service life models. However, the amount of data obtained from real structures is rather scarce and poorly supplied with essential background information. Consequently, most of the data used is based on short-term laboratory tests performed on small, young, crack-free, well-cured concrete or mortar specimens using an accelerated electrical method. However, such laboratory results have proven to be less suitable to evaluate real structures. Thus a more thorough research is urgently needed on C_{crit} covering aspects like type of cement, humidity conditions, micro-cracking etc.

4 CONSIDERATIONS ON THE PROBABILISTIC IMPLEMENTATION OF THE SLS

One of the most practical ways to perform a probabilistic analysis is by Monte Carlo (MC) simulation. The PF is determined by the number of times the outcome of the simulation falls within the failure region defined by the limit state equation. Each simulation represents the verification of the same LS equation. The LS equation is defined by a model equation which, in this particular case, is the calculation of the time to reinforcement depassivation due to the presence of chlorides such as presented in the DuraCrete or in the fib Model Code, among others.

Typically $1x10^6$ simulations are used for this type of analysis. To perform a simulation, it is necessary to randomly generate values for the parameters of the limit state equation. Each model parameter is randomly sampled from its probability distribution function (PDF), using the inverse transform method, to generate the sample (or simulation) value. Once the PDF's of the various parameters are known, the PF is based on the evaluation of the limit state function for a large number of simulations. The PF is estimated by the following expression:

$$p_f = \frac{1}{N} \cdot \sum_{j=1}^{N} I[g(x)] \qquad [6]$$

in which I [g(x)] - indicator function; g(x) - limit state equation.

The reliability index β can be calculated from the PF by using the inverse of the standard normal distribution function, Φ( ), assuming that the outcome of the simulations is a normally random variable based on the Central Limit Theorem.

$$\beta = -\Phi^{-1}\left(p_f\right) \qquad [7]$$

However, it should be noted that if the reliability index is calculated based on the actual PDF of the outcomes of the LS equation, the values when compared are not exact, but very similar. This results from the inherent randomness associated with the creation of the PDF of the LS equation .

The MC simulation is a popular method as it is easy to implement, being both intuitive and relatively simple to use. The use of the MC simulation requires some knowledge of statistics and probability calculations. Many of the problems and errors that occur result from the incorrect use of the simulation method, or the lack of comprehension for the physical meaning of the model equation and its parameters. As the parameters are mostly stochastic, this is a potential source of error in the simulation.

4.1 Considerations on Parameter Definition

The outcome of the simulation is dependent on the correct choice of PDF to represent the parameter and on the sensitivity to a change of the PDF parameters (e.g.: average and standard deviation). The PDF should fit the available parameter data accordingly, not only in the neighborhood of the average value, but in some cases also in the distribution tails. The PDF of the parameter should take into account the physical limitation of the parameter. Negative values for concrete cover and migration coefficient will have no physical meaning. As another example, parameters such as the age factor have upper and lower boundaries. Howver, these parameters are often modeled with PDFs that do not take this into account. Figure 3 presents a normal and lognormal PDF for concrete cover, with μ = 45 mm and σ = 15 mm. From Fig. 3 it can be seen that by using the lognormal distribution to define the parameter, negative values for concrete cover do not occur. The distribution is skewed towards the constraint. This also has an effect on the outcome of the simulation. Figure 4 presents two PF vs. time curves where the PDF of the concrete cover has been changed according to Fig. 3. By observing the performance curve in Fig. 4, a difference in performance can be observed. For early ages, the use of a lognormal PDF for concrete cover has resulted in an increase of the time to limit state failure. The calculation of the PF was based on $1x10^6$ simulations. When concrete cover was simulated with a normal PDF, 866 negative values were detected.

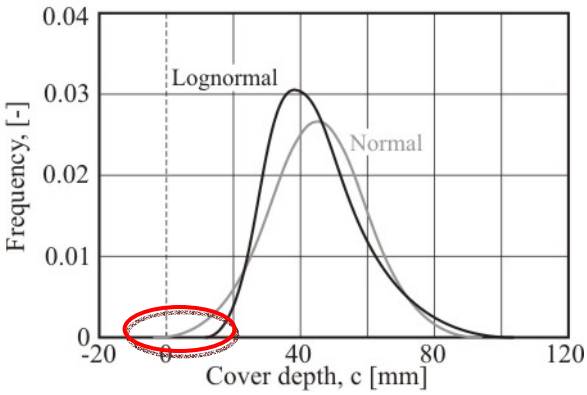

Figure 3. Comparison of the PDF for concrete cover (m = 45 mm, s = 15 mm)

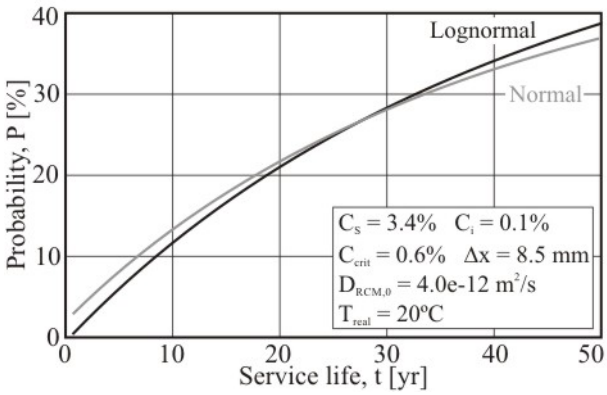

Figure 4. PF vs. time for simulation with different PDF for concrete cover.

As mentioned before, the outcome of the simulation is also dependent on the sensitivity to a change of the PDF parameters. In addition, some limit state equation parameters have a greater influence on the outcome than others. The most influential parameters are concrete cover, age factor and the migration coefficient, and to a lesser degree, the critical chloride content [Ferreira 2007]. The sensitivity of the limit state equation parameters can be seen by the influence on the simulation outcome introduced by changes in the PDF parameters. To demonstrate this further, two examples are given: the first in which the average value of the concrete cover is increased successively whilst the standard deviation is

maintained constant (see Fig. 5); and, the second where the coefficient of variation (CV) is varied from 10 % to 30 % whilst maintaining the average constant (see Fig. 6).

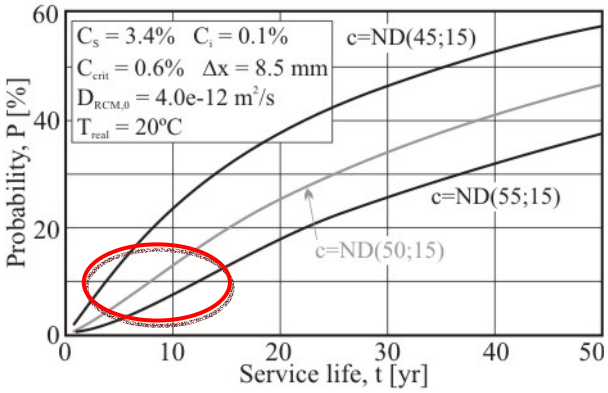

Figure 5. Influence of average value of concrete cover on the PF.

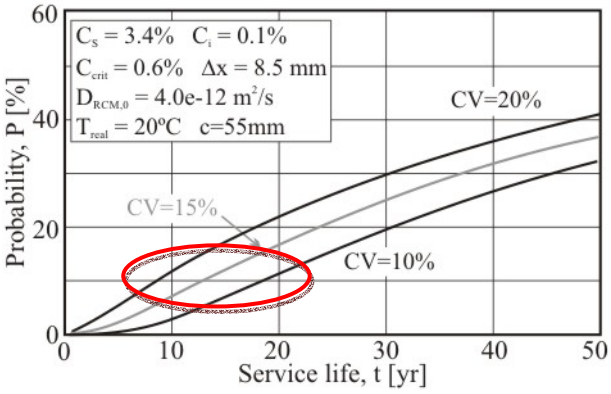

Figure 6. Influence of standard deviation value of concrete cover on the PF.

In Fig. 5, the effect of change of the average of the concrete cover on PF is shown. As the concrete cover is an influential parameter, the changes in PF are clearly visible. In Fig. 6, the same influence is observed, with respect to the influence of the standard deviation of the concrete cover.

Previously, the importance of the physical meaning of the limit state equation parameters in their stochastic characterization was shown. For some parameters, the stochastic nature describes the inherent variability (e.g.: temperature, chloride surface concentration), and the quality of the construction and the materials used (e.g.: concrete cover, migration coefficient). On the other hand, the age factor, a, depends on the type of cement used and the prevailing exposure conditions. The variation of these parameters implies a change in the material used, i.e. concrete or cement. As an example, by maintaining the average value of the age factor constant and by varying the CV between 10 % and 30 %, different PDF's are obtained, as shown in Fig. 7.

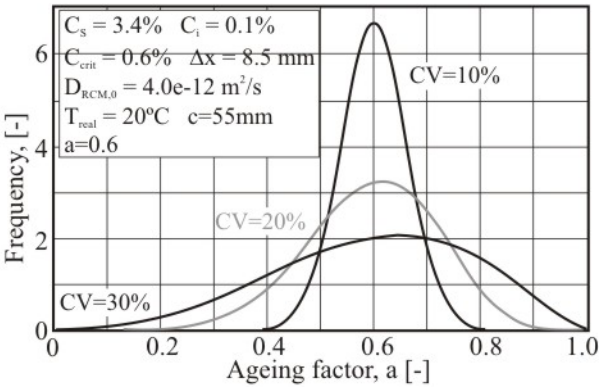

Figure 7. Effect in change of the age factor PDF on the simulation outcome.

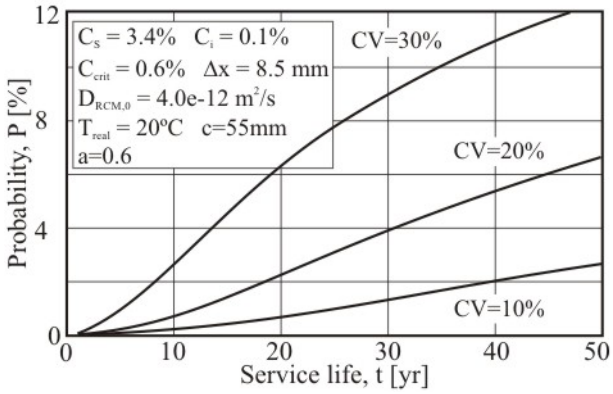

Figure 8. Comparison of the beta PDF for the age factor: a = 0.6, COV = 10%, 20% and 30%.

The age factor may vary between 0 (there is no influence with time) and 1 (the influence is the greatest). The values between these two limits represent the influence of different cements (among other factors) on the development of the migration coefficient over time. In Fig. 7, the different PDF's obtained as a result of using different CV's show how wider spread values are considered for the age factor. For a CV of 10%, the age factor varies between 0.4 and 0.8. For a CV of 30%, the age factor varies between 0.1 and 1.0. This implies that several different cement types are considered simultaneously to characterize the performance of the concrete. There is no consensus as to the appropriate values for the age factor for a given cement. As an example, in a marine environment values for a CEM I can vary from, for example, 0.3 [fib Model Code 2006] to 0.55 [E-465 2005]. As a

result, the effect on the performance is apparent, as shown in Fig. 8. The larger the CV, the more concrete (or cement) types are apparently being considered.

5 CONCLUSIONS

At present a probabilistic approach appears not to be suitable for durability design of real structures. Clear and concise definitions of probability of failure and reliability index are needed, even if by convention, so that that in all durability design (modelling) the same performance criteria have to be fulfilled. In addition, input values of model parameters may vary considerably and values are still under discussion. As an example, a more practical definition of the ageing factor is required. The material characteristic is often overlooked which seriously influences the outcome. A determinisitic use of this parameter should be considered.
As a result, durability design appears to be volatile, mainly due to parameter sensitivity. Models should consider more stable outcomes. In addition, probabilistic simulation is prone to user manipulation. Models should be accompanied by limitations to parameter values as well as recommended PDF.
Both Deem-to-satisfy and probabilistic approach should be evaluated and advantages should be combined as to result in an improved but still practical approach.

International Standards on Durability and Sustainability of Construction Works

Christer Sjöström [1]
Wolfram Trinius [2]
Hywel Davies [3]
Jacques Lair [4]

T 45

ABSTRACT

The European Directive on Construction Products (CPD) establishes a set of essential requirements on construction products to be fulfilled throughout the "working life" of the construction works. The demands expressed in the directive is one significant driver, international attention another. Both CEN through a "task force on durability" and ISO through TC59/SC14 "Design Life" are addressing the subject. The work of ISO has led to the establishment of a suite of procedural standards on service life planning, including service life declaration and service life assessment methodologies, useful to be applied in the declaration and the application of service life information.

The political agendas related to sustainable development and the understanding that building and construction is a key industrial sector to implement sustainability principles have led to the establishment of ISO TC59/SC17 "Sustainability in building construction". Being the first ISO subcommittee expressly dealing with sustainability in relation to an industrial sector, the work focuses on economic, environmental and social aspects of sustainability relative to buildings and construction works.

Together with the established standards on service life and the concept of performance-based building, all the three provide a procedural reference point for the consideration of sustainability aspects. They all benefit when applied in common context, and can provide each other with necessary information. On a European scale this common context is elaborated with the work of CEN TC350. The status of development, key drivers and key success factors are elaborated in this paper.

1 INTRODUCTION

There is a pronounced momentum and progress internationally and in Europe to provide the building and construction sector market with standard approaches and methodologies for service life planning and sustainable construction issues. These standards published or in different stages of preparation, are all performance based and give procedural guidance to actors in the building and construction sector.

The ISO set of standards on Service Life Planning developed by ISO TC59/SC14 and on Sustainability in Building Construction prepared by ISO TC59/SC17 form the basis for the emerging European standards by CEN TC350 on Sustainability of Construction Works.

2 PERFORMANCE OVER TIME, DIRECTIVES AND REQUIREMENTS

The performance concept in building is receiving a renewed interest. After having been very much in focus and discussed during the 1960 – 70:ies there is today a revitalisation. The performance concept is crystal clear as to its basic idea, and application is common practice in most industrial sectors. However, in construction this is yet far from the situation. The strive towards sustainable construction, increased international trade within construction, with building products and construction services, and a general call for improving the innovation climate in the construction industry may well speed up the performance approach in building. Where earlier the green focus in building was solely about environmental impact assessment, a move towards a sustainable construction concept incorporates economic, social, and cultural aspects, i.e. a move from assessment of impacts to an assessment of performance. Environmental performance can, however, not be described without a well-defined performance (over time) of the constructed asset as a reference point [Trinius & Sjöström 2005].

2.1 The European Construction Products Directive, CPD

The CPD [Council of the European Communities 1988], adopted in December 1988 by the EU Council, is a good example of a performance directive. Created with the aim of removing barriers to trade in this specific area, following the white paper on the internal market approved by the Council in June 1985, it does per se have little direct reference to sustainability. However, the CPD has a clear bearing on the view on performance over time of buildings (construction works) and has as such provided an important direction for international, European, and national work on standards and codes. The CPD fixes the essential requirements for construction works (both buildings and civil engineering works). There are six essential requirements which apply to the works as set out in annex I of the directive:

- Mechanical resistance and stability;
- Safety in case of fire;
- Hygiene, health and the environment;
- Safety in use;
- Protection against noise;
- Energy economy and heat retention,

These requirements must, subject to normal maintenance, be satisfied for an economically reasonable working life. The CPD has, however, not the aim of harmonising the regulations on works of the Member States but rather of bridging the "works" and the construction products put on the European market and used in these works. It therefore specifies the level of performances of these products: the products "have such characteristics that the works in which they are to be incorporated, assembled, applied or installed, can, if properly designed and built, satisfy the essential requirements...". This is the notion of "fitness for the intended use" of a construction product. The link between the essential requirements of the works and the product characteristics to be assessed is fixed in Interpretative Documents [CEC 1994; CEC 2004]. The Interpretative Documents, IDs, have been drafted on the basis of existing regulatory requirements of the Member States, each ID containing necessarily one chapter on the requirements of the works and one on the characteristics of the products, in principle

allowing to accommodate the requirements for the works.

The CPD specifies further that a construction product is fit for its intended use if it conforms to a, 1. harmonised European standard (drafted by CEN/CENELEC), 2. European Technical Approval (issued by an EOTA[1] member) or, 3. non-harmonised technical specification (e.g. a national technical specification) recognised at Community level, the three being denoted technical specifications. According to the CPD: "The products must be suitable for construction works which (as a whole and in their separate parts) are fit for their intended use, account being taken of economy, and in this connection satisfy the following essential requirements where the works are subject to regulations containing such requirements. Such requirements must, subject to normal maintenance, be satisfied for an economically reasonable working life". Furthermore, the IDs provide that product standards and Guidelines for European Technical Approval (ETAGs) "should include indications concerning the working life of the products in relation to the intended uses and the methods for its assessment".

3 STANDARDS ON SERVICE LIFE PLANNING AND SUSTAINABILITY

3.1 ISO TC59/SC14 Design Life

The ISO 15686 standards, produced by TC59/SC14, are:

• ISO 15686-1 General principles
Part 1 gives the general principles and procedures that apply to design, when planning the service life of buildings and constructed assets.

• ISO 15686-2 Service life prediction procedures
It describes a procedure that facilitates service life predictions of building components. The general framework, principles, and requirements for conducting and reporting such studies are given.

• ISO 15686-3 Performance audits and reviews
This part is concerned with ensuring the effective implementation of service life planning. It describes the approach and procedures to be applied to pre-briefing, briefing, design, construction and, where required, the life care management and disposal of buildings and constructed assets.

• ISO/WD 15686-4 Data requirements/data formats
This technical specification will describe the data requirements needed to carry out service life planning considering various service environments and other in-use conditions. In co-operation with the International Alliance for Interoperability, IAI, the aim is also to describe IFC[2]compliance for the ISO 15686 series.

• ISO/DIS 15686-5 Life cycle costing
Provides guidance on developing a model of the capital and running costs of the project, so that the overall costs can be assessed, and how this data can be used for financial appraisal.

• ISO 15686-6 Procedure for considering environmental impacts
The standard provides guidance on assessing the relative environmental impacts of alternate service life designs, and to identify the interface between environmental LCA and service life planning.

• ISO 15686-7 Performance evaluation for feedback of service life data from practice
Provides a generic basis for performance evaluation and feedback of service life data from existing buildings and constructed works.

• ISO 15686-8 Reference service life and service life estimation
The standard describes how to provide, format and extract Reference Service Lives of components, e t c, to establish the service life of the same in a particular usage. It also provides the Factor Method to carry out such estimations.

[1] European Organisation for Technical Approvals
2 IFC = Industrial Foundation Classes

• ISO/AWI 15686-9 Service life declarations
Aims at giving guidance to construction products manufacturers and standard writers on addressing durability and service life declarations in product standards. The work is performed in close co-operation with a CEN Task Force on Durability, which was set up to support European product standard committees (see below).

• ISO/CD 15686-10 Using requirements for functionality and ratings of serviceability during the service life
The standard provides process guidance for managing the capability of a building or other constructed asset through the service life of that asset to meet the stated levels of requirements.

At the end of 2007 all standard documents included in ISO 15686, except Parts 4 and 10, are published or in a stage near to final publication. Maintenance is at the moment discussed as new area of standardisation.

3.2 The CEN Task Force on Durability

The CEN Task Group on Durability was established in 2003 as a result of that year's CEN Construction Sector Network Workshop, held in Malta.

The Group was given two tasks within the scope of support to product standards committees. Firstly, to produce a short-term guiding document on durability and service life assessment and declaration for those standards committees still working on a 1st generation of harmonised product standards. This resulted in an up-date of the CEC Guidance Paper F on Durability [CEC 2004]. Secondly, to produce a long-term guiding document on durability and service life for 2nd generation product standards. Both guiding documents should be as far as possible harmonised with the approaches and concepts of the ISO 15686 standards. The ISO 15686-9 is the result.

3.3 ISO TC59/SC17 Sustainability in Building Construction

The technical committee on building construction (TC59) addresses sustainability in its subcommittee 17 "sustainability in building construction". A suite of standards is under development, aiming to set a broadly agreed basis for the establishment, communication and application of sustainability information relative to buildings and construction works.

The work program addresses the three pillars of sustainability (economic, environmental and social aspects). The documents on "General principles", "Terminology" and "Sustainability indicators" address the full scope of sustainability aspects, while the documents on "Environmental declaration of building products" and "Framework for methods for assessment of environmental performance of buildings" are clearly restricted to environmental aspects and environmental impacts.

The suite of standards addresses the general concept of sustainable development in the building and construction sector through the document on general principles (ISO FDIS 15392). This document provides the conceptual basis for the other documents in the suite of standards. The report on terminology (ISO 21932) fulfils two core functions, primarily – to the standard developers - it provides the subcommittee as well as other related subcommittees of TC59 with an engine to harmonise its terms and definitions, and secondly – to the reader of the standards - it provides a collated list of terms and definitions related to buildings and sustainability.

Sustainability indicators are useful for the simplification and communication of sustainability information. The ISO standard on a framework for sustainability indicators (ISO 21929) provides the conceptual basis for such sustainability indicators. With the latest adaptations of the SC17 work

program, the standard in sustainability indicators will be complemented with established lists of indicators, bringing the concept closer to application.

The following documents are more restricted in their scope, as they relate essentially to environmental aspects.

The document on environmental declaration of building products (ISO 21930) has been developed at the same time and in close harmonisation with the development of ISO 14025. It brings the concepts from ISO 14025 to the specific considerations to be tackled when addressing construction sector products.

A framework for the assessment of environmental performance of buildings is provided in ISO 21931-1. A new work item proposal is under preparation in order to address also other construction works than buildings. The newly established working group on construction works will identify the needs to complete or amend existing work items and will establish ISO 21931-2 on the assessment of environmental performance of construction works other than buildings.

3.4 CEN TC350

CEN TC350 was born out of the Commissions Mandate 350, aiming to harmonise European approaches for environmental declaration of building products. The variety and the conceptual differences between existing declaration programs were understood as a potential source of market confusion. The initial discussions in CEN rapidly clarified that this mandate could be addressed, but also clarified that the standardisation task would need to embed the environmental declaration of products both within the application context of the products – read that products are to be addressed at hand of their functional application in a building – and that the environmental declaration becomes more meaningful when relating to performance of the product and the building as well as to other sustainability aspects. Consequently, the concept of "Integrated building performance" became subject of CEN TC350. It was also early decided that the work by CEN TC350 should build on the ISO 15686 standards on Service Life Planning, and the standards developed by ISO TC59/SC17.

The work program of CEN TC350 contains:

- the establishment of a framework document containing the overall concept of assessing integrated building performance, including environmental performance, life cycle cost performance and quantifiable health and comfort aspects.
- the establishment of a report on the description of the building life cycle, indicating the route from a building description to a life cycle description, including concepts such as performance-based building and service life planning
- the establishment of product category rules for the environmental declaration of building products
- the indication of the application of generic data sets as back-ground information for the establishment of environmental product declarations
- communication formats for environmental product declarations
- guidance on the application of environmental product declarations as information source for a building assessment
- calculation methods for the assessment of environmental performance of buildings.

The work program is currently established to address all sustainability aspects in terms of environmental, life cycle cost and health and comfort performance on a conceptual level (framework and life cycle description), but is focussed on environmental declaration and environmental assessment on the more detailed level. Work items addressing economic and social performance in more detail will be pre-established, also to indicate the clear ambition of TC350 to cover these fields of work.

CEN TC350 has not yet published standard documents, the work is underway and intended to be concluded by 2010.

4 DISCUSSION AND FUTURE PERSPECTIVES

Figure 1 shows the service life planning process, and the vital role played by the client. The design and construction process is only a brief part of a building life, but is the period during which the essential conditions for its life performance are established.

Refurbishment, repair and maintenance constitute a major part of all building and construction activities, in fact in most societies some 35% of the total. Maintenance and maintenance management has scarcely at all been mentioned in this article, only as a possible up-coming area for standardisation within ISO TC59/SC14. The area is very important and presently in focus by CEN TC319. It should e.g. be noted that the CPD view on the working lives of construction works builds on declared working lives of products under the assumption of a normal maintenance. What is then a normal maintenance? The normal maintenance of a product or building part must be declared for a reference in-use situation, and this could be of vital importance for future standardisation.

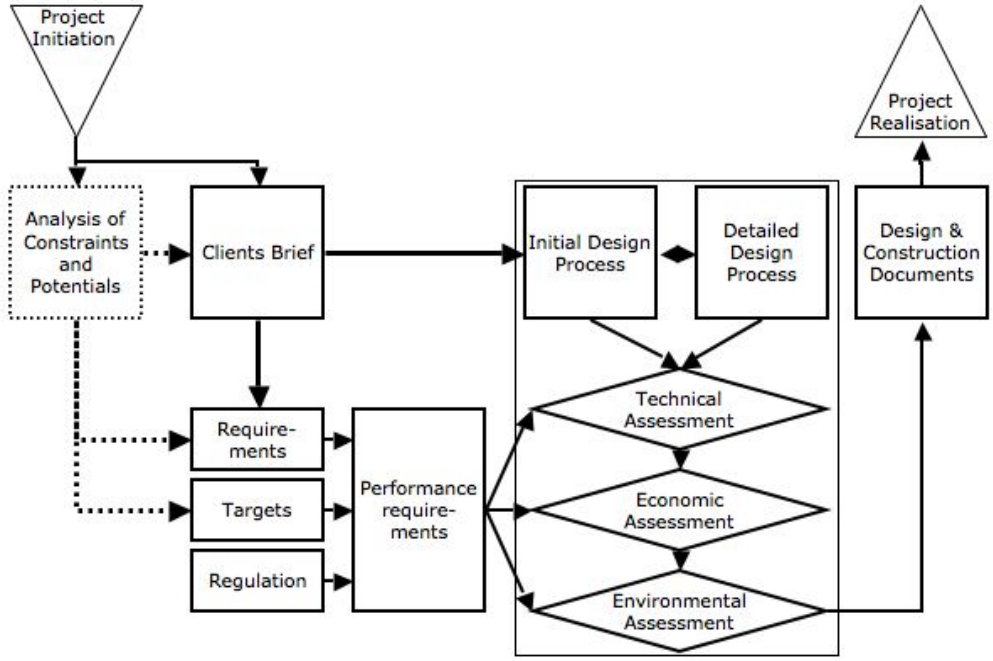

Figure 1. The service life planning process. The figure also highlights the important role of the client in the process.

The building and construction sector worldwide focuses pronounced challenges. These challenges are well encompassed and described by the three CIB Priority Themes, Sustainable Construction, Performance Based Building, and Re-valuing Construction, and also in essence identified and integrated in similar action plans or RTD-policies for the sector by e.g. the UN, WTO and EU.

Sustainable Construction contains the well-known identification of the building and construction sector to be the single most important industrial focus area if sustainable development in our societies is to be reached. The sector contributes some 40% of the green house gas emissions, consumes more than 40% of all energy and material resources, and is responsible for some 40% of all waste produced. The theme, well described by Agenda 21 for Sustainable Construction [CIB 1999], is since more than a decade a focus and priority area in international and European RTD-priorities, and a driving force in innovation and market development. How this is addressed by international standardisation is e.g. described by Sjöström and Davies [Sjöström & Davies 2005] and Sjöström et al [Sjöström et al 2006].

There is since many years a development towards performance concepts in building and construction, i.e. to via performance requirements on the constructed works describe and market the expectations on the functionality and serviceability of the works. The reasons for performance based building concepts are easily understood. Performance is closely connected to end customer values, it is in essentially neutral as to the technical solutions to meet the performance requirements, it is supposed to stimulate innovation, and contrary to deemed-to-satisfy technical specifications it does not so easily under-pin trade barriers. Directives, codes, regulations in e.g. the EU shall be performance based, and this is also a mandatory requirement on ISO standards. CPD is a very early example of a performance based (new approach) directive. Performance Based Building and Sustainable Construction are complementary. It can be argued that Sustainable Construction will necessitate the building and construction sector to follow the Performance Based route.

Re-valuing Construction focuses the apparent and pronounced potential for change and improvement in the building and construction sector. This includes not the least renewed and improved processes (business, and other) in construction and management, improved up-take of R&D-results, broader and more efficient use of ICT, industrialisation, profitability on invested capital, and value for money for end-users.

The standards earlier described, produced or in process, are all performance based and addresses the life cycle aspects of building and construction with focus on service life planning and sustainability. These instruments on the market will help define the business environment and the market. The opportunities offered are identified and addressed by an ongoing European funded RTD-project, STAND-INN [Europe Innova 2006]. The STAND-INN project addresses new manufacturing processes based on IFC standards and the performance based standards for sustainable development with the objectives of creating new and more efficient business processes in the construction sector. The idea is that new manufacturing processes based on IFC standards will facilitate the construction sector great potential for cost reduction and productivity increase and thereby improving the competitiveness of the building and construction industry. An ultimate goal will be to allow designers and other actors in the design process preceding new construction, planning of facility management or refurbishment, to integrate long-term performance aspects, life-cycle costing and environmental Life Cycle Analysis (LCA) into their decision making.

Another recently started EU project, Smart-ECO, (www.smart-eco.eu), [Trinius et al 2008], addresses questions related to the extent to which innovation, both technical and non-technical, can contribute to promoting sustainability in the building sector. The project embraces the EU concept “Eco-buildings” and relates to both the ISO TC59/SC17 and SC14 standards, as well as the CEN work, to an overall “vision of sustainable building”.

These projects and the earlier described standardisation depict a future perspective, based on only a few of the manifold activities to reach a sustainability conscious building and construction sector.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge all the international and European experts co-operating in and contributing to the ISO and CEN work on standardisation on life cycle performance of constructed works.

A Durability Assessment Tool for the New Zealand Building Code

ABSTRACT

Materials and construction methods continue to evolve. The empirical knowledge derived from traditional building practice is often insufficient for predicting durability problems with emerging materials and construction techniques. Consequently the capability for robust durability assessment of new products and techniques is an essential platform for supporting an innovative, dynamic building industry.

The New Zealand Building Code (NZBC) is primarily performance-based: only for a few classes of materials, such as timber and concrete, do prescriptive 'deemed-to-satisfy' solutions exist. For other situations, the Code offers only the advice that suitable durability performance may be demonstrated through laboratory testing, a documented history of use, or by analogy with the behaviour of similar building components. Little further guidance is provided concerning how these criteria might be satisfied in practice.

In response, this paper describes the development of an overarching durability verification framework for assessing building materials, components and systems under the NZBC. The aims of the project include systematising existing durability knowledge and verification methods, identifying critical knowledge gaps to guide future research, and making this information available in a convenient manner to a wide range of potential users. The latter goal is achieved through the development of an interactive web-based interface to the underlying information.

1 INTRODUCTION

It is hardly surprising that a strong demand for robust durability research and information has featured repeatedly on building industry needs surveys. Functional and durable construction is essential both for the health and well-being of owners and occupiers and the credibility of the industry. Consequently, the consideration of materials performance is critical over the entire building life-cycle, from initial construction to in-service maintenance, and finally renovation, alteration or retrofitting.

Furthermore, while operation normally accounts for the largest proportion of environmental costs over the life-cycle of a building, the intrinsic service life of the structure lies at the core of the concept of sustainable construction. Until durability performance can be predicted accurately, the feasibility of assessing the sustainability merits of alternative construction styles at the design stage remains doubtful.

2 DURABILITY UNDER THE NZBC

Ensuring that buildings have an appropriate durability has always been an important aspect of building regulations. This is emphasised by the current NZBC, which includes the functional requirement that: "*Building materials, components and construction methods shall be sufficiently durable to ensure that the building, without reconstruction or major renovation, satisfies the other functional requirements of this code throughout the life of the building*" [Building Industry Authority 1992].

The NZBC is a performance-based rather than prescriptive code, intended to permit innovative solutions and minimise the constraints placed on building design or choice of materials and techniques, providing the mandated minimum performance levels are achieved. The Code's B2 Durability clause is the single exception to this philosophy, setting default lifetimes for building elements depending on their criticality of function and ease of replacement (Table 1). These durability provisions apply to any part of the building which is fulfilling another Code requirement (e.g. structural stability or fire performance) but do not extend to aesthetic considerations.

Table 1. A summary of the performance requirements for building elements specified by the NZBC B2 Durability clause. Note that the mandated service life allows for routine maintenance, but not reconstruction or major renovation.

	Nature of Building Element	*Required Service Life*	*Typical Examples*
(i)	Provides structural stability, *or*	50 years	▪ Load-bearing walls
(ii)	Difficult to replace, *or*		▪ Buried electrical wiring
(iii)	Failure undetectable thorough normal maintenance regimes		▪ Building wraps behind masonry veneer walls
(i)	Moderately difficult to replace, *or*	15 years	▪ Building envelope cladding
(ii)	Failure undetectable during everyday occupancy of building		▪ Sealants and flashings
(i)	Easily replaced, *and*	5 years	▪ Architectural coatings
(ii)	Failure readily apparent		▪ External gutters

The reason for retaining this prescriptive aspect in an otherwise performance-based code is essentially one of consumer protection: it was considered inappropriate to allow the service life of buildings to be

effectively set by market forces, particularly given that a significant proportion of owners would have little expertise in evaluating the relative benefit of construction styles and materials [Bennett 1998]. Note that despite this prescription, the choice of materials for producing building elements of the required durability is left unregulated.

2.1 Industry Reaction

Specifying durability in terms of building element service life has a number of drawbacks. These include the issues of perception involved in judging difficulty of replacement and the potential mismatch between Code requirements and the expectation of owners who, for example, are often surprised to discover the roof of their house only needs to last 15 years. Chown and Oleszkiewicz [1997] offer some of the most telling criticism of this approach, noting that it may only be truly practical where the building element in question is essentially inaccessible (so that service life is independent of maintenance) and the rate of deterioration under the in-service environment is known. Otherwise, building designers, certifiers and owners assume a significant burden in determining and documenting material and component service life in various environments, based on an assumed level of maintenance. Often the information necessary to do this rigorously is not readily available.

This contention is supported by a survey of construction industry perspectives on the issue of durability and the B2 clause in particular [Clark and Bennett 2001]. As shown in Fig. 1, lack of reliable information was widely cited by survey respondents across all sectors of the industry as a primary barrier to the achievement of durability design.

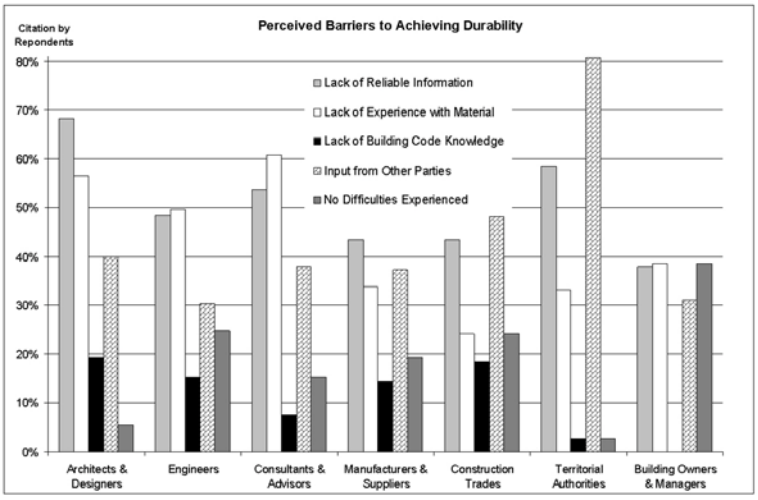

Figure 1. Perceived barriers to achieving the NZBC durability requirements, as identified by surveying the New Zealand construction industry. Data from Clark and Bennett [2001].

Perhaps the perception of an absence of reliable information is unsurprising, given that the same respondents identified ‘trade literature’, ‘industry information’ and ‘past experience’ as the most important sources of information concerning the durability of building materials (Fig. 2). It is also notable that the industry places a good deal of reliance on fitness-for-purpose systems appraisals similar to the European Agrément system.

One particular disappointment, given the reliance on trade literature, is that manufacturers have proven reluctant to invest the time and money necessary to establish reliable service life; formal declarations of Reference Service Life and the tabulation of modification factors, as described in ISO 15686-1 [ISO 2000], are almost unknown despite the usefulness of the concept.

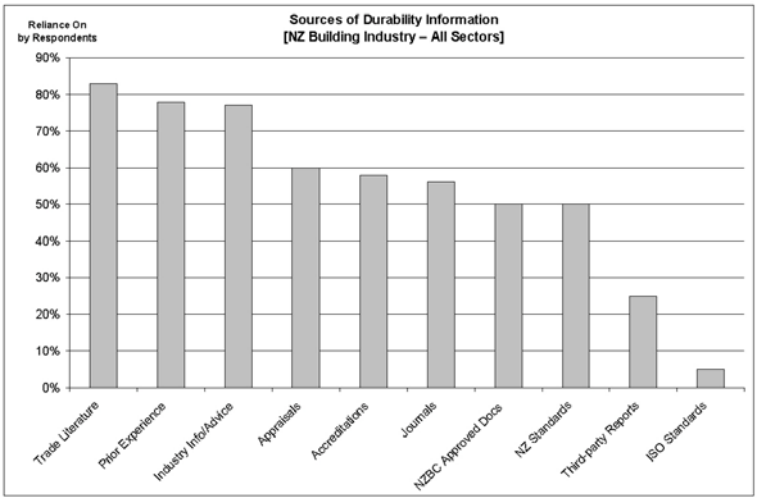

Figure 2. Importance of durability information sources, ranked from survey respondents in the New Zealand construction industry. Data from Clark and Bennett [2001].

2.2 Establishing Compliance

Part of this difficulty arises because, despite the unquestioned importance of the subject, there is no broadly applicable methodology available to verify that building materials, components and construction methods will meet the performance requirements of the NZBC B2 Durability clause. Manufacturers and, especially, the statutory bodies responsible for certifying buildings as compliant with the Code, frequently wish to rapidly assess the expected service life of a new material, or even a conventional one in a new environment. The absence of a list of specific test methods that will generate a 5, 15 or 50 year durability rating is consequently a source of frustration.

For a restricted range of building materials and techniques, the NZBC incorporates the concept of 'Acceptable Solutions'; prescriptive construction methodologies that, followed to the letter, will ensure Code compliance. Acceptable Solutions primarily exist for time-honoured construction methods (e.g. timber-framed or concrete construction, earth buildings) that draw on a background of many years' actual service history and development under New Zealand conditions. Even where an Acceptable Solution ordinarily covers durability compliance, the situation becomes complex when new materials with uncertain capability and interactions are introduced. A topical example in New Zealand is the marketing of copper azole (CuAz) and alkaline copper quaternary (ACQ)-based preservatives as a replacement for the environmentally less favourable copper-chrome-arsenic (CCA) treatment traditionally used to improve the durability of *Pinus radiata* timber. Recent research [Kear et al 2007] has demonstrated a significantly enhanced risk of zinc corrosion with these newer treatments, placing into question the established specifications for galvanised fastenings. When such developments occur, there is a pressing need both to effectively disseminate the research findings to practitioners and to provide robust guidelines for assessing the durability of the new materials.

In cases where an explicit durability evaluation is required, the NZBC documents an approved verification methodology, known as B2/VM1. Unfortunately B2/VM1 offers only the generic guidance that proof of performance should be demonstrated by in-service history, laboratory testing, or analogy with similar products/situations. Anyone involved with materials testing will appreciate that this advice is both valid and a profound over-simplification of the process required. In practice, there is no shortage of durability-related test methods for a vast variety of materials and potential applications. However, a considerable amount of skill is necessary to collate and synthesise this information in a reliable and appropriate fashion. Examples of the need for expert judgement include: considering whether the degradation methods in accelerated tests (heat, moisture cycling, freeze-thaw, UV exposure etc) are appropriately matched to real-world causes of deterioration; assigning quantitative service life predictions on the basis of qualitative rankings of observed durability; and

assessing likely variation in performance due the different macro- and micro-climates, materials interactions, intensity of use and maintenance that come with a specific instance of use on a particular building.

The provision of additional information is an obvious next step to ameliorating these difficulties and removing the barriers to durability design identified in Clark and Bennett [2001]. The standards published, and in preparation, for the ISO 15686 series on 'Design Life' provide valuable guidance and a uniform approach to the assessment of durability. However, whether this knowledge can easily be assimilated into future Code revisions remains unresolved. Also, the intent of these documents is not to provide details on the durability of specific materials, or even prescriptive methodologies for the determination of durability. Consequently, to solve the practical and immediate challenges faced by the New Zealand construction industry, there is a demand for more specific guidance documents that will take into account the properties of construction materials, their potential uses, and their performance in the environments within which they are likely to be used. The BRANZ Durability Assessment Tool is a response to this need.

3 BRANZ DURABILITY ASSESSMENT TOOL

BRANZ is an independent provider of information, research, materials testing and consultancy services to the building and construction industry, with a predominant focus on the needs of New Zealand clients. The Durability Assessment Tool is an initiative to improve the breadth, completeness and cogency of durability information available to the local industry. In essence, it involves the compilation of a database of authoritative and independent durability and compatibility information that covers the building components and materials commonly used in residential construction. Ultimately it is anticipated that this will be delivered as an interactive web-based tool, with the potential to generate an audit trail for verification of compliance with the service life requirements of the NZBC. To succeed in this role, the database will serve both as a convenient 'roadmap' to existing Acceptable Solutions and as an actively evolving repository of new information and research, generated both at BRANZ and elsewhere.

The delivered tool is intended to be helpful to people with a wide range of knowledge and experience. Envisaged users include designers, statutory bodies, manufacturers and wholesalers, in addition to building science researchers.

3.1 Expected Outcomes

The Durability Assessment Tool is explicitly expected to provide the following benefits:

- A catalogue of existing durability information, including précis of, and references to, current Acceptable Solutions.
- A resource for the development of compliance methods for novel building materials and a means of exposing these ideas to the wider industry for critique.
- An explicit mapping of gaps in durability knowledge for current building materials and environments of use, serving to focus the direction of future research.
- A potential method to demonstrate the compliance of a building with the B2 Durability clause of the NZBC.

On a broader theme, the hope is to provide the industry with the appropriate knowledge, tools and confidence to produce durable buildings that meet or exceed their owner's expectations of

performance. Research by Nana [2003] has also demonstrated the potential for a substantial economic benefit from efficiency gains in building and construction due to a knowledge-rich construction sector.

The choice of a computer-driven database over printed material for delivery reflects both the need to manage the complexity of the collected information and the increased use of online resources for information seeking due to time scarcity. The integrated and commercially-neutral nature of the web tool is intended to counter two of the principal drawbacks of online research: sophisticated search engines such as Google are domain independent, which can lead to information overload – 1.4 million hits for 'building durability' – while portals specifically targeted to the construction industry are often compromised by their marketing focus.

3.2 Design

The current framework for communication with the database, shown in Fig. 3, has a modular structure designed to provide answers to three basic questions:

1. *What are the **Performance Requirements** of the NZBC for a nominated building component?* To begin, the user selects the building components of interest, either by keyword search or point & clicking on interactive graphical models of a house. The database returns the corresponding required service life. The durability demand for the component is a function of location and purpose, not composition, so this information can be easily updated with future revisions to the Code.

2. *Which **Verification Methods** are suitable to demonstrate the requisite performance?* At this point the user defines the composition of the component and the environment under which it has to perform. From this, the database returns an existing ***Acceptable Solution*** (typically existing national standards containing durability test methods), an appropriate ***in-house BRANZ verification method***, or the answer that ***no reliable service life prediction*** method is presently available. Fig. 4 shows an example screenshot. These two modules together (*Performance* and *Verification*) will determine B2 Durability clause compliance for the NZBC, and may be all some users (e.g. statutory authorities) are likely to be interested in.

3. *What **Specialist Advice** underlies this information?* This module provides the justification for the earlier material and a compendium of durability information organised under uniform tabbed subject headings, as shown in Fig. 5, which will grow and develop as new information such as research results become available. Gap analysis of this collection of information also generates the roadmap for future research.

The purpose of this structure is to provide a clear division between normative and informative material (i.e. Code requirements vs advice) and it simplifies modification in case of changes to mandated durable life. The structure also allows a single model to be maintained for multiple classes of user.

3.3 Project Status

With the preliminary design concept developed, current effort at BRANZ is focussed on populating the database with sufficient information to allow the most pressing gaps in current durability knowledge to be identified and prioritised. A working prototype of the interactive web tool is currently in development for distribution to interested parties to provide the feedback necessary to evolve improvements in the interface and functionality.

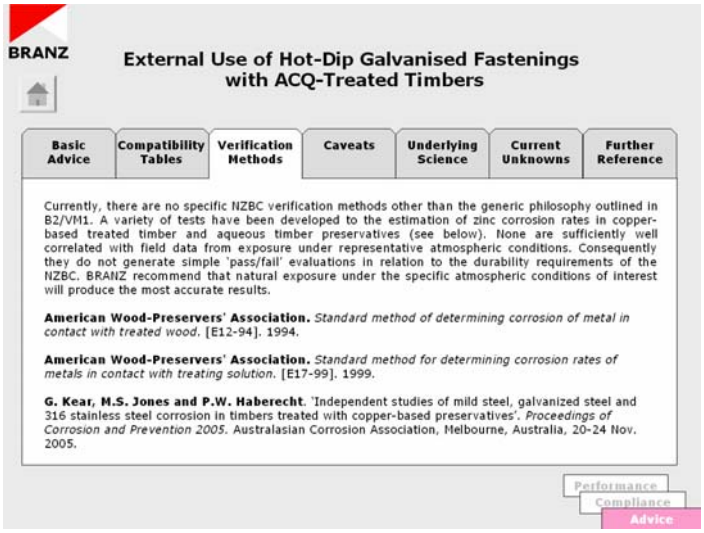

Figure 5. Example guidance from 'Advice' module for ascertaining durability of hot-dipped galvanised fastenings when used with ACQ-treated timber.

4 CONCLUSIONS

New Zealand has had a mandatory requirement for durability in its national Building Code since 1992. In theory this should have stimulated industry awareness of the issues behind achieving appropriate service life of building materials and foster an active interest in the development of standards and methodologies that could facilitate good durability design.

In practice, the transition from prescriptive to performance-based solutions has not been without its difficulties and the potential innovative and economic benefits have yet to be fully realised. New Zealand is a small country and there are few independent organisations with the technical resources and breadth of expertise to carry out rigorous assessments of materials durability. This is particularly evident when new, or composite, building systems are introduced to the market.

While based on sound scientific and engineering precepts, durability assessment remains as much art as science. This should change as the adoption of uniform assessment philosophies facilitates reliability-based service life prediction techniques. However, from a pragmatic perspective it is still essential that researchers, manufacturers and standards bodies continue to develop and refine predictive test methods for individual materials and their applications. It is hoped that the Durability Assessment Tool will prove a compelling initiative to collect these methods in a convenient and user-friendly form, promulgate them through the construction industry and stimulate the development of new ideas and techniques.

ABSTRACT

The strategically very important building and construction (B&C) industry is now facing a paradigm shift, from where the buildings and building products are no longer considered only as physical objects, but are rather seen as service arenas designed to facilitate management of life cycle performance and value adding services to meet changing end user needs. This paradigm shift, coupled with the drive for customer orientation, sustainability and ICT deployment is regarded as the key driver for change and improvement in the B&C sector. New manufacturing processes based on the IFC standards will create new and more efficient business processes, thus facilitating the construction sector's great potential for cost reduction and increased productivity and competitiveness. Focus on improving the integration of open IFC- and performance based standards for sustainable construction into business processes (A2) is thus the main objective of the project, addressing also the role of standards in developing sustainable building products and services, including sustainable housing (A1), as well as standards in public procurement processes.

The suite of IFC standards for shared information exchange has the potential to change the entire B&C industry. These standards form the foundation and structure for effective e-collaboration practices, B2B and B2C exchanges, and B2A/building permit and public tendering procedures.

1 INTRODUCTION

The "STAND-INN" project (integration of performance based building standards into business processes using IFC standards to enhance innovation and sustainable development) was developed for the Coordination Action call "Standards in support of innovative business solutions" FP6-2005-INNOV-8, 15/04/2005. STAND-INN addresses the "Action 1.2.1.7 - Standards in support of innovative business solutions". It focuses on its objective 2: "*To facilitate the integration of open standards into business processes", h*owever, addressing also the two other objectives of the call: "*To facilitate the integration of open standards into the design of new products and services*", and "*To stimulate innovation through reference to standards in public procurement*".

STAND-INN, which is scheduled for 26 months to end late 2008, addresses new manufacturing processes based on IFC standards and performance based standards for sustainable construction with objectives of creating new and more efficient business processes in the construction sector. This will facilitate the sector's great potential for cost reduction and increased productivity and competitiveness, furthering sustainable development.
The Consortium comprises 28 members from 11 European countries (Norway, Finland, France, UK, Sweden, Italy, Lithuania, Spain, Portugal, Germany, Belgium, and with 5 European– wide networks (IAI, CIB, ECCREDI, ENBRI, CEN), entailing major stakeholders from industry including SMEs, users, R&D and standardization as well as 2 partners from China.

The work plan entails developing guidance material for improved innovation with respect to the IFC based design of business processes (WP1-Action 1, with links to design and performance of building products (WP2 -Action 2), -to sustainable housing (WP3-Action 1 and 2), and public procurement (WP4-Action3), as well as carrying out a series of work-shops on the themes (WP5) and developing handbooks on "best –practice" and pilots (WP6), and policy recommendations to enhance innovation (WP7). Some results will be exhibited in this paper.

2 STATE OF THE ART AND DRIVERS FOR CHANGE

The construction sector is strategically important for Europe, providing the buildings and infrastructure on which all other industries, and public bodies, depend. The sector employs more people than any other industrial sector, but because most firms in the sector are small and medium-sized enterprises (SMEs), its contribution to European GDP and its importance for the overall economic performance is often not fully recognized. In all it has been estimated that 26 million workers in the EU-15 depend on the construction sector, comprising 2,5 million enterprises (97% SMEs) and an investment of € 910 billion (10%of GDP) (ECTP 2005a).

This sector is now facing a paradigm shift, moving from a situation where the building and building products are considered as physical objects to one where the built assets are service arenas designed to supply and manage a set of environmental and other functional performance services throughout its total life-cycle with changing end user needs. It shifts attention from the traditional focus on hand-over and the defects period, to the years beyond-whether or not the supplier has (e.g. through a public private partnership) a commercial interest in that performance. This paradigm shift, coupled with the drive for customer orientation, sustainability and ICT deployment is regarded as the key drivers for change and improvement in the B&C sector. (ECTP 2005b, c)

2.1 An Inconvenient Truth-an Unsustainable Construction Sector

Global mean temperature coincides with CO2 content in atmosphere. The CO2 content is way above any former level, and it is skyrocketing, causing climate change with disastrous consequences for mankind (IPCC 2007).
The construction sector has a key influence on sustainability (ECTP 2005a). Its environmental impact is high because

- Buildings and the built environment uses 50% of the materials taken from the Earth's crust.
- During their life cycles buildings comprise the largest energy consuming sector with the almost half of the primary energy used and generating about 40 % of all greenhouse gas emissions in Europe.
- Waste produced from building materials are the source of 25 % of all waste generated.
- The building sector also has a major economic impact (10 % of the GDP of the EU).
- People spend almost 90 % of their time inside buildings.

This is why the industry - led ECTP so firmly and consistently states "becoming sustainable" as part of their vision (ECTP 2005a) and key targets for their Strategic Research Agenda (ECTP 2005b).

A key success factor towards the adoption of sustainability-related innovative foundations (i.e., standards, concepts, products, and process) in the Construction sector is that the knowledge and information is made available for decision makers and other stakeholders involved in the value and supply chain. It is necessary to provide new information-intensive services in order to successfully bring the knowledge produced (along the process) into its intended application.

Here is where the IFC model comes into play, since it targets the information used (in theory by all actors involved in the building process) to represent a construction product during its entire life cycle.

2.2 Customer Orientation And ICT Driven Interoperability Of The Building Process

The inefficiency and lack of information interoperability of the building process is a major cause for high production cost, building damages, etc. A NIST US report (2004) states "Inadequate interoperability in the US Capital Facilities industry costs approximately $ 15.8 billion annually, representing 2% of industry revenue".

Thus the construction process needs to decrease production costs and increase productivity. It must also change from a supply to demand/user driven focus across the building life cycle (ECTP 2005a,b). To achieve these goals requires business process innovation and a realisation that ICT based building standards provide the ' glue ' which can dramatically improve the performance of the value chains.

The process for change is driven by the International Alliance for Interoperability (IAI), which has more than 600 members across the world (www.iai-international.org). The IAI, supports, or oversees the *whole life cycle of developing and deploying integrated project working using interoperable solutions* (Liebich 2007). This has been IAI's reason for establishing the new branding buildingSmart, with the broad scope to support the whole adaptation process:
"buildingSMART is integrated project working and value-based life cycle management using Building Information Modelling and IFCs"

3 BUILDINGSMART-DEVELOPMENT AND IMPLEMENTATION OF IFC COMPATIBLE BIM

buildingSMART is the principal standard for information exchange and sharing across the whole construction life cycle, which is now being incorporated into major software products and the use of which is now being required by an increasing number of major clients throughout the world. It covers all the international specifications (BIM, IFC,IFD,IDM,etc) and technologies developed to meet the vision of IAI. Its adoption can bring about major changes/improvements in business processes for the

whole value chain. By providing a facility for shared information, it can provide a catalyst for the change from a contractor/supply driven industry to a more user/demand driven industry, Fig. 1

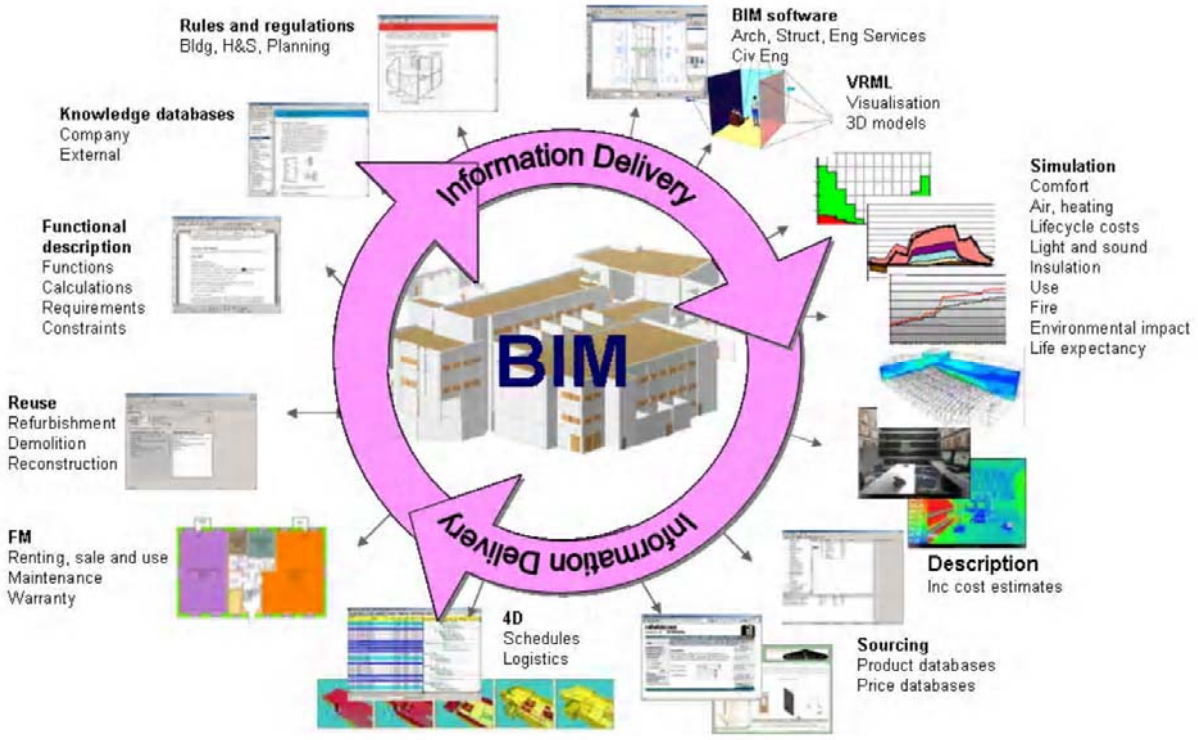

Figure 1. The information delivery over the building life-cycle.

3.1 BIM

Building Information Modelling (BIM) is a new and promising building design and documentation methodology. BIM is the term applied to the creation and use of coordinated, consistent, computable information about a building project in design, in construction and in building operation and management. The term has been adopted recently to replace ‘ Computer Aided Design ’ (CAD) so that the emphasis is placed on ‘ information ’ and ‘ modelling ’ . BIM is sometimes referred to as a ‘ virtual building ’ because it can be used as a simulation of the real building.

A ‘ BIM ’ is the collection of objects that describe a building. BIM software applications have been developed using ‘ object oriented ’ methods. This means that they work with ‘ objects ’ . An object represents an instance of ‘ things ’ used in building construction, that can include:

- - physical components (e.g. doors, windows, pipes, valves, beams, light fittings etc.),
- - spaces (including rooms, building storeys, buildings, sites and other external spaces),
- - processes undertaken during design, construction and operation/maintenance,
- - people and organizations involved,
- - relationships that exist between objects.

Within BIM, the geometric representation of an object is an attribute. This differs from CAD which works with geometry items like lines, arcs and circles from which geometric representations of objects can be created and stored.

BIM covers geometry, spatial relationships, geographic information, quantities and properties of building components (for example manufacturers' details). It can be used to store the results of

analysis and modeling of engineering requirements. BIM can be used to demonstrate the entire building lifecycle including the processes of construction and facility operation. Quantities and shared properties of materials can easily be extracted. Scopes of work can be isolated and defined. Systems, assemblies, and sequences are able to be shown in a relative scale with the entire facility or group of facilities.

Increasingly, BIM can also be used to support knowledge rich applications including:

- Sustainability analyses including building assessment (such as LEED, BREEAM), energy performance declaration, life cycle costing,etc
- Requirements checking through ensuring that requirements expressed by a client are met by the design or that design requirements are met by construction.
- Checking designs against statutory requirements like building codes and regulation.

A BIM is a repository for digital, three-dimensional information and data generated by the design process and simulations—it ' s the design, fabrication information, erection instructions, and project management logistics in one database. The BIM will exist for the life of a building and can be used to manage the client ' s asset.

An integrated BIM stores all the building relevant information during the total life-cycle of the building and provides access to that information for participating members.

A recent study by EraBuild shows that industry is gradually starting to use the concept of BIM, and that architects are the most adaptive to the new technology (Kiviniemi et al 2007). The major construction companies in the Nordic countries have all adopted BIM technology, but so far to a lesser extent the IFC compatible BIM.

3.2 IFC, IFD and IDM

In general, to enable interoperable flow and sharing of information contributing to the creation of a Product Model, three specifications/standardisations must be in place. These are;

- An exchange format, defining HOW to share the information. IFC (Industry Foundation Classes) (an ISO standard in development) is such a specification.
- A reference library, to define WHAT information we are sharing. The IFD Library (International Framework for Dictionaries) (an implementation of ISO 12006-3) serves this purpose.
- Information requirements, defining WHICH information to share WHEN. The IDM (Information Delivery Maual) approach (also an ISO standard in development) forms that specification.

This is the triangle of standards forming the basis for the product modelling that has been developed and implemented in other major industries, see Fig. 2. Now the AEC industry is at the core of change, and this change will facilitate the needed compliance with sustainability, user requirements etc

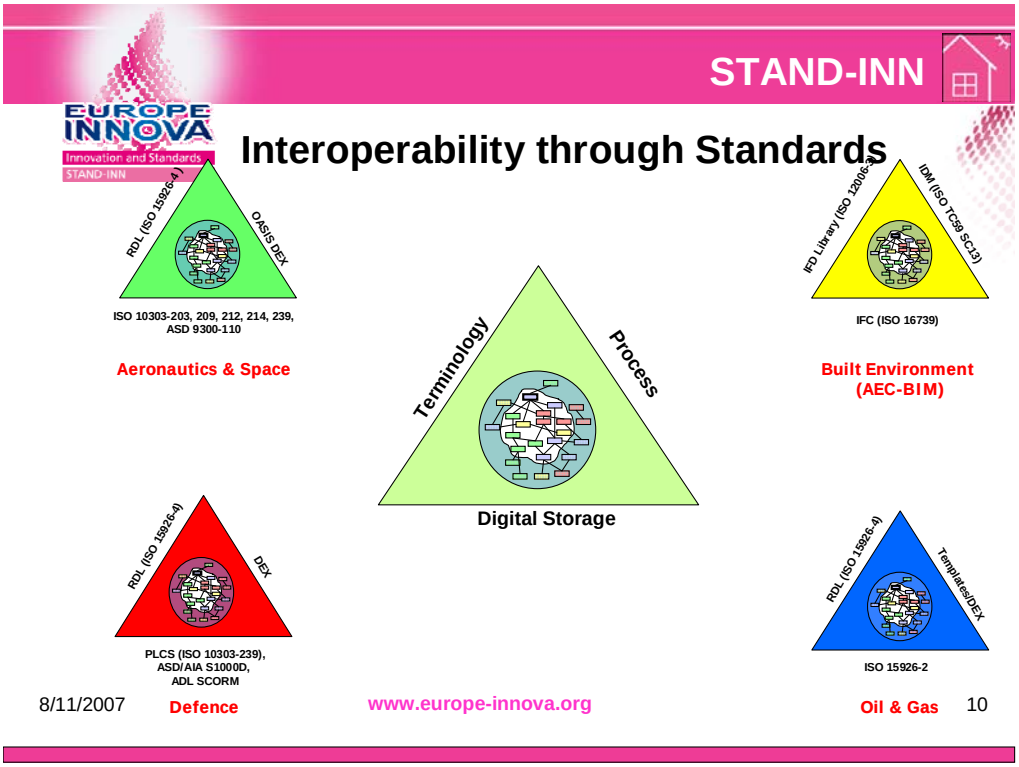

Figure 2. The interoperability triangle of standards for major industries

The development, maintenace, implementation and dissemination of IFC and IFC enabled products is part of the buildingSmart initiative of the IAI. IFCs are the result of an industry consensus building process. They contain common agreements on the content, structure and constrains of information to be used and exchanged by several participants in construction and FM projects using different software applications. The result is a single, integrated schema (or data model [1]) representing the common exchange requirements among software applications used in construction and FM specific processes.

The term IFC is used for the underlying schema and for data content structured according to the schema. The IFC schema is an open, publicly available and industry-wide standard for structuring and exchanging construction and FM specific information among software applications. The latest IFC extension release, IFC2x3, was published in year 2006.

In its simplest form IFD is a mechanism that allows for creation of multilingual dictionaries or ontologies, and would probably better have been named International framework for Ontologies. The name is used both for the IFD library and for the organization running and maintaining it. The model itself is pretty simple seen from a implementers view but it is proven to be very flexible and can therefore result in several different implementations. The structure of IFD is given in ISO 12006-3, that was formally published in April, 2007, and is a result of many years of standardization work by the ISO TC59/SC 13/WG 6 work group. Populating the IFD library is now a core activity. More info available at http://dev.IFD-library.org

The purpose of IDM is to define the information that one AEC/FM industry user needs to provide to one (or more) other AEC/FM industry users to support their work. This means that IDM delivers information at specific points in the business process. As well as defining the information that is needed, IDM also includes the idea of a 'Manual'. That is, it gives guidance to users on providing the information both at a general level and specifically for individual software applications. The aim is to

1 The term "schema" is used in order to avoid the confusion between data model and project model.

capture all of the information for all business requirements for the whole building lifecycle and for all building project participants. More info is avaialble at http://idm.buildingsmart.com .

Basic information and state of the arts reports about BIM, IFC; IFD and IDM's have been developed by the STAND-INN project (Wix et al 2007)

4 SUSTAINABILITY ASPECTS AND IFC SUPPORT

In order to assess the integrated performance of buildings it is necessary to regard a building as a whole with required performance and functions to fulfill. One of the objectives of STAND-INN is to integrate environmental indicators with BIM/IFC following the scheme of things presented in international standards dealing with environmental aspects of buildings.

Recently, CEN has established the standardisation work 'Sustainability of construction works' under the mandate 350 (CEN 2005), building also on the key features of all relevant ISO standards in their drafting. The standards will describe a harmonized methodology for assessment of environmental performance of buildings and life cycle cost performance of buildings, as well as the quantifiable performance aspects of health and comfort of buildings.

The primary standards and aspects of sustainability are considered in WP2, (Trinius 2007), and the aspects cover Economic, Environmental, and Social impacts as well as the Long Term Performance (related to Reusability of buildings, Adaptability to changes, and Service Life Planning), see Fig. 3.

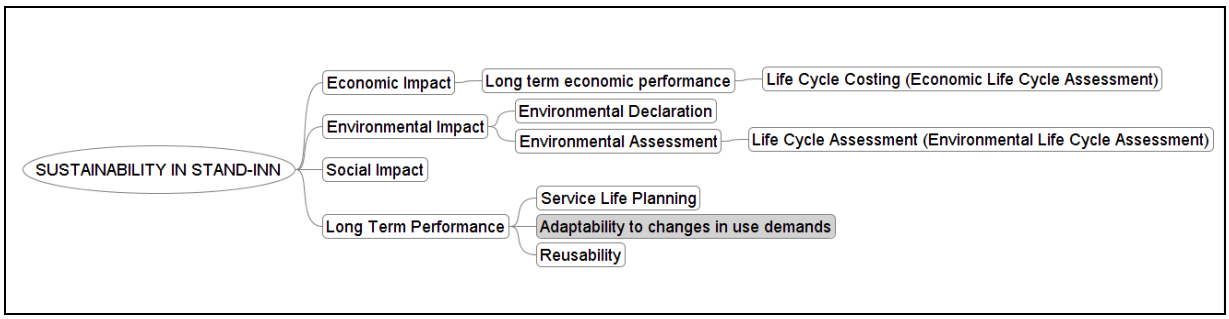

Figure 3. STAND-INN taxonomy for sustainability

The information needed for sustainable building design and construction is not only data in the form of 'environmental indicators' but also data about building site, local environmental conditions, technical performance of building components and systems etc., knowledge about the behaviour of building components in alternative conditions, information about needed measures of care and maintenance etc.

All these areas are important. The aspects and some of their contents is presented in different phases of the building process, as shown in Fig. 4. Even though the BIMs are presented here as separate models, it must be noted that the information exchange standard ensures the interoperability between different information models. In practice, some of these models may be as one model.

	REQUIRED	DESIGNED	CONSTRUCTED	DELIVERED	ACHIEVED
PERFORMANCE IN USE	• user requirements • desired performance in use	• designed technical solutions • estimated performance	• constructed building	• validated conformity	• user satisfaction • performance in use
ENVIRONMENTAL IMPACTS	• targeted environmental impacts over the life cycle	• estimated environmental impacts over the life cycle	• environmental impacts during construction	• estimated environmental impacts in use	• environmental impacts of building and its use
ECONOMIC IMPACTS	• targeted whole life costs • targeted business benefits and value of the facility	• estimated life cycle costs	• construction costs	• estimated running costs	• running, maintenance and refurbishment costs, recycling, reuse, demolition and waste disposal costs • value of facility
OTHER	• targeted social, cultural and institutional impacts		• construction safety • construction ethics		• social impacts in the neighbourhood • impacts to the cultural heritage

Figure 4. Innovative sustainable building and building information models.

Wix et al (2007) collected instances on the usage of BIM/CAD and application software for sustainability on projects to determine the extent of use, successes obtained and possible potentials. Sustainability applications fell into two groups. The first group includes those applications that are easily amenable to BIM integration whilst the second group includes those applications whose benefit has yet to be fully realized.

Energy performance declaration and life cycle costing fall into the first category as these can be more easily understood in the context of current software use. Environmental impact, service life and other applications fall into the second category. But this second group of applications can offer major benefit as is shown by the best practice examples.

6 CONCLUSIONS AND RECOMMENDATIONS

Some STAND-INN conclusions so far

1. The IFC and use of BIM have great potential for value creation during the whole life of buildings at least in the following areas
   - Focus on customer and end-user requirements and sustainability within the building process and life cycle phases
   - Increasing transparency in the decision-making process and re-engineering the building process with new business opportunities for new and existing actors
   - Cost saving to all actors and a better project economy
   - Improved possibilities for early stage analysis about: best practice design, construction cost, energy consumptions, environmental impacts, lifecycle cost, performance in use, flexibility, adaptability, indoor climate, usability and maintainability
   - A comprehensive and common international knowledge model database with standardized ICT tools, objects and communication rules and available best practices examples.
2. Standards act as catalyst for innovation and the integration of sustainability standards onto the suite of open IFC standards facilitating BIM, will greatly enhance the construction sector's need towards sustainable development.

3. Government (public procurement) plays an essential and decisive part in this tranformation of the construction sector, acting as the policy maker, regulator and by far the biggest customer, thus as the key player driving innovation and sustainable development.

A Review of the European Commission Construction Products Directive Reaction-to-fire and Fire Resistance Classification of Building Materials and Components

Nuri Serteser [1]
Mustafa Özgünler [2]

T 45

ABSTRACT

Fire is one of the most important dangers both buildings and its users. All the livable buildings have to be resistant to fire at some degree and have to provide evacuation of the people safely till the fire brigade intervention. It needs to be stand along with the fire as a whole with all the parts constituting it. At the same time the materials of the building have to be selected amongst non-flammables or if not it have to be not releasing smoke and poisoning gases.

Each country evaluates the fire performance of materials and construction products according to their own standards and regulations. This diversity creates different standards and evaluation criteria of materials amongst the members of European Community endeavoring like a unique state in Europe. The Construction Products Directive (CPD-89/106/EEC) that has been applied in accordance with the approximation of laws and has been accepted for free trade of the construction products amongst the member states of European Union deals with the essential provisions must be satisfied by the construction products and the related matters. The classification of the reaction-to-fire performance of construction products as explained in Commission Decision 2003/632/EC and classification of the resistance-to-fire performance of construction products, construction works and parts as explained in Commission Decision 2003/629/EC has become operative by issuing a notification of Turkish Ministry of Public Works. The same classification system has also adopted by Institute of Turkish Standards (TSE) and has been issued as TS EN 13501-1.

1 INTRODUCTION

New building materials and elements that have a great interrelationship with construction industry are discovered in everyday. By the developing technology new materials are widely used in design and construction of nowadays buildings by designers. Lots of the sectors have an interconnection with construction sector and depending on the investment activity and the economic stabilization of the governments these are affected in a good or bad proportion. According to the economical data of some new members of EU, Poland, Czech Republic and Hungary alone, the turnover was 38 billion Euro in 2003 and the market is estimated to be growing at an average rate of +4.2% per year as explained official web site of EU [EC 2008].

Although the quality and performances of the building materials in production and in application are taken under guarantee by the legislations of the each EU member countries individually, each country has different standards and test procedures for the building materials. This has also affected free trade of the materials amongst EU members. In order to eliminate the legal differences like customs taxes, restriction of amounts and the technical differences like standards and classification systems of materials European Free Trade Association (EFTA) has attempted and new arrangements has been constituted enclosing the member countries [Demirel & Altındaş 2007], [Demirel & Altındaş 2006]. The importance of harmonization on the technical arrangements, standards and conformity assessment has been emphasized and common arrangements in 23 sectors have been adopted for the free trade of reliable matters amongst the member countries [Diz 2007].

CEN has issued Council Directive 89/106/EEC of December 21'st 1988 on the approximation of laws, regulations and administrative provisions of the member states relating to construction products [EC 2008]. As a candidate member of EU this directive has been accepted by our country's Ministry of Public Works and related to the execution of Commission decision of 2003/632/EEC amending decision 2000/147/EC as regards the classification of the reaction-to-fire performance of construction products and Commission decision of 2003/629/EC amending decision 2000/367/EC as regards the classification of the resistance-to-fire performance of construction products, construction works and parts has been published in the official gazette of Turkish Republic [TÜYAK 2005].

2 COUNCIL DIRECTIVE 89/106/EEC

The materials produced have to satisfy the procedures of the harmonized standards of European Commission. In the absence of harmonized standards, European Technical Approval (ETA) is used for the conformity procedures of the materials. In the absence of both of them the local standards have to be obeyed to answer the basic requirements [TMPW 2008].

The basic requirements are explained in interpretative documents. The interpretative documents explain the basic requirements of the directive. These are mentioned in turn as follows: mechanical resistance and stability; safety in case of fire; hygiene, health and the environment; safety in use; protection against noise; energy economy and heat retention.

According to the sub group of the directive "safety in case of fire" a construction works must be design and built such as:

- the load-bearing capacity of the construction lasts for a pre-determined time,
- the production of smoke and spread of fire is limited along with working,
- the spread of fire to the neighboring buildings is limited,
- occupants or the users of the construction can leave alone or can be evacuated securely,
- the safety team is in secure when they are working inside the construction [EC 2008].

The behavior of the material against fire is very important and sometimes has a vital effect when it's used in building construction. The features of a building material in a fire like heat contribution, combustibility, flame spread, smoke and poisoning gases and droplet formation has to be known

before using it on the design. Under certain temperature and pressure conditions the building materials are tested in an accredited laboratory and according to the behavior on the fire the materials classified. The purpose of reaction to fire testing is to determine whether a material fuels a fire. The EU reaction to fire evaluation criteria are the material's ignitability, rate of heat release, rate of spread of flame, rate of smoke production, toxic gases, flaming droplets/particles and/or a combination of these safety aspects.

DIN 4102 standard for the classification of the building and isolation materials has been widely used in the Fire Protection Regulation of Turkey, 2002. The materials has been divided mainly two main groups (A [non combustible] and B [inflammable]), the group A materials has been divided into two sub-groups (A1 [non-combustible building materials without portions of inflammable building materials] and A2 [non-combustible building materials with portions of inflammable building materials]) and the group B materials has been divided into three sub-groups (B1 [flame resistant building materials], B2 [normal inflammable building materials] and B3 [light inflammable building materials]) according to the fire test results [TÜYAK 2005].

3 NEW CLASSIFICATION OF BUILDING MATERIALS

The new building material standards and test procedures that will be valid throughout EU members against fire have been constituted by taking the local fire regulations into account. The new building material classification has been issued in Commission decision of 2003/632/EEC amending decision 2000/147/EC as regards the classification of the reaction-to-fire performance of construction products and has been accepted as a Turkish Standard, TS EN 13501-1. EN 13501-1 provides the reaction to fire classification procedure for all construction products, including products incorporated within building elements. Products are considered in relation to their end use application. This document applies to three categories, which are treated separately in this standard: construction products, excluding floorings and linear pipe thermal insulation products; floorings; linear pipe thermal insulation products. The symbols and classes of reaction to fire performance for construction products excluding floorings can be seen in Table 1 below [CONSLEG 2003], [TSE 2007]. The only building materials can carry CE mark if it is appropriate for the classification conditions of reaction-to-fire for the materials. In another words CE marking on a product indicates to all authorities that the product is in compliance with the essential health and safety requirements of all directives that apply to the product.

Symbols

ΔT	temperature rise
Δm	mass loss
t_f	duration of flaming
PCS	gross calorific potential
FIGRA	fire growth rate
THR_{600s}	total heat release
LFS	lateral flame spread
SMOGRA	smoke growth rate
TSP_{600s}	total smoke production
Fs	flame spread

Table 1. Classes of reaction to fire performance for construction products excluding floorings [CONSLEG 2003], [TSE 2007]

Class	Test method(s)	Classification criteria	Additional classification
A1	EN ISO 1182 ([1]) and	$\Delta T \leq 30$ ºC; and $\Delta m \leq 50$ %; and $t_f = 0$ (i.e. no sustained flaming)	—
	EN ISO 1716	PCS $\leq$ 2,0 MJ.kg^{-1} ([1]) and PCS $\leq$ 2,0 MJ.kg^{-1} ([2]) ([2a]) and PCS $\leq$ 1,4 MJ.m^{-2} ([3]) and PCS $\leq$ 2,0 MJ.kg^{-1} ([4])	—
A2	EN ISO 1182 ([1]) or	$\Delta T \leq 50$ ºC and $\Delta m \leq 50$ % and $t_f \leq 20$s	—
	EN ISO 1716 and	PCS $\leq$ 3,0 MJ.kg^{-1} ([1]) and PCS $\leq$ 4,0 MJ.m^{-2} ([2]) and PCS $\leq$ 4,0 MJ.m^{-2} ([3]) and PCS $\leq$ 3,0 MJ.kg^{-1} ([4])	—
	EN 13823 (SBI)	FIGRA $\leq$ 120 W.s^{-1} and LFS < edge of specimen and $THR_{600s} \leq$ 7,5 MJ	Smoke production ([5]), and flaming droplets/ particles ([6])
B	EN 13823 (SBI) and	FIGRA $\leq$ 120 W.s^{-1} and LFS < edge of specimen and $THR_{600s} \leq$ 7,5 MJ	Smoke production ([5]), and flaming droplets/ particles ([6])
	EN ISO 11925-2 ([8]) *Exposure =30s*	Fs $\leq$ 150 mm within 60s	
C	EN 13823 (SBI) and	FIGRA $\leq$ 250 W.s^{-1} and LFS < edge of specimen and $THR_{600s} \leq$ 15 MJ	Smoke production ([5]), and flaming droplets/ particles ([6])
	EN ISO 11925-2 ([8]): *Exposure =30s*	Fs $\leq$ 150 mm within 60s	
D	EN 13823 (SBI) and	FIGRA $\leq$ 750 W.s^{-1}	Smoke production ([5]), and flaming droplets/ particles ([6])
	EN ISO 11925-2 ([8]): *Exposure =30s*	Fs $\leq$ 150 mm within 60s	
E	EN ISO 11925-2 ([8]) *Exposure =15s*	Fs $\leq$ 150 mm within 20s	Flaming droplets/particles ([7])
F	No performance determined		

(*) The treatment of some families of products, e.g. linear products (pipes, ducts, cables, etc.), is still under review and may necessitate an amendment to this decision.
(1) For homogeneous products and substantial components of non-homogeneous products.
(2) For any external non-substantial component of non-homogeneous products.
(2a) Alternatively, any external non-substantial component having a PCS $\leq$ 2,0 MJ.m^{-2}, provided that the product satisfies the following criteria of EN 13823 (SBI): FIGRA $\leq$ 20 W.s^{-1}; and LFS < edge of specimen, and ►**C1** THR_{600s} ◄ $\leq$ 4,0 MJ and s1 and d0.
(3) For any internal non-substantial component of non-homogeneous products.
(4) For the product asa whole.
(5) s1 = SMOGRA $\leq$ 30m^2.s^{-2} and ►**C1** TSP_{600s} ◄ $\leq$ 50m^2; s^2 = SMOGRA $\leq$ 180m^2.s^{-2} and $TSP_{600s} \leq$ 200m^2; s3 = not s1 or s2.
(6) d0 = No flaming droplets/particles in EN 13823 (SBI) within 600s; d1 = no flaming droplets/particles persisting longer than 10s in EN 13823 (SBI) within 600s; d2 = not d0 not d1; ignition of the paper in EN ISO 11925-2 results in a d2 classification. 2000D0147 — EN — 03.09.2003 — 001.001 — 5
▼**B**
(7) Pass = no ignition of the paper (no classification); fail = ignition of the paper (d2 classification).
(8) Under conditions of surface flame attack and, if appropriate to the end-use application of the product, edge flame attack.

In the European standardization system, building products are divided to seven classes on the basis of their reaction-to-fire properties. There among other things additionally the measure for the smoke development and burning dripping off enter classification also. The description of building products classifications excluding floorings can be seen in Table 2 [Innofirewood 2008].

Table 2. The classification of building products description excluding floorings [Innofirewood 2008]

Class	Performance description	Examples of products
A1	No contribution to fire	Product of natural stone, concrete, bricks, ceramics, glass steel and many metallic product
A2	"	Products similar to those of class A1, including small amounts of organic compounds
B	Very limited contribution to fire	Gypsum boards with different (thin) surface linings, fire retardant wood product
C	Limited contribution to fire	Phenolic foam, gypsum boards with different surface linings (thicker than Class B)
D	Acceptable contribution to fire	Wood product with thickness ≥ about 10 mm and density ≥ about 400 kg/m^3 (depending on end use)
E	"	Low density fireboard, plastic based insulation products
F	No performance requirements	Product not tested (no requirements)

The smoke development features of the products are represented with s1 (very limited smoke production), s2 (limited smoke production) and s3 (not satisfy the demands of s1 and s2) and dripping features of the products are symbolized with d0 (no flaming droplets or particles), d1 (no flaming droplets or particles persist) and d2 (not satisfy the demands of d0 and d1) according to the amount of production. The classification of floorings and linear pipe thermal insulation products are represented almost the same like Table 1 with the exception; the flooring products are named with subscript "fl" and the others are named with subscript "L" by the name of the class (like C_{fl}, B_L). So the building products are called with the additional symbols like B-s2, d1, D-s1, d2. The additional symbols are restricted with s1 and s2 just in the floorings product classification for fire.

The roof materials and its coverings are also classified according to the reaction-to-fire by CEN. Commission decision of 2005/823/EC amending decision 2001/671/EC as regards the classification of the external fire performances of roofs and roof coverings has been printed and according to the four test methods, four product classes have been constituted. The description of each class can be seen in Table 3 below [CD 2001], [CD 2005].

Table 3. Description of roof product classes for external fire performances [CD 2001], [CD 2005]

Class	Performance description
B_{ROOF} (t1)	Burning brand alone
F_{ROOF} (t1)	
B_{ROOF} (t2)	Burning brand + wind
F_{ROOF} (t2)	
B_{ROOF} (t3)	Burning brand + wind + radiation
C_{ROOF} (t3)	
D_{ROOF} (t3)	
F_{ROOF} (t3)	
B_{ROOF} (t4)	Burning brand + wind + supplementary radiant heat
C_{ROOF} (t4)	
D_{ROOF} (t4)	
E_{ROOF} (t4)	
F_{ROOF} (t4)	

4 NEW CLASSIFICATION OF BUILDING ELEMENTS

The building elements have to be resistant to fire. This is important for evacuating the building users safely and also important to give enough time for intervention of fire brigade. A fire resistant building element or product must have the features of stability, integrity and isolation. These features of a

building element are examined in accredited laboratories under certain heat and pressure conditions. The test procedures of TS 1263, TS 4065 and DIN 4102 are obeyed in our country and the building elements regarding fire resistance are classified into five categories according to the test results. The fire resistance categories of building elements can be viewed in Table 4 [TÜYAK 2005].

Table 4. Fire resistance categories of building elements [TÜYAK 2005]

Class	Fire resistance (min)
F30	30-59
F60	60-89
F90	90-119
F120	120-179
F180	above 180

Commission decision of 2003/629/EC amending decision 2000/367/EC as regards the classification of the resistance-to-fire performance of construction products has been issued in official journal of the European Union. The classifications are expressed in tables for the separating, load bearing building elements and the related materials, materials used in ventilation systems, services, materials used for controlling smoke and heat. A sample table of the building element resistant-to-fire classification and the symbols used can be seen in Table 5 below [CD 2000], [CD 2003].

Symbols

R	Load-bearing capacity
E	Integrity
I	Insulation
W	Radiation
M	Mechanical action
C	Self-closing
S	Smoke leakage
P or PH	Continuity of power and/ or signal supply
G	Soot fire resistance
K	Fire protection ability
D	Stability duration under constant temperature
DH	Stability duration under the standard time-temperature curve
F	Functionality of powered smoke and heat ventilators
B	Functionality of natural smoke and heat ventilators

Table 5. Load-bearing elements without a fire separating function [CD 2000], [CD 2003]

Applies to	walls, floors, roofs, beams, columns, balconies, stairs, walkways									
Standard(s)	EN 13501-2; EN 1365-1,2,3,4,5,6; EN 1992-1.2; EN 1993-1.2; EN 1994- 1.2; EN 1995-1.2; EN 1996-1.2; EN 1999-1.2									
Classification : -										
R	15	20	30	45	60	90	120	180	240	360
Notes	-									

The symbols are used alone or two, three of together with the time in minutes according to the building element type. Time intervals must be 15, 20, 30, 45, 60, 90, 120, 180, 240 or 360 minutes. This represents the total or each criterion's minimum need for fire resistance (EI60, REI 90 etc).

5 CONCLUSION

Council Directive 89/106/EEC of December 21'st 1988 on the approximation of laws, regulations and administrative provisions of the member states relating to construction products has brought new arrangements in many sectors. Especially newly classification of building materials and products related to reaction-to-fire has changed radically by the desicion. After issuing the standard of EN13501-1 that has been adopted and issued as a local standard named TS EN 13501-1.

Although DIN 4102 standards and test methods has been adopted for the classification of building materials reaction-to-fire and fire resistive building elements in Fire Protection Regulation of Turkey 2002, the new classifications and test methods of CEN have been accepted in the latest version of fire regulation and has been announced in December 19'th 2007. The new reaction-to-fire classification of building materials has been arranged again according to the TS EN 13501-1 and has been shown in a table in annex part of the regulation. The new building material classification for reaction-to-fire except floorings can be seen in Table 6 below [TYKY 2007].

Table 6. The classification of building materials for reaction-to-fire except floorings according to TS EN 13501-1 [TYKY 2007]

Class	**TS EN 13501-1**
Non-combustible	A1
Non-combustible building materials with portions of inflammable building materials	A2-s1,d0
Flame resistant	B, C-s1, d0
	A2-s2, d0 A2, B, C-s3, d0
	A2, B, C-s1, d1 A2, B, C-s1, d2
(at least)	A2, B, C-s3, d2
Normal flammable	D, s1, d0 D, s2, d0 D, s3, d0 E
	D, s1, d2 D, s2, d2 D, s3, d2
(at least)	E-d2
Light flammable	F

Our country moving along to being a "real" member country of EU has performed very important development for harmonization of laws, standards and conformity assessment procedures yet. But the most development can be achieved by the execution and implementation of this rules and standards in our daily lifes.

How Workmanship Should Be Taken Into Account in Service Life Planning

Appu Haapio [1]
Pertti Viitaniemi [2]

T45

ABSTRACT

The aim of this study is to analyse how workmanship should be included and taken into account in service life planning. In service life prediction, buildings and building components are assumed to meet certain quality requirements. According to the standard ISO 15686-1, if the skills and levels of workmanship do not meet the manufacturer's recommendation or the codes' workmanship standards, their effect on service life should be considered. However, the standard does not say how.

The quality of the construction influences the maintenance of the building, the life cycle cost, and also the environmental impact. Therefore, the skills and levels of workmanship should be emphasised more in service life planning.

1 INTRODUCTION

The service lives of different building products and components are different. According to the standard ISO 15686-1 [2000], the service life of the inaccessible parts should be the same as the service life of the building. In another words, the service life of the accessible parts can be shorter than the service life of the building. If the service life of a component is shorter than the building's service life, the component needs replacement. As an example, if the design life (intended service life) of a building is 150 years, the suggested design lives are [ISO 2000]:

- 150 years for inaccessible or structural components
- 100 years for components where replacement is expensive or difficult
- 40 years for major replaceable components
- 25 years for building services
- (easy-to-replace components may have design lives of 3 or 6 years)

In service life prediction, building materials and components are assumed to meet certain requirements. If the skills and levels of workmanship do not meet the manufacturer's recommendation or the codes' workmanship standards, their effect on service life should be considered, according to the standard ISO 15686-1. However, the standard does not say how.

1.1 Aim of the Study

The aim of this study is to analyse how workmanship should be included and taken into account in service life planning. The skills and levels of workmanship should be emphasised more, since the quality of the construction influences the maintenance of the construction, the life cycle costs, and also the environmental impact. Legal responsibilities have occasionally been referred to in this study only to give a wider prospect. However, they are not the focus of this study.

1.2 Content of the Study

In the first section, the research area is briefly introduced, the aim of the study is stated, and the content of this study is listed. In the second section, the focus is on the agents affecting the service life. In the third section, the skills and levels of workmanship are discussed. In the fourth section, the future of the assessment of the skills and levels of the workmanship is speculated.

2 AGENTS AFFECTING THE SERVICE LIFE

Service life is '*the period of time after installation during which a building or its part meet or exceed the performance requirements*' [ISO 2000, ISO 2004]. In forecasting the service life of a building (or a component), the objective is to establish whether it can be expected to exceed the required design life with adequate reliability. [ISO 2000] In forecasting the service life, there are critical issues which need to be taken into consideration:

- Agents of degradation
- Dose and intensity
- Combination of agents

2.1 Agents of Degradation

There are several agents, which affect the service life of building materials and components during their lifetime. In the standard ISO 15686-1 Annex C (taken from ISO 6241), these agents of degradation are classified by their nature:

- Mechanical agents (i.e. snow loads, vibration from traffic)
- Electromagnetic agents (i.e. solar / UV)
- Thermal agents (i.e. heat, fire)
- Chemical agents (i.e. air humidity, ground water, bird droppings)
- Biological agents (i.e. bacteria, moulds, termites) [ISO 2000]

After identifying the agents, it is important to assess the dose and the intensity of the agents. They are often evaluated over a reference period of time, e.g. a year. Westberg *et al.* [2001] point out the degradation agents can be considered one by one, but also the combination has to be taken into consideration. One agent may create a favourable environment for another agent. Therefore, the recognition of the combination is vital.

The durability of building materials relates closely to the service life of building materials. There are several studies on the durability of building materials. Van Acker *et al*. [2003], for example, tested the biological durability of wood in relation to end-use. Kamdem *et al*. [2006] studied the durability of heat-treated wood, and Saraswathy & Song [2007] studied the durability of concrete. However, as Brischke *et al.* [2006] point out, durability and service life are not synonyms. Service life is '*the period of time after installation during which a building or its part meet or exceed the performance requirements'*, and performance is '*the qualitative level of a critical property at any point of time considered'* [ISO 2000]. Durability is a property leading to a certain service life, but it is influenced by different agents in service. [Brischke *et al.* 2006]

2.2 Pre-İnstallation Factors İnfluencing the Service Life

There are several factors, which may affect the service life of building materials, or components, even before their service life begins, before they become a part of the building. This important subject area has been less addressed in research. In this study, these factors are called pre-installation factors. The window is used as an example here.

- The design of a window might be faulty. For example, a vertically low and horizontally wide window is challenging for the hinges if they are on the vertical side of the window frame. Or there might be mistakes in the measurement – the window frame is too small for the window opening.
- The quality of the raw materials might not meet the requirements. The moisture content of the wood might be too high, or there might be too many knots in the wood material.
- The manufacturing processes might cause damage to the window frames. The hinges and the fasteners might not be installed properly. The insulating tape might be tightened too much in the corners.
- The components are not stored properly during the manufacturing processes or at the construction site. For example, an excessive moisture content of wooden frames during the manufacturing and installation may cause cracking of the frames later on. Furthermore, rough handling of the products may damage them; i.e. cracks on the window frames can expose them to moisture.

- The installation of the window might not meet the requirements. The moisture content of the surroundings of the window opening might be too high during the installation. Later on, the wooden window frames may crack. Also, the installation instruction may have been neglected.

The pre-installation factors reducing the service life of the window, mentioned above, are similar to the pre-installation of other building materials and components. The different phases; design, raw material production, manufacturing, storage, and installation, influence the service life of the building material or component greatly. All these pre-installation factors cause the reduction of the service life of the building material or component, even before it begins. However, sometimes the damage appears later, during the use of the building. The faulty design of the window does not necessarily appear immediately after installation. Heavy rain, for example, may emphasise oversights in the installations of the window. Problems occur if rain water stays on the horizontal surface. A faulty product might have to be replaced with a new one. Due to this, the environmental load of production is already doubled. Also, there are environmental loads from the disposal of the faulty product. Furthermore, the faulty product and its replacement might have caused damage to the surrounding products, or even to the structure of the building, and reduced their service lives as well.

There is no point predicting or assessing the service life of building materials or components, if the pre-installation factors are not taken into consideration as they greatly affect the service life of a building. Due to these factors, the building materials or components may never reach the predicted service life. The possibility was lost somewhere in the phases of design, raw material production, manufacturing, storage, or installation. If the pre-installation factors are not taken into consideration, the significance of the service life planning is minor.

Considering the influence of the pre-installation factors on the service life of the building components, the comparison of the different raw materials becomes less significant. If the component does not reach the predicted service life due to the pre-installation factors, there is no point in comparing the service lives of components with different raw materials. The focus should be on assessing the pre-installation processes, and on how to avoid, or at least minimise, the possible damages to the building components during the pre-installation processes.

ISO 15686-3 [2002] focuses on describing the approach and procedures of service life performance audits. Audits are undertaken to provide a reasonable assurance that the required service life performance will be achieved. ISO 15686-3 [2002] provides a choice between formal independent audits and less formal internal review procedures. Both service life performance audits and reviews emphasise the pre-briefing, briefing and design stages of the construction projects. The emphasis of the construction, operation, refurbishment and disposal stages is secondary. The distinction between core and secondary audits is not intended to be definitive. However, this distinction does not seem justified. For example, the purpose of an audit at the construction stage is '*to assess whether correct or intended materials / components have been used and installation instructions have been properly implemented*' [ISO 2002]. If these two aspects are not assessed, it lessens the credibility of the service life performance audits. The use of incorrect materials or unqualified installation may reduce the predicted service life as well as cause damage to the surroundings.

3 SKILLS AND LEVELS OF WORKMANSHIP

The service life of a building varies from decades to even centuries. As mentioned earlier, the service life of the inaccessible parts of the building should be the same as the service life of the building, but the service life of the accessible parts can be shorter. When the service life of accessible parts is shorter than the service life of a building, they need maintenance and replacement during the building's service life. The maintenance and the replacements can be proactive or reactive [see Haapio & Viitaniemi 2008]. The maintenance and the refurbishment of the existing buildings are critical issues for sustainable building, especially in Europe. In Europe, the building stock is older than in

North America, where the urban areas grow rapidly [Kohler & Moffatt 2003]. Furthermore, the number of renovations caused by obsolescence is increasing, as the requirements and needs of the tenants grow [see Haapio & Viitaniemi 2008].

3.1 Examination Procedure for Approval

Before a new building is handed over to the building contractee (the owner) in Finland, the contractor convenes the constructor, and possibly the authorities, to the examination procedure for approval. The aim of the examination procedure for approval is to check that the building meets the requirements agreed in the contract. After one year, there is warranty repair by the contractor. However, there are damages, and faults which take more than one year to appear. The warranty period varies depending on the type of damage or fault. In these situations, the legal responsibilities have to be clarified. The clarification of the legal responsibilities becomes more problematic when sub-contractors are used.

The number of sub-contractors has been growing during the last decades. The sub-contractors work for the (main) contractor, but the constructor has made the contract with the (main) contractor. Basically, the sub-contractors are responsible to the (main) contractor, and the (main) contractor is responsible to the constructor. The more sub-contractors there are, the more difficult the project is to manage, and the project becomes logistically challenging. Also, supervising the level of workmanship becomes more difficult as the number of the sub-contactors increase.

Recently, schedules on the construction site have tightened even more. If one phase of the project is late, in the worst case the whole project will be late. If the building is not ready at the time agreed on in the contract, there will be fines. Unfortunately, when the schedule is tight, and the process is falling behind, sometimes a few steps are rushed, or even disregarded to save time.

3.2 Condition İnspection of the Buildings

When an old single family house is sold in Finland, the condition of the house is normally inspected by a professional, specialised in condition inspection. The aim of the condition inspection is to check the quality of the building, and survey possible faults and damages, for example, possible moisture damage. In addition, recommendations for future maintenance can be given, for example, an estimation of the renovation of the pipes. At some level, the condition inspection could be introduced to the new / newish buildings. For new buildings, the assessment of the installation damages could be useful.

Condition inspection is an excellent way to assess the quality of the building. If it is done regularly, maybe every 10 years, it could act as a plan for maintenance and refurbishment, and later on as a register of the maintenance actions. Even though the service lives of products and components are presented, they are only predictions. The building products and components might be exposed to agents of degradation which are not taken into account in service life prediction, or the maintenance of the building has been neglected. There is also a possibility that the pre-installation factors have damaged the products, but the damage appears only after several years.

3.3 Follow-up of the Building Defects

As an example, four sets of row houses were built in the end of 1970s on the coastal area in Finland. In the buildings red tiles were used as cladding. In total, three lots of red tiles were used. Unfortunately, one of the lots was faulty; the temperature of the burning process had been too low, and also some of the tiles were heterogeneous. During the winter time on the coastal area, the weather is often windy. The wind itself did not damage the tiles, but the rain which came with the wind did. During the rain, the tiles got too wet. Later, the weather got colder and the water in the tiles froze. During the warmer weather, the frozen water in the tiles melted. When this happened several times,

bits of the tiles (circa 3-4 mm thick) cracked from the surface, especially from the tiles in the south and west side of the buildings.

Westberg *et al*. [2001] have described the degradation process of a material in terms of: Agents → Mechanism → Effect. The façade was attacked by low temperature and moisture (agents), and frost expansion (mechanism) probably caused the cracking (effect). The tiles had to be changed. If the tile lots had been tested by the manufacturer before the brickwork, most probably the faulty tiles would have been found. However, considering the amount of produced tiles, testing all the tile lots would be very expensive, and time consuming. In this example, the changing of the tiles was difficult; only one of the tile lots was faulty, but which tiles belonged to that lot? The three lots had been mixed in the construction site. Otherwise, it would have been easy to trace back the faulty tiles. Furthermore, there was another factor, which may have contributed to the damage; the design of the buildings. There were no eaves to protect the walls from the direct rain. If there had been eaves, maybe the faultiness of the tiles would have been revealed much later, or maybe never.

At some level, an open data base for building defects would be an improvement. Probably, the data base would operate best on a national level as the collection of data and the maintenance of the data base would probably be easier to organise on a national level. Also, there are local building codes, local building traditions, and climate differences in different countries. However, the national data bases should be organised in a way which enable the exchange of the information between different countries. For example, a couple of big hall buildings have fallen apart in recent years in north and central Europe. Research groups, some international, have been established to analyse to the causes of the crashes. The gathered knowledge from these groups is utilised in the development process of the standardisation.

4 DISCUSSIONS

The EU has eased the mobility of labour within its member countries. There is a keen competition on building contracts and professional workmen. The lack of professional workers is currently a big concern within the construction sector, at least in Finland. Unfortunately, grey markets are boost in these kinds of circumstances. The number of sub-contractors has been growing over the past decades. Supervising the level of the workmanship becomes challenging as the numbers of the sub-contractors increase. Due to the mobility of labour, there are often several different nationalities in a construction site. In different countries, the building culture, the working methods, and the code of building regulations is different. This complicates the circumstances even more. At worst, it may be a matter of industrial safety. Moreover, professional pride is often not what it used to be. Before a construction worker used to show his work and say, *'This is what I built'*. Today, he shows his wallet, and says, *'This is what I earned'*.

The maintenance and the renovations of existing buildings are critical issues for sustainable building, especially in Europe. The service life of a building can be decades or even centuries. The service lives of the components vary from a few years up to the service life of a whole building [ISO 2000]. But during the building's long service life, manufacturing processes and products are developed. Matching old and new techniques and products is challenging, especially considering the lack of professional workers.

There are several factors, which may affect the service life of building materials or components, even before their service life begins, before they become a part of a building. These pre-installation factors cause financial loss and environmental damage. A component damaged by the pre-installation factors may damage the surroundings as well, and thereby increase the financial loss and environmental damage. Unfortunately, this important subject area has been less addressed in research. Therefore, a thorough analysis on the pre-installation factors and their impact on the components and their surroundings is vital. It is essential to analyse the pre-installation processes in order to pinpoint the

black spots of the processes. The focus should be on how to avoid, or at least minimise, the possible damages to the building components during the pre-installation processes. Development of the processes might also be required.

Special attention should be paid to the control phase. All the faulty components should be excluded already at the production plant; they should never reach the construction site. If the pre-installation factors have damaged the component, it will not meet the predicted service life. In addition, it may cause damage to the surrounding components. Control at the construction site should also be emphasised. For example, the storage of the components and the installation of the components are extremely important phases. Furthermore, the traceability of the components should be assured. Tracing back the manufacturer and the production lot of the faulty component is essential. The other components of the same production lot could be checked for possible damages before they cause damage to the surroundings.

The distribution of the liability could improve the quality of the building components, and installation. There could be certificates for every work phase for the contracting parties (e.g. producers, manufacturers, assemblers, and installers). By signing the certificate, they would guarantee that they have done their part according to the building code and the certificate. The signature would make the person responsible. However, this would increase bureaucracy. Naturally there are legal responsibilities for faulty materials and components. This could help to trace the responsible person, because in some cases it is very difficult to prove who is responsible. If the names of architects, designers, constructors, and inspectors were engraved on a plate on the front wall of the buildings, would the quality of the building be any better?

ACKNOWLEDGMENTS

The Importance of LCA and Service Life Prediction in Sustainable Design

A. Berrin Çakmaklı [1]

T 51

ABSTRACT

The building sector has a greater impact on the global environment or faces a greater obligation to improve its environmental performance. In buildings that have really long life cycles; renovation and refurbishment contribute more significantly in their life cycle assessment (LCA) that is a methodology for assessing the environmental performance of a product over its full life cycle. At that point, accurate service life prediction plays important role in LCAs. Estimated service life of components, which is a function of reference service life in conjunction with other factors, is generally considered in usage phases of their life. For building components, the occupants decide to make replacements taking into consideration their functional service life.

In light of sustainable principles and policies it makes more sense to renovate or refurbish old buildings. Energy consumption in hotels is one of the highest compared to other building types. These refurbishments are really important because the hotels should follow the fashion in order to offer best services. Many of the services to hotel guests are highly resource intensive, whether it concerns energy, water or raw materials. To assess the life cycle of hotels and their components is really useful to understand the importance of LCA from the point of view of sustainability.

This study was about to assess the life cycle of the refurbishment project of the five star hotel in Ankara. The estimated service life of changing materials especially the finishing ones is really shorter than their reference service life. A LCA tool, ATHENA is used for analyzing this refurbishment project. According to the results of software analysis, a material matrix was proposed.

1 INTRODUCTION

As the world's population continues to expand, environmental management should include environmental quality and extend it in time over the long-term on a sustainable basis. Implementation of resource-efficient measures in all areas of human activity is imperative. Industrialization is necessary for any real development and also it can be achieved in an environmentally sound manner. In sustainable economy, materials use will be guided by a hierarchy of options: firstly, to avoid using any nonessential item; secondly, to reuse a product; and thirdly, to recycle the materials to form a new product. Growing universal awareness of protecting the living and non-living environment leads to more enlightened decisions to achieve a sustainable development. Sustainable development is "the challenge of meeting growing human needs for natural resources, industrial products, energy, food, transportation shelter and effective waste management while conserving and protecting environmental quality and the natural resource base essential for future life" [Bartelmus, 1994].

Buildings should benefit humans, the community, and the environment. However, nowadays buildings are one of the biggest threats to environment; they consume significant quantities of energy at all stages of their life cycle and this causes short and long term environmental and economic problems on local and global scales. According to Edwards [1998], the building sector, including housing, comprises 30-40% of the world's total energy demand and approximately 44% of the total material use. Building professionals are increasingly becoming involved in dealing with these problems and as a result of this a new approach has been adopted. Designing for sustainability is an approach to the design, construction and operation of buildings and their surroundings to improve the relationship between the buildings, environment and occupants. Sustainable or "green" buildings include appropriate use of land and landscaping, the use of environmentally friendly materials that have closed loops, and attention to the life cycle effects of the building's design and operation.

2 SUSTAINABLE DESIGN PRINCIPLES

2.1 Life Cycle Assessment

The entire building process in its relation to the environment in terms of energy use and emission, between taking from environment and bringing back into the environment should be assessed. Life Cycle Costing (LCC) and Life Cycle Assessment (LCA) are two complementary methodologies, which measure the performances of products or systems in the units appropriate to each emission type or effect category. As defined by IS0 14040 [1997: iii, withdrawn and revised as ISO 14040: 2006] ,
"LCA is a technique for assessing the environmental aspects and potential impacts associated with a product, by:

- compiling an inventory of environmentally relevant inputs and outputs of a system.
- evaluating the potential environmental impact associated with those inputs and outputs.
- interpreting the results of the inventory and impact phases in relation to the objectives of the study.".

LCA has been identified as a strong tool that can be considered as a scientifically established method for generation of the necessary decision support system. Defining sustainable materials and encouraging their use seems to be one of the biggest challenges for the developers of green building rating systems. That challenge must be met by a better integration of LCA techniques and LCA based decision support tools in whole building rating and certification systems.

One of the great difficulties in assessing the environmental effects of resource extraction is that so many of the environmental effects that concern people — for example, the effects on biodiversity, water quality, soil stability and so on — are very site specific and not easily measured. For that reason they are often left out of life cycle inventory studies or given only passing mention.

LCA is a dynamic and iterative assessment process, which assesses the environmental impacts of products and services from a cradle -the place or moment where the raw materials or resources are taken from nature into the technical system- to grave perspective -the place and time when the products or used resources are returned to nature. Society of Environmental Toxicology and Chemistry is the first international organization that has studied the LCA principle systematically. ISO then proposed a framework that involves four interrelated phases; goal and scope definition phase, inventory analysis phase, impact assessment phase and interpretation phase; seen in Figure 1.

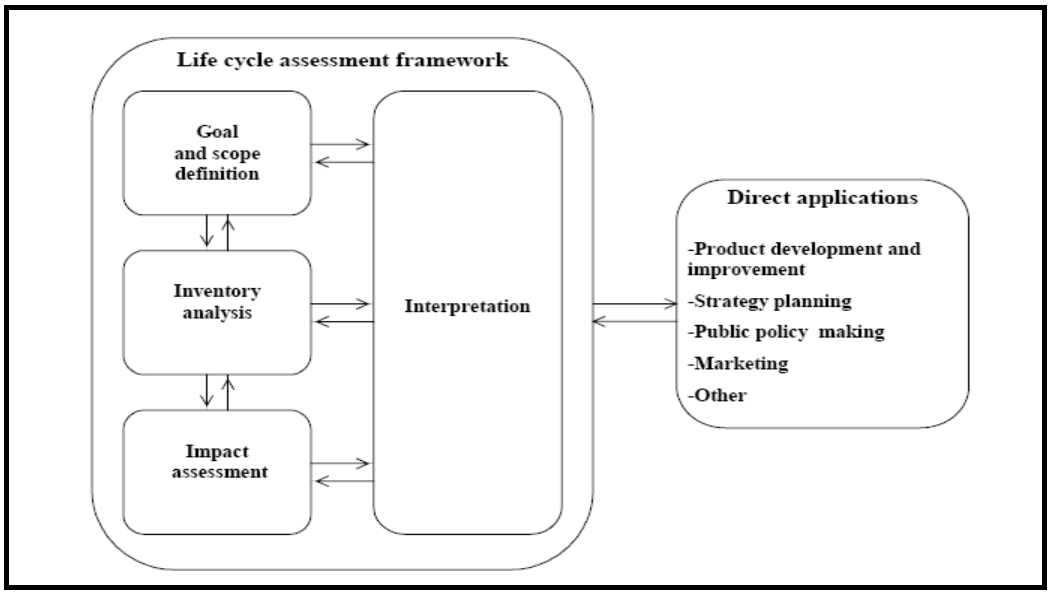

Figure 1. The four phases of an LCA [ISO 14040 Standard, 1997: 4].

2.2 Service Life Prediction

When the LCA methodology is applied to a building product, it is seen that an important parameter in LCA of buildings and building materials is the prediction of service life because the environmental loads per year is inversely proportional to the service life. According to Nunen et al. [2004], "The role of service life in LCA is underestimated which results in inconclusive assessment values". Understanding its role is really important to make accurate prediction about the environmental impact. The concept of Reference Service Life of Component (RSLC) was firstly introduced in ISO 15686-1 [2000, under development as ISO 15686-8], and defined as the "service life that a building or parts of a building would be expected or predicted to have in a certain set of reference in-use conditions". The objective of the service life planning was also stated as "to assure, as far as possible, that the service life of the component will be at least as long as its design life" [ISO 15686-1, 2000, under development as ISO 15686-1]. Not only long total service life of building but the service life of components is really important to decide the replacements. Most assessment methods that are carried out regard the service life as a fixed item. However, the buildings specific data are needed for types of maintenance and service life estimation. The fixed service life within the current assessments, the different phases within service life and the rate of replacement of components are important issues in LCA. Variation in materials or design solutions causes a calculated comparison between the various environmental burdens, and an optimization can be made.

2.2.1 Factor Method

In ISO 15686-1 [2000, under development as ISO 15686-8], the "Factor Method" was described as a means for addressing this problem. This method was used to modify a RSLC to obtain an estimated service life of the components (ESLC) of a design object, by taking account of the difference between the project-specific and the reference conditions. This was carried out by adjusting the RSLC by a function with a number of factors, each being from a particular factor class and reflecting a difference between the two sets of in-use conditions in the factor class. If the ESLC is known, the exact amount of material used throughout the overall service life is known as well. In its simplest form, the function was the product of the factors, as summarized below:

ESLC = RSLC * factor A* factor B * factor C * factor D * factor E * factor F * factor G

Where:

A = Material / Component factor B = Design factor C = Workmanship factor
D = Internal environment factor E = External environment factor F = In-use factor
G = Maintenance factor

Table 1. Examples of factors, relevant to building services plant (Saville & Moss; 2002: 4)

Factor	Examples
A Quality of components	Manufacture, storage, transport, materials, protective coatings
B Design / detailing	Incorporation into the building, detailing, system design
C Installation / workmanship	Site management, standard of workmanship, climatic conditions during installation
D Indoor environment	Aggressiveness of environment, ventilation, condensation
E Outdoor environment	Location of building, micro and macro environment, sheltering, pollution levels, weathering factors
F In-use conditions	Commissioning, hours/frequency of use, mechanical impact, category of users, wear, tear
G Maintenance	Quality and frequency of inspection and maintenance, accessibility for maintenance

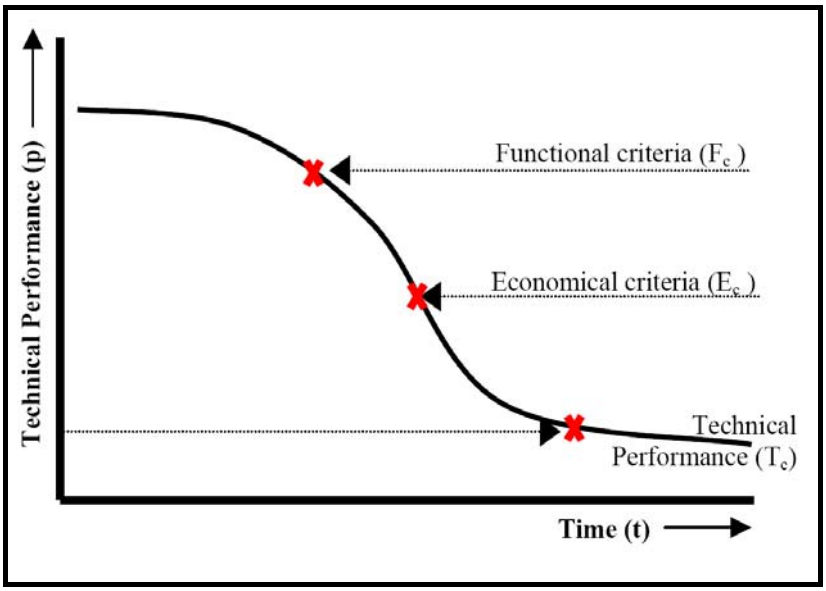

Figure 2. Different types of end of life [Nunen et al., 2004: 5].

In the ISO Standards, three kinds of end of life; technical, economical, and functional end of life; are seen in the building sector. The reference service life of components is the technical service life. The technical service life is over when the component can no longer sustain its performance. Economical end of life occurs when another component can be switched with lesser costs. The functional end of

life occurs first and the component's service life is over, when the component does not carry out the function people demand of the component.

Nunen et al. [2004] mentioned that Trend and Related factors should be added while calculating the ESLC because the sensitivity to fashion trends could decrease the functional service life of any component due to fashion changing. The other factor, Related factor comprised of two features: first one was the ease of the accessibility of a product that is replaced and the ease of replacing the combination of different components. For example, the replacement of a complete building part, like window frame, was easier than any component, frame without glass.

3 REFURBISHMENTS OF HOTEL BUILDINGS

It is obvious that most options in the design process to reach the best available environmental performance are available for new buildings only. However, the rebuilding of existing buildings presents opportunities to improve the buildings' environmental performance. Renovating an existing building can save money, time and resources with existing infrastructure and public transportation, enhancing convenience and reducing sprawl. Adaptable buildings are likely to use the same amount of space and materials more efficiently on average over their entire life. The annualized reduction in embodied and replacement energy, and the annualized reduction in solid waste generation from renovation and demolition are the successes of adaptability. It is noticed that rebuilding, including maintenance; activities represent almost half of the environmental impact in the residential and commercial sector. Among commercial buildings, accommodation facilities were unique with regard to operational schemes, the type of services offered, as well as the resulting patterns of natural resource consumption. Many of the services to hotel guests were highly resource intensive, whether it concerned energy, water or raw materials [Erlandsson, Levin, 2004].

Hotels should follow the technological improvements and apply them to their design processes. To maintain to highest standards to customers is really significant for hotels to remain competitive.
If a hotel was to be environmentally friendly, it should be constructed using environmentally sensitive materials. These materials should generally be less toxic, more durable and stronger, made of recycled materials, or environmentally certified. They should also have low embodied energy and be produced and available locally, in order to avoid transport-related impacts. An environmentally responsible design generated a number of benefits including considerably lower resource consumption and operational costs, as well as improved comfort and productivity for the occupants. The corporate image was also improved, thereby attracting new customers, as people came to prefer the "green" alternative. Hotels designed according to sustainability principles were called as "sustainable hotels".

Stipanuk & Roffman [1992] classifies renovations for hotels in three categories:

- Minor renovation (6 year cycle): the scope of a minor renovation is to replace or renew the non-durable furnishings and finishes within a space without changing the space's use or physical layout such as replacing carpets, wall coverings, drapery, and bedspreads; minor painting; and touching up the furniture.
- Major renovation (12 to 15 year cycle): the scope of a major renovation is to replace or renew all furnishings and finishes within a space, and may include extensive modifications to the use and physical layout of the space itself like replacement of all furniture, bedding, lighting, replacing floor finishing and artwork.
- Restoration (25 to 50 year cycle): the scope of a restoration is to completely gut a space and replace systems that are technically and functionally obsolete, while restoring furnishing and systems that can still be used, given current needs of the facility such as interior demolition of entire guestroom floors to reconfigure the mix of rooms and placement of bathrooms.

Making lifetime estimation in preliminary design stage is advantageous in refurbishing programming. The user activities, deterioration agents, and mostly visual obsolescence define the life expectancy of finishes in relation to the maintenance policy concerning renewal cycles. For example, long life

expectancy is one of the main criteria in selecting doors, windows and their components because frequent replacement of them is an expensive and time taking work in a refurbishment project. Special designs for carpeting, wallpapers, upholstery and curtains could limit the future replacements so it was not preferable. And gave examples to this by indicating the lifetime expectancy for carpets in guestrooms as 6 years, for drapes and spreads as 5 years, for beds 15 years, for mattresses 12 years, Venetian blinds 8 years and furniture 10 to 12 years due to Hilton International Engineering Manual.

4 REFURBISHMENT OF CASE STUDY BUILDING

Although Ankara is not a coastal city, nor a mountain resort, it is the capital city and therefore hosts many delegations, which is why it has many hotels. This being the case it needs to have world-class hotels to accommodate the official guests. This in turn means that the hotels in Ankara have to be kept up to date and must be renovated every how and then to meet the high standards of equivalent hotels elsewhere. According to data taken from Ankara Chamber of Architects, the percentage of hotels renovated in the six year period 2000-2006 is almost 53%.

Renovation works in hotels were undertaken mostly from the point of view of customer satisfaction. The guests were asked to fill up a questionnaire to assess their satisfaction. Some of the questions were posed to determine those aspects which impressed the guests most. The aim was also to find out whether the guests were bored with the decor or not. Unless there was a sudden change in fashion trends, this was one of the reasons of refurbishment. For example, in the case hotel for this paper, there were light-colored marble tiles and vanity basin with matching faucet fittings in the bathroom of the guestrooms before refurbishment. Although these fittings and fixtures were in good condition, they were replaced with darker new marble cladding and fittings only because of the changing fashion trends; as seen below in Figure 3 and Figure 4.

Figure 3. Fittings before refurbishment

Figure 4. Fittings after refurbishment.

Data pertaining to refurbishment/renovation project of five star hotel in Ankara was gathered in 2005 and photographs of the refurbished rooms were taken in 2007. This hotel belongs to an international chain which operates 2,700 hotels in 70 countries. Although, major renovations included such public areas as the lobby, conference-meeting rooms, ballroom, restaurants etc, only data for guestrooms has been analyzed in this paper, as the design decisions for one room is repeated hundreds of times over.

In order to assess the environmental impacts of the materials most commonly replaced during this refurbishment project, a life cycle assessment tool (ATHENA) is used. After entering the bill of quantity (BOQ) of guestrooms as the input to the software, the summary tables were obtained as the output and common materials that were used in all case guestrooms could be evaluated.
As an output of this software, the projects were evaluated according to six indicators. These were:

- Primary Energy Consumption: Absolute primary energy consumption by fuel type for each life cycle stage as well as annual operating energy.
- Solid Waste: Recovered matter resulting from the production and delivery process.
- Air Pollution Index: Inflows and outflows that contribute pollutants to the air.

- Water Pollution Index: Inflows and outflows that contribute pollutants to the water.
- Global Warming Potential: How much a given mass of greenhouse gas is estimated to contribute to global warming over a specific time interval.
- Weighted Resource Use: The quantities of raw materials or intermediary products consumed.

Table 2. BOQ of guestroom floors of the case hotel included common materials.

Material	**Unit**	**CASE HOTEL**
Levelling Conc. - Screed	m3	1576.7357
1/2" Fire-Rated TypeX Suspended	m2	4854.608
5/8" Fire-Rated TypeX Gypsum Board	m2	3051.488
Paper Tape	tones	13.5629
Water Based Latex Paint	l	1719.1080
Hardwood Skirting	m2	424.8825
(Modular) Brick Wall	m2	228.48
Plaster, gypsum spackling	m2	76199.024

Table 3. The impacts of seven common materials according to six indicators derived from software.

MATERIALS		**Primary Energy Consumption (MJ)**	**Solid Waste (KG)**	**API**	**WPI**	**GWP (KG)**	**Weighted Resource Use (KG)**
CASE HOTEL	**Levelling Conc.**	3244607	102758	48898	2	350177	4332806
	Gypsum Board	647917	22922	10324	1	24763	106365
	Paper	402919	6210	6223	0	14914	41270
	Water-Based Paint	50739	53	497	0	944	3343
	Hardwood	21128	89	199	0	610	12495
	Brick	246331	1263	3304	0	8933	26757
	Plaster	433034	4	139	0	781	1223392

5 CONCLUSION

The choice of materials and components has an important role in determining energy performance. Environmentally responsible specification of building materials and components includes the consideration of embodied energy, reusing, recycling, resource efficiency and local and global environmental impacts. As a result, the proposed matrix was devised and ecological scores were given to seven materials used, as shown in Table 4. Points were given to them according to their LCA. For primary energy consumption, solid waste, air pollution index, water pollution index, global warming potential and weighted resource use; the highest point, seven, was given to the material, which has the maximum impact; and the lowest point, zero, was given to the material, which has no impact.

According to Table 4, the maximum score, which is forty-two and being the most damaging material in this refurbishment work, belongs to levelling concrete mostly depended on the cement manufacture; the minimum score, which is 9, belongs to hardwood which is the least damaging material. As a result of this, use of levelling concrete and gypsum board should be minimized in refurbishment projects or alternative energy sources and processes should be found during manufacturing cement in order reduce the damage to the ecosystem. For these two materials, the recycling, reducing and reusing strategies are most significant. Filtering methods should be used while manufacturing in order to reduce the air and water pollution. Hardwood has the minimum ecological score so wooden materials mostly should be preferred while refurbishing.

Table 4. Proposed matrix

MATERIALS	Primary Energy Consumption	Solid Waste	API	WPI	GWP	Weighted Resource Use	Ecological Scores
Levelling Concrete	7	7	7	7	7	7	42
Gypsum Board	6	6	6	6	6	5	35
Paper	4	5	5	0	5	4	23
Water Based Paint	2	2	3	0	3	1	11
Hardwood	1	3	2	0	1	2	9
Brick	3	4	4	0	4	3	18
Plaster	5	1	1	0	2	6	15
7 points = Most damaging 0 point = No damaging							

In this case hotel while refurbishing, wooden suspended ceiling was replaced by gypsum board ceilings, which are not as durable as wood. Even the wooden pelmets were replaced with gypsum ones. From these examples it can be seen that sometimes good quality and durable materials are replaced with those of poorer quality and strength and also have worse impacts to nature. Additionally, the structures with permanent joints, anchors and glues should be avoided, since the hotel maintenance and renovation guideline offer a shorter useful life than their expected life. It would be prudent to use replaceable material and components with de-mountable joints. Since furniture is changed after every 8 to 10 years, it is advisable not to use fixed furniture or parts, such as wall mounted headboards or night stands. It would also be more economical and healthy if floors were covered with wooden parquet or marble tiles depending on the climatic region, and rugs were used instead of wall to wall carpeting, which attracts dust and stains easily. These rugs can be washed or replaced at considerably lesser costs.

Life Cycle Management Tool For Buildings

Erkki Vesikari [1]

T 51

ABSTRACT

Uncertainty in future needs of maintenance, repair and rehabilitation (MR&R) of buildings and new real estate management requirements have led to the need for special life cycle management systems and tools. The programme “MaintenanceMan” was aimed to be a new kind of life cycle management tool which fulfils the requirements of many stakeholders such as owners, contractors, designers and maintainers. The program “MaintenanceMan” can be characterised as predictive, optimising, integrated, life-cycle based and probabilistic.

The life cycle management tool “MaintenanceMan” was meant to be a prototype of a later commercial program. The preliminary version of the tool was programmed as a Visual Basic Application on Microsoft Excel. Only the building envelope, i.e. the facades, balconies and roof coverings were included in the system but the system can be extended to cover any parts of buildings. Several optional materials are available. By the help of the program it is possible to plan the future MR&R actions for modules (building parts) and to find the optimal maintenance strategy with regard to financial, functional and ecological aims. The functional condition analysis is probabilistic and based on the Markov Chain method.

The design process includes three stages: MR&R action design, project design and annual resources design. The MR&R action design is specific to each module of a building and results in MR&R action profiles with action specifications and timings. In the project design single actions are combined into groups of actions which are planned to be executed in the same project. At the last stage of design the annual project programs are prepared taking into account the annual budget.

1 INTRODUCTION

Uncertainty in future needs of maintenance, repair and rehabilitation (MR&R) of buildings, and new real estate management requirements have led to the need for special life cycle management systems and tools [Vanier 2001]. In response to this need a new life cycle management tool called "MaintenanceMan", was developed.

The existing version of the tool was programmed as a Visual Basic Application on Microsoft Excel and was not as such meant for commercial use. Rather it was planned to serve as a prototype of a later commercial application. It covers the building envelope, i.e. the facades, balconies and roof coverings. Several material groups are incorporated: concrete, steel plate, wood, masonry and rendering for facades, concrete for balconies and concrete tile, steel plate and bitumen membrane for roof coverings. For each product group several options with varying materials and details are reserved. The system allows later complementation of both building parts and material groups.

The life cycle management system can be described with the following terms /1,2/: predictive, optimising, life cycle based, integrated and probabilistic. It is “predictive” as it uses service life models by which it is possible to predict the service life of the modules (building parts). It is “optimising” as it is possible to use the programme for optimising the maintenance strategy. It is “integrated” and “life cycle based” as it includes life cycle analyses for functional performance (condition), MR&R costs and environmental impacts. It is also “probabilistic” as the degradation analysis is probablistic allowing studies at different risk levels [Söderqvist & Vesikari 2006].

The programme MaintenaceMan works on modular basis. It means that the buildings are divided into structural parts which are called “modules”. The modules serve as the units for inspection, analysis, design and execution of actions. A module can be a part of a structural element or consist of several structural elements. The essential thing is that the materials and the environmental stresses are the same within a module. Examples of modules would be “steel roof” or “masonry façade to the west”, “balconies to the south” etc.

2 FEATURES OF MAINTENANCEMAN

2.1 General Process

Figure 1 shows the general process of life cycle management by MaintenanceMan. The process starts from the inspection of structures and ends in the execution of projects. Between the start and the end of the process, the programme MaintenanceMan produces project execution plans in three phases:
1. Action planning
2. Project planning and
3. Annual resources planning

The action planning is a combination of manual and automatic processes. The specification of MR&R actions is performed manually for each module using the displays of programme MaintenanceMan. The timing of these actions is, however, performed automatically by the life cycle based condition analysis of the system (ref. Chapter 2.3). The automatically produced lists of actions with timings (life cycle action profiles) can be later altered manually. The life cycle costs and environmental impacts of MR&R actions are calculated concurrently.

Project planning means combination of single MR&R actions into a group of actions which is planned to be executed at the same time and by the same contractor. In the project design the level of design is changed from the module level into the building level and the optimisation of the repair strategy is considered from a wider perspective. The module level actions are grouped into projects so that

synergy profit could be gained. The programme MaintenanceMan automatically combines the actions assuming tentatively that all actions scheduled for the same year are performed in that year as a single project. However, the designer can manually share the actions ascribed to a year into several projects and specify an action to be implemented in any year and in any project.

From project design the designer proceeds to annual resources design. The annual resources design means giving the final timing for projects so that the annual project costs are in harmony with the annual budget. For balancing the project costs with the budget the designer can rearrange the timings of projects and, if that is not enough, the designer can skip to the "project design" or even to the "action design" to make altorations to the planned actions and projects so that when returning back to the "annual resources design" the costs and resources can be balanced.

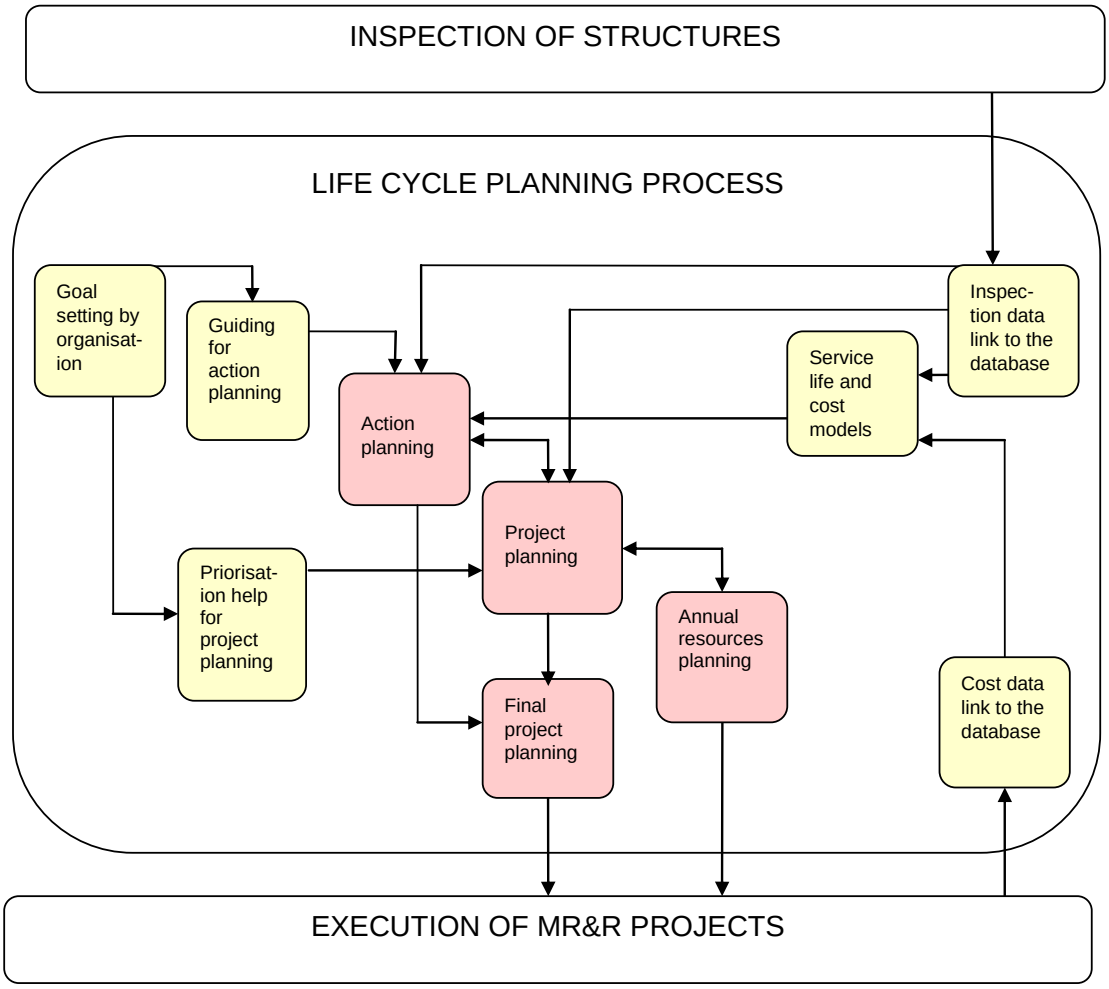

Figure 1. Life cycle management process of MaintenanceMan.

2.2 Data Flow

In the course of all three design phases, data for the buildings, modules and MR&R actions are needed. These data come from a set of databases representing buildings, modules, and repair systems.

The databases of buildings and modules can be produced by the user through the displays of MaintenanceMan. These databases include data concerning identification, materials, structures, exposure, fabrication, maintenance history and condition. The condition data consists of module specific degradation and damage data gathered by inspections.

The database of modules contains also the data of MR&R action specifications to be applied during the life of the module. The user of the program is supposed to specify these actions before entering into the analysis process. However, in case the user omits to do this default specifications are used.

Databases of repair systems contain data of MR&R systems used in the management system. They are not directly revisable by the user. However, the databases of repair systems contain many selective data items that the user can choose from through the displays. As the assortment of repair systems is different for each product group a separate repair system database is reserved for each of them.

The life cycle analysis process is organised so that the same process can be used irrespective of module, material or repair system at hand. Only the initial data, which are gathered in the "Data table of the active module", change when operating with sequential modules.

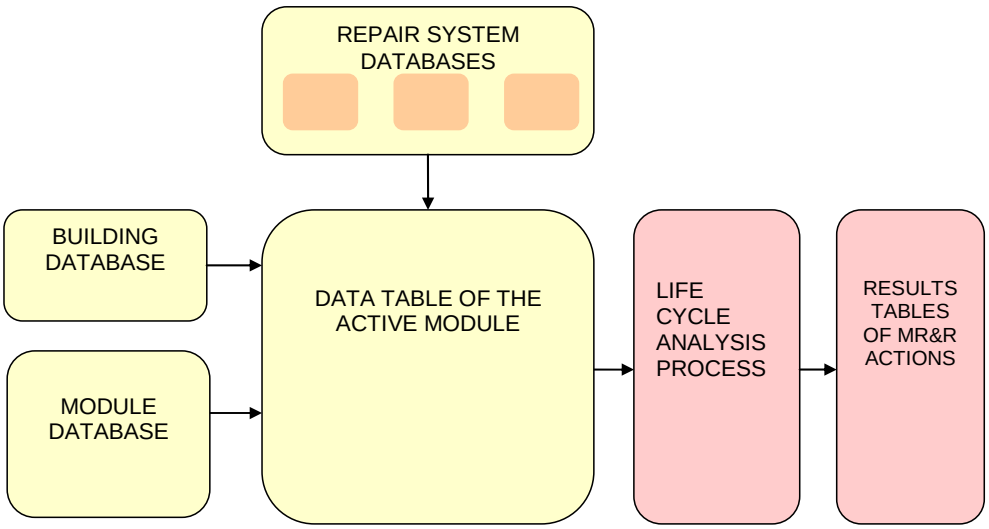

Figure 2. Data flow in the programme MaintenanceMan.

2.3 Life Cycle Analysis Process

The core of the programme MaintenanceMan is the combined condition, cost, and environmental impact analysis (Fig. 3). The condition analysis is based on the service life models and the Markov Chain method by which the annual condition state distributions of modules are evaluated through the whole design period. By the Markov Chain method the condition prediction of modules is changed from a deterministic condition analysis to a stochastic one. Specifically, an automatic condition guarding system is established on the Markov Chain based condition analysis. Every time the condition limit state is exceeded with the maximum allowable probability the defined repair action is triggered. The triggering of repair action in a certain year causes automatically application of the action effect matrix (of transition probabilities) instead of degradation matrix which is normally used in the Markov Chain analysis. Also the costs and environmental effects resulting from the MR&R actions are automatically added to the cost and environmental impact counters by the side of the condition analysis. The process is described in more detail elsewhere [Söderqvist & Vesikari 2006; Vesikari 2003].

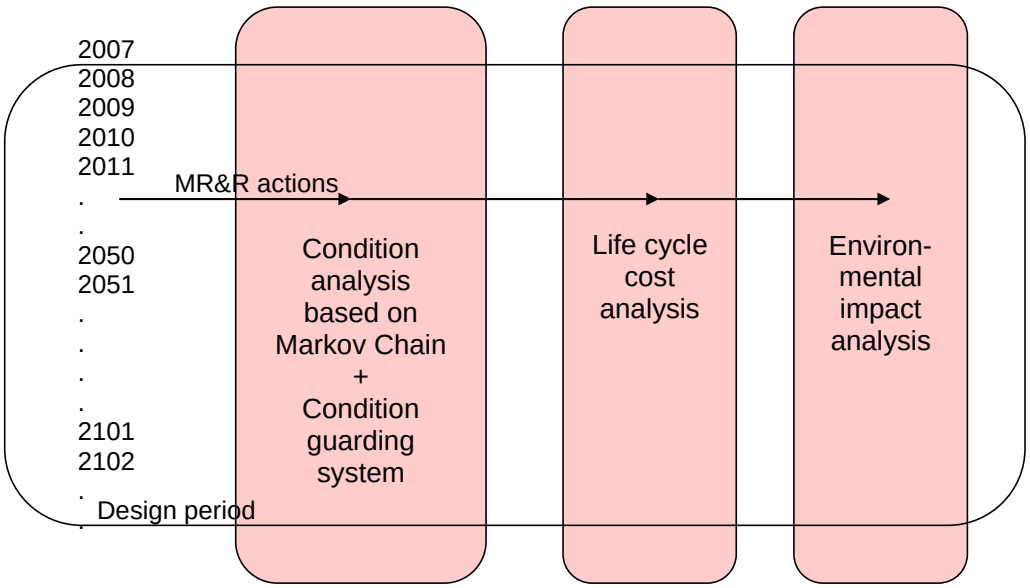

Figure 3. Combined condition, cost, and environmental impact analysis.

3 OPERATION WITH MAINTENANCEMAN

3.1 Establishing Databases of Buildings and Modules

If the building has not been analysed before by the programme MaintenanceMan the first thing that the user is supposed to do is to establish the databases of buildings and modules. In this the user operates with the input data displays of MaintenanceMan. Figure 4 shows the dataform of the module database. When adding condition data (resulting from inspections) or defining future MR&R actions other data forms are used.

3.2 Life Cycle Planning

The “action planning” is performed automatically by the programme MaintenanceMan. The timings of MR&R actions are defined by the service life models, Markov Chain based condition analysis, and the condition guarding system. The results of the design are shown for each module in three displays: (1) Results of MR&R actions, (2) Results of costs, and (3) Results of environmental impacts. Figure 5 shows the results display of MR&R actions.

In Figure 5 the results can be seen in two tables: Actions resulting from unpredictable damages (above), and actions resulting from predictable degradation (below). The tables contain data on identification of module, year of action, specification of action and volume of action. The costs and environmental impacts of actions are presented in other displays. If the designer is not satisfied with the automatically performed plan he/she can make modifications in the plan by the buttons below the tables.

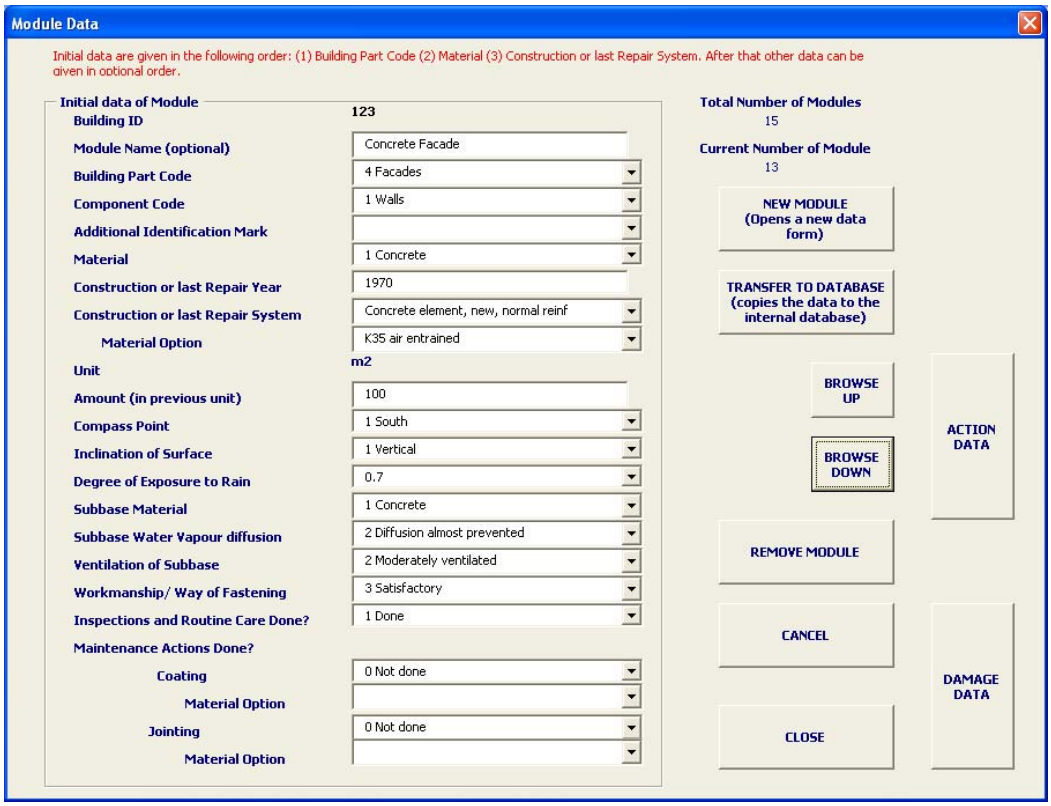

Figure 4. Dataform of the module database.

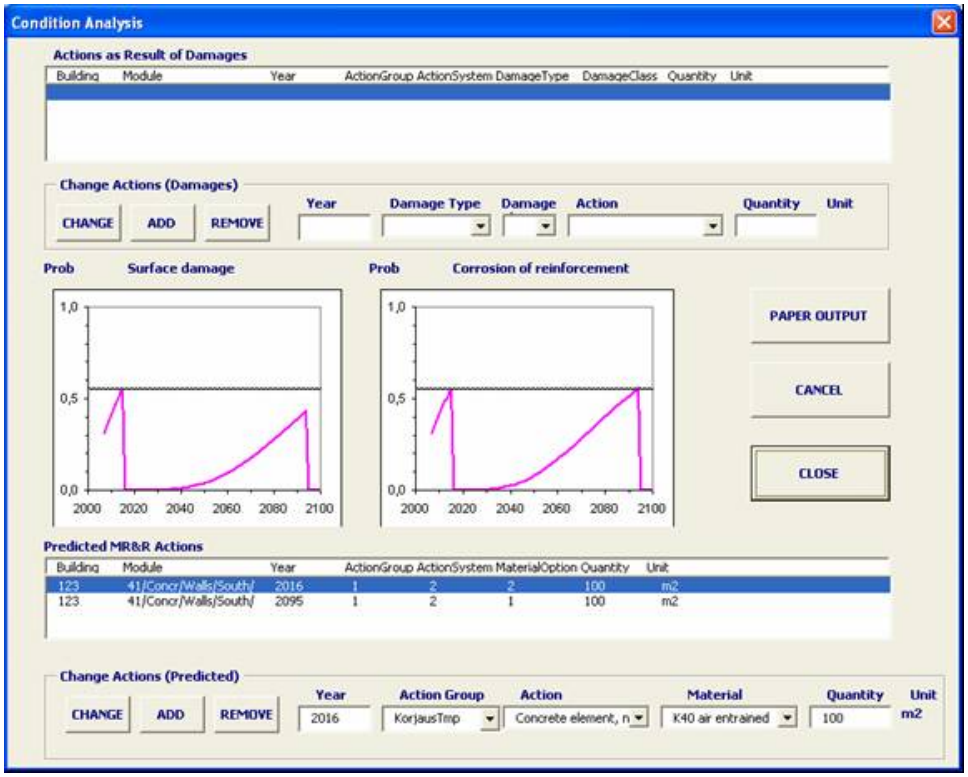

Figure 5. Display of the planning results.

Other displays are provided for summarised data for the whole building and for the whole design period. The display of life cycle costs is presented in Fig. 6.

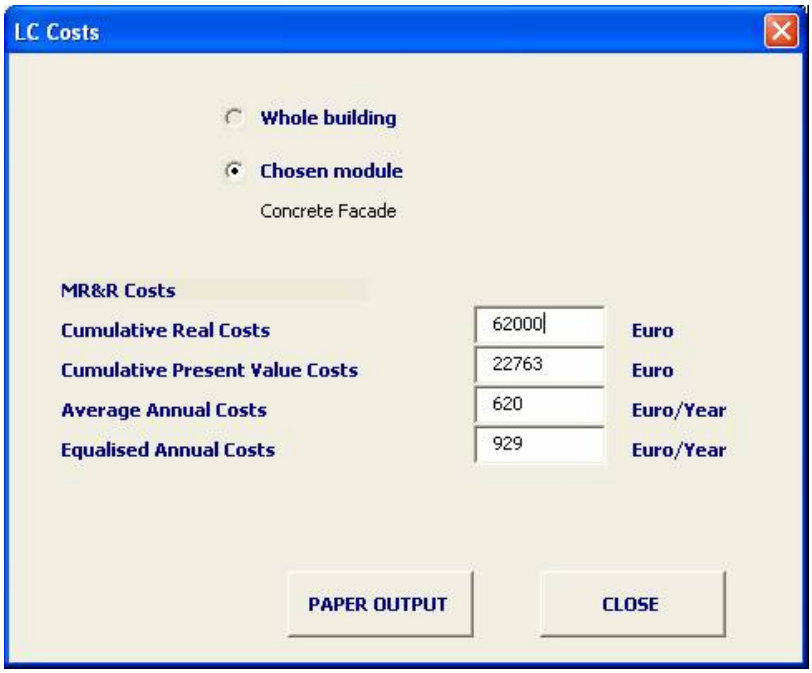

Figure 6.. Summerised data on Life Cycle Costs.

3.3 Optimisation with Maintenance Man

Comparative costs calculations can be conducted by the programme MaintenanceMan. A couple of examples are given in Tables 1 and 2. In Table 1 optional repair methods for concrete facades are compared. In Table 2 alternative repair methods of bitumen membrane roofs are compared. The time frame in these examples is 100 years and the discount rate is 4%. With the discount rate of 4% the discount factor after 50 years is 0.141 and after 100 years 0.020. It means that the relative contribution on MR&R costs for any action after 50 years is small and after 100 years insignificant. That is why the residual value after 100 years is omitted. In case several repears occur during the selected time frame the applied repair method is always the same.

Table 1. Repair methods of concrete facades. Present Value costs and equalised annual costs.

Repair method	*PV Cost Euro/m²*	*Equalised annual costs Euro/yr/m²*
Concrete element, new, normal reinforcement	228	9.29
Concrete element, new, rst reinforcement	253	10.32
Concrete element, tiled	271	11.09
Concrete outer slab, normal reinforcement.	169	6.89
Concrete outer slab, rst reinforcement.	168	6.88
Thermal isolation 45-50mm + fibercement sheet	160	6.51
Thermal isolation 45-50mm + polymerconcrete sheet	160	6.51
Thermal isolation 45-50mm + steel plate	131	5.35
Thermal isolation 45-50mm + rendering	151	6.17

Table 2. Repair methods of bitumen membrane roofs. Present Value costs and equalised annual costs.

Repair method	*PV Cost Euro/m²*	*Equalised annual costs Euro/yr/m²*
1-layer rubber bitumen membrane roof	21.0	0.86
2-layer rubber bitumen membrane roof	23.9	0.97
Renewal of whole roof structure	53.0	2.16
Additional rubber bitumen membrane on the old roof	13.2	0.54

4. CONCLUSIONS

A life cycle management tool "MaintenanceMan" was produced as a response to the obvious need in the area of life cycle planning and maintenance management. The programme MaintenanceMan was aimed to be a new kind of life cycle management tool which fulfils the requirements of many stakeholders such as owners, contractors, designers and maintainers. The management system of MaintenanceMan can be characterised as predictive, optimising, integrated, life-cycle based and probabilistic.

MaintenanceMan was meant to be a prototype of a later developed commercial application. The preliminary version of the tool was programmed as a Visual Basic Application on Microsoft Excel. For the time being only the "envelope" of the building, i.e. the facades, balconies and roof coverings are included in the system but the system can be extended to cover any parts of the buildings. Several optional materials are available. By the help of the program it is possible to plan the future MR&R actions, projects and resources and to find the optimal maintenance strategy with regard to financial, functional and ecological goals.

Simulated Long-term Thermal Performance of a Building That Utilizes a Heat Pump System and Bore Hole

Jan Akander [1]

Daniel Hallberg [3]

T51

ABSTRACT

Over the last decades, installation and use of heat pumps has grown rapidly in Sweden, to the extent that these mainly or partly heat roughly 25 % of the heated floor space in single-family houses. A majority are ground coupled where the heat exchanger is a borehole of 60-220 m depth. As the heat pump system operates, heat extraction will in time reduce borehole temperatures, rendering lowered efficiency of the heat pump system thus directly affecting its economical and environmental aspects.

Within the building sector, durability and life performance dynamics of energy systems is often not reflected upon. System performance and efficiency is assumed to be static over time, changing only due to different operation scenarios. This paper serves to quantify the long-term thermal performance degradation of a component, in this case the borehole, and how the degradation of this component affects performance-over-time of an entire system, in this case the heating system of the building. A dynamic thermal simulation model is used to assess the long-term thermal performance of the borehole. The building, which the heat pump serves, is assumed to be a typical Swedish house with normal energy consumption. Simulation results show that the depth of the borehole is of great importance to limit over-time temperature drops. The efficiency of the heat pump system is directly dependent of temperatures in the borehole. How the overall system performance is affected by component performance degradation, is highlighted.

1 INTRODUCTION

Installation and use of heat pumps has rapidly grown in Sweden during the last decades. Today, Sweden has the largest heat pump market in Europe, with more than 690 000 installed residential heat pump systems that heat approximately 25 % of the heated floor area of single family houses [Forsén 2007]; [Forsén *et al*. 2007]. A majority of the installed heat pumps are ground coupled where the heat exchanger is a borehole, while air-to-air, exhaust air and air-to-water heat pump systems are steadily increasing in popularity [Forsén *et al*. 2007]. During the 1980's, heat pump technologies were regarded as an "alternative energy technology" which reduced energy consumption and environmental impact. A recent investigation states that a residential electric heat pump with a **S**easonal **P**erformance **F**actor (SPF) of 2.5-3.0 will give an approximately equal CO_2-contibution to the atmosphere as a heating system based on burning fossil fuel [STEM 2002]. This, however, depends on how the electricity on a national basis is generated. In general, heat pumps are considered to reduce energy consumption, but it is important to increase the SPF to keep the environmental and economical arguments for installing residential heat pump systems.

When the heat pump coupled with a **B**orehole **H**eat **E**xchanger (BHE), the depth is 60-220 m. As the heat pump system operates, heat extraction from the BHE will in time reduce ground temperatures. Because of this effect, the efficiency of the heat pump system reduces, which directly affects its economic performance. These changes require a performance over time assessment for the BHE's due to their intended long-term usage as components in heat pump systems. By mathematical modelling, the long-term thermal performance of a BHE and its influence on the efficiency (SPF) of the heating system can be simulated.

2 OBJECTIVES

This paper presents the simulated long-term thermal performance of a heat pump system with a single heat extraction BHE equipped with an U-pipe. Since the performance of the heat pump is directly influenced by the temperatures at which heat is collected (the low temperature) and released (the high temperature), an over-time reduction of the lower temperature will have a negative influence on the over-all performance of the heating system: a greater temperature difference will require more driving electricity. By means of computational simulations, the order of magnitude of performance degradation is estimated. Since the simulations consider long-term runs, models are kept simple with monthly data input. Simulations cover a 50-year period in a case study where buildings are situated in Stockholm, Sweden. Energy requirements of two buildings are simulated: one which can be regarded as an average single-family dwelling in the Swedish stock and the other that is built in correspondence with the Swedish building regulation BBR12 [Boverket 2006]. The methodology presented in this paper is applied in the "LMS-ByggaVilla" project that is presented by Hallberg *et al.* [2007].

3 ESTIMATION OF THE HEATING REQUIREMENT

The primary reason for analysis of heating reqirement is to provide an annual load profile that renders realistic monthly heat extraction from the BHE. This profile may be obtained from measured or assumed data or from detailed simulations. A simple method degree-day method is presented below.

Two residential single-family houses are considered. A "new house" built in one storey according to the most recent Swedish building regulation BBR12 [2006] is simulated. The house has a heated floor space corresponding to the average size of houses completed in 2005, 124 m² [Statistics Sweden 2007], and has construction U-values that fulfil building regulation requirements (Tab. 1). It is assumed that 70 % of the heat in the exhaust ventilation air is recovered and transferred to the supply air. Air infiltration corresponding to 0.1 air changes per hour is also modelled.

Table 1. Building envelope components area and U-values applied to the modelled new house.

Construction	*Area* [m²]	*U-value* [W/(m²·K)]
Roof	124	0.13
Floor	124	0.15
Walls	92.7	0.18
Windows, doors	24.8	1.3

The other residence, "the old house," has a heating requirement that is set equal to the average single-family dwelling of the Swedish building stock. The space heating requirement is around 15 000 kWh/year and the heated space floor area is 144 m² [STEM 2007].

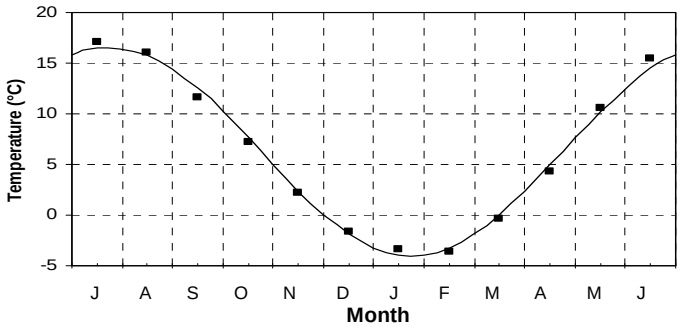

Figure 1. Monthly outdoor temperatures [Nevander *et al.* 1994] and a harmonic curve fit for Stockholm. Note that the x-axis starts at July.

The heating requirement is estimated by means of the degree-day method. A sinus curve is fit to monthly climate data (Fig. 1), in this case data for Stockholm. From estimations on when the heating season starts and ends, the degree-days are found by the integration of the difference between approximated outdoor temperature and the indoor base temperature. The indoor base temperature is dependent on heat gains in relation to heat loss coefficients of each building.

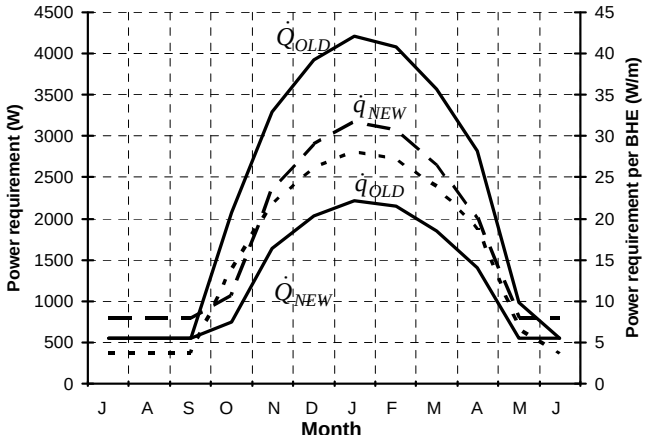

Figure 2. The plot starts with July. The y-axis to the left shows the heating requirement profile (filled curves $\dot{Q}_{NEW}$ and $\dot{Q}_{OLD}$) for each house. The y-axis to the right shows heating requirement per meter BHE (dashed), here **70 m BHE for the new house** ($\dot{q}_{NEW}$), **150 m BHE for the old house** ($\dot{q}_{OLD}$).

There is no space-heating requirement during the summer, but heat will be extracted from the BHE to provide the building with **D**omestic **H**ot **W**ater (DHW). Heat for DHW production is hypothetically constant every month. The annual DHW consumption usually corresponds to some 4 800 kWh [STEM

2007] for a family of four. Figure 2 shows the annual energy requirement profile. The estimated space heating requirement of the new house is 5 990 kWh/year, and for the old house 15 000 kWh/year.

4 MODELLING OF THE HEAT PUMP AND THE BHE

The simulations consider a BHE under the influence of a building that has a defined energy requirement – thereof the previous section. Given the energy requirement of the building, this method will automatically calculate heat extraction and efficiency of the system. The resolution of input data is on a monthly basis, power peaks will be lost when monthly data is utilized. This will affect output data for reasons discussed below.

4.1 Heat Pump Modelling

Heat pumps in Sweden commonly supply heat to spaces and to DHW. In practice, heat pumps deliver heat to DHW at temperatures of around 55 °C while space heating usually is supplied at variable (floating) condensation temperatures, which are dependent on outdoor temperatures. Efficiency is enhanced as the condensation temperature is reduced. For a house heated by radiators, as is assumed in this case, the maximum supply temperature of 55 °C is permitted when outdoor conditions have design values. It is assumed that the condensation temperature increases linearly as temperatures outdoor drop towards design conditions (so-called outdoor temperature compensation).

During peak power periods, the heat pump itself will not cover the heating requirement since these are commonly installed to embrace about 70 % of the power requirement, whilst providing the building with 90 % of the energy requirement [STEM 2006]; all this to enhance the efficiency of the heat pump system. Auxiliary systems, in most cases an electric coil in the heat pump, will provide the remaining energy (10 %) during the coldest outdoor conditions. In the present work, it is assumed that the heat pump fulfils 100 % of the heating requirement.

The efficiency of a heat pump is often characterized by the **C**oefficient **o**f **P**erformance (COP), Eq. 1, which indicates rate of heat flow delivered from the heat pump in relation to the rate of energy flow (electricity) supplied to the process. Another measure of efficiency is the **S**easonal **P**erformance **F**actor (SPF), Eq. 2, which for a given time period considers the amount of output heat in relation to how much energy has been utilized to fulfil the heating requirement. COP and SPF differ in the auxiliary energy, which represents heat from another heat source and/or electricity supplied to run other components in the heat pump system, such as pumps or control devices. In this work, the auxiliary energy is set to zero, which gives these two factors the same value.

$$COP = \frac{\dot{Q}}{\dot{W}_t} \quad , \quad SPF = \frac{Q}{W_t + E_{aux}} \qquad (1), (2)$$

where

$\dot{Q}$ is rate of output heat from the heat pump in operation, [W]

$\dot{W}_t$ is the rate of energy input to the heat pump (compressor work) in operation, [W]

Q is energy output during a considered period of time, [J] or [kWh]

W_t is energy supplied to the heat pump (electricity) during the period, [J] or [kWh]

E_{aux} is heat or electricity supplied to the heat pump system during the period, [J] or [kWh]

The relationship between COP (in this case also SPF) and temperatures at which the refrigerant in the heat pump evaporates and condensates is, with Carnot's efficiency η, expressed in Eq. 3 so that

$$COP = \eta \cdot \frac{T_{cond}}{T_{cond} - T_{evap}} \qquad (3)$$

with

T_{cond} denoting condensation temperature of the refrigerant of the heat pump, [K]
T_{evap} denoting evaporation temperature of the refrigerant of the heat pump, [K]
η denoting efficiency of a true process in relation to the Carnot process, [-]

Since temperatures within the heat pump process seldom are measured, these are within this work estimated on basis of statistics from products [Forsén 2007]. The refrigerants evaporation temperature is assumed to be ΔT_{evap} = 4 K less than the temperature of the cold carrier fluid in the evaporator of the heat pump. The refrigerants condensation temperature is in turn assumed to be ΔT_{cond} = 1 K higher than the temperature of the supply DHW or supply water for space heating. Carnot's efficiency, η, is assumed to be constant in time; here using the value 0.45.

By solving the set of equations above, Eq. 4 (here on a monthly basis) is obtained which gives the relationship between the heating requirement and the heat that is extracted from the BHE, such that

$$Q_{extracted} = \left[1 - \frac{1}{\eta}\right] \cdot (Q_{SH} + Q_{DHW}) + \frac{T_{cold} - \Delta T_{evap}}{\eta} \left[\frac{Q_{SH}}{T_{SH} + \Delta T_{cond}} + \frac{Q_{DHW}}{T_{DHW} + \Delta T_{cond}}\right] \quad (4)$$

where

Q_{SH} and Q_{DHW} are space- and DHW heating requirements, respectively, [kWh] or [J]
T_{cold} temperature of the cold carrier exiting the heat pump, [K]
T_{SH} and T_{DHW} are supply temperatures for space heating and DHW, respectively, [K]
ΔT_{evap} and ΔT_{cond} are temperature differences between the refrigerant and carrier in the heat exchangers of the evaporator and condenser, respectively, [K]

The difference between heating requirement and the extracted heat corresponds to energy that is supplied to the heat pump process. Note the role of the evaporation temperature, here represented by $T_{cold} - \Delta T_{evap}$. When the temperature in the BHE decreases over time, T_{cold} will also decrease and render reduced heat extraction. This, in turn, means that the heating requirement will be fulfilled by increased use of heat compressor energy and/or auxiliary energy.

4.2 Borehole Modelling

The modelling of a single BHE is described in detail by Stojanović *et al.* [2005] and here briefly summarized. The borehole, U-pipe and ground are modelled by means of a RC-network that simulates heat exchange and temperatures in the time domain. However, parameters of the RC-network are pre-processed and optimized on basis of the dynamic thermal response in the frequency domain. An advantage of this modelling method is that it establishes a simplified yet sufficiently accurate thermal BHE model, which requires less computing time and power compared with a traditional finite difference/element model. This facilitates system simulation over several decades.

In this work, the U-pipe of polyethylene has an inner and outer radius of 0.017 m and 0.02 m, respectively. It is filled with a 25 % ethanol-water mix. Ground properties are set to Swedish mean values: the thermal conductivity to 3.5 W/(m·K) and the volumetric heat capacity to $2.2*10^6$ J/(m^3·K). The filling material between the pipe and the ground is water. A minor change is done in the new model: The star network between pipes and the ground of the earlier model is replaced by a thermal resistance between the mean cold carrier fluid temperature and the ground. This thermal resistance is given the value 0.10 K/(W/m), which is the mean of a high value for filling water with low convection rate, 0.138 K/(W/m) [Gustavsson 2006], and measured values obtained from Hellström and Kjellsson [2000]. Initial temperatures of the undisturbed ground are dependent on site location. The temperature for Stockholm is estimated to be 7.5 °C at a depth of 100 m [Kjellsson 2004].

5 RESULTS AND DISCUSSION

Heat extraction from a BHE will in time reduce temperatures of the surrounding ground, as illustrated in Fig. 3. In order for the cold carrier fluid to absorb heat, its temperature must be lower than that of the ground and it is at this lower temperature that the heat pump will obtain heat. In time, the reduction in ground temperature will diminish as the BHE and its surroundings approach a state of equilibrium. Figure 4 illustrates monthly temperatures: after the tenth year, temperature reduction is negligible. A temperature that deserves attention is that of the cold carrier that exits the heat pump and enters the BHE. It is tolerated that this temperature occasionally is lower than 0 °C, but should not occur over for periods longer than a few weeks per heating season.

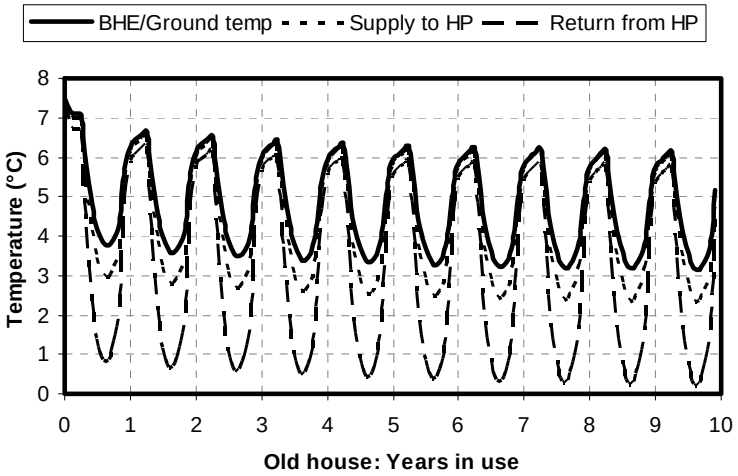

Figure 3. Fluctuation in the BHE/ground interface temperature and the temperatures of the cold carrier fluid of the old house during the first decade of use.

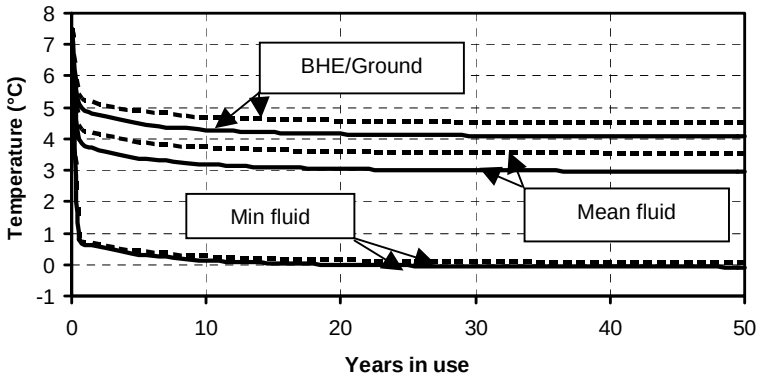

Figure 4. Annual mean values of the BHE/ground wall temperature and cold carrier fluid mean temperatures are plotted for 50 years of use. The minimum monthly average of each year is also plotted; in this case the fluid exiting from the heat pump which enters the BHE. Dashed curves for the old house; filled curves for the new house.

It is at the predicted equilibrium stage that the design of the energy system should be performed. In Sweden, the design of a BHE considers a 10-year heat extraction. This case study shows that the predicted equilibrium stage is reached after approximately 10 years.

The measure of efficiency of the heat pump system is SPF. The reduction in BHE temperatures decreases heat extraction, as can be seen in Eq. 4, and thereby SPF. For the two cases shown here, change in SPF is illustrated in Fig. 5. In the computational runs, the over-time SPF is compared with a SPF that would have been obtained if the cold carrier (thus BHE) constantly has the same temperature

as the undisturbed ground. Reduction of SPF is larger for the new house since more heat is extracted per meter of BHE. This is also seen in Fig. 4: the mean fluid temperature is lower.

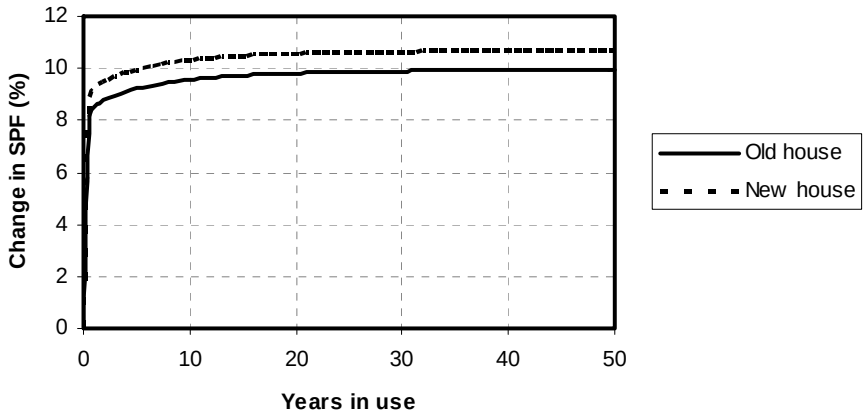

Figure 5. The change in SPF over time for the new and the old house in comparison to the maximal SPF that hypothetically can be obtained if the temperature of the BHE does not reduce.

Whereas Fig. 5 displays changes in relation to undisturbed ground temperatures, it is of interest to compare performances during the first and the last year: keeping in mind that greatest change occurs during the first year. Table 2 shows values, which conclude that the temperature reduction of a BHE has a minor influence on supplied energy. SPF is higher for the old house since the energy for DHW (high temperature heating) is a smaller part of the total heating requirement.

Table 2. Comparison between the 1st and the 50th year of operation. *El* depicts supplied electricity.

House	*SPF Year 1* [-]	*SPF Year 50* [-]	*SPF decrease* [%]	*El Year 1* [kWh]	*El Year 50* [kWh]	*El increase* [%]
New house	2.99	2.93	2.0	3609.5	3683.5	2.1
Old house	3.22	3.16	1.9	6155.3	6275.7	2.0

The assumptions made during the course of the modelling should be noted. The BHE delivers heat only by heat conduction in the ground (no flow of water etc) which gives “pessimistic values”. On the other hand, there are no other near-by heat sinks/sources, and the fact that the modelled heat pump delivers 100 % of the energy (no auxiliary sources or components) gives “optimistic values”. Future work will consider these aspects and an attempt will be made to introduce failure statistics where components within the heat pump itself fails to work.
This work has served to illustrate how a long-term temperature reduction in the BHE, influences the thermal performance of the entire system. After some 10 years, temperature reduction in the BHE is negligible. On basis of this study, the reduction in BHE temperature will after 50 years give an increase of the annual electricity consumption corresponding to 2 %, provided that the building and system continuously has been exposed to a “normalised” annual climate. Annual variations in real climate give larger discrepancies in energy consumption.

Measuring Economical Risk in Life Cycle Management

Fulvio Re Cecconi [1]
Marco Pitzalis [2]

T 51

ABSTRACT

Life cycle base management of building and building assets is strictly bound to economical management in many cases: a company that owns its facilities and need to reduce maintenance costs or to get better building performance for the money spent; a private company that is involved in a PPP, PF Initiative, etc. This strong relationship brings the need for tools to measure and minimize economical risk in life cycle base management of building. A Life cycle management process can be divided in sub-processes (inventory registration, condition survey, service life performance analysis, maintenance analysis, maintenance optimization, maintenance planning). Some of these sub-processes are more relevant than other for economical risk and this paper shows first results of a research, conducted at the Polytechnic of Milan, aimed to identify and deal with risk related activities in building maintenance planning. Two points of the life cycle management process are analyzed with deep details: the identification of maintenance activities to be done on a building and the estimation of costs related with these activities. For the first point the paper shows an evolved approach to FMECA based on risk management techniques to measure the probability of not including a maintenance operation that will be necessary. For the second point the paper shows a methodology developed at the BEST – Polytechnic of Milan to estimate maintenance costs within a probabilistic approach.

1 INTRODUCTION

In construction industry [Loosemore, 2006] “it is necessary for firms to strike a balance between the avoidance of all risk on the one hand and risk-seeking behavior on the other. The challenge is not to avoid risk but to take calculated risks by recognizing and managing them effectively”. The traditional approach to risk management, risks are offloaded to the weakest part in the supply chain, generally a sub-contractor, is now showing its limits with new form of building procurement like Built to Order (BOT), Private Public Partnership (PPP) or Private Finance Initiative (PFI). A new [Loosemore, 2006] “life cycle approach to risk, which emphasizes the collective responsibility and interdependence of all involved in each stage of the building procurement process” is indeed needed.

2 RISK IN LIFE CYCLE MANAGEMENT

2.1 Introduction to Life Cycle Management

In 1993 ISO TC59/SC14/WG9, Design Life of Building, was started with the purpose of documenting steps to be taken at various stage of the building cycle to ensure that the resulting building will last for its intended life without incurring large unexpected expenditures. Since then methods and tools for obtaining a systematic life cycle base management strategy on the European level have become major objective and focus of the European Union Action Plans and FW program.
The life cycle based management and maintenance planning approach includes condition assessment, predictive modelling of performance changes, maintenance analysis and maintenance, repair and refurbishment (MR&R) planning and decisions. Most of newly developed approaches aimed to turn today’s reactive and short-term design, management and maintenance planning towards an optimised and long-term technical approach. An example of this new approach can be found in LIFCON LMS [LIFECON 2004], where the life cycle management process is divided into six sub-processes: Inventory recording; Condition survey; Service life performance analysis; Maintenance analysis; Maintenance optimization; Maintenance planning.

2.2 Introduction to Risk Management

Introducing a risk assessment system applied to life cycle management is the way to obtain more reliable results about maintenance costs and time.
We talk about risk assessment because, according to the literature and the ISO guide 73, it includes both risk analysis (risk identification and risk estimation) and risk evaluation. All the phases of a typical risk assessment approach and their relationships are described in figure 1.

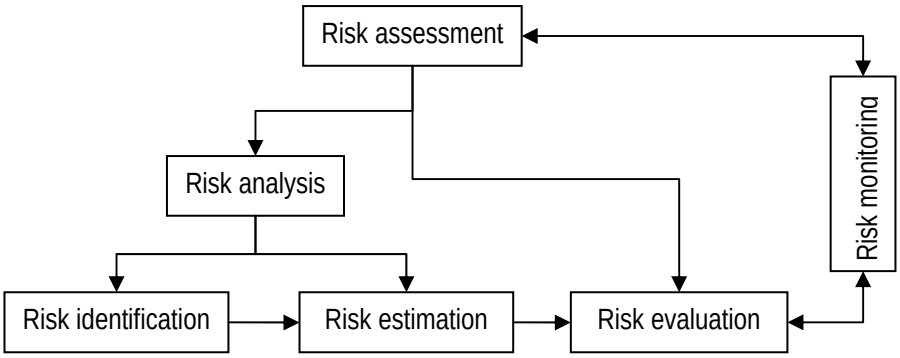

Figure 1. Risk management phases [ISO guide 73]

In this paper the three basic steps identification, estimation and evaluation of risks will be pointed. The aim of the first step, risk identification, is to find out and describe every possible failure for building components and their potential negative consequences. In order to do this FMEA (Failure Mode Effect Analysis) method is used.
During the risk estimation phase risks are measured, assigning a probability and a severity grade to the events and combining these data to achieve the risk dimension that is the fundamental parameter to determine risk response. This is of course a key point in risk analysis and the reliability of final results depends on various factors: the quality and quantity of available information about frequencies of the events; the presence of historical data about gravity of consequences; the accuracy of the technique used to measure the risks.
In many cases, because of the lack of statistical data in building sector, the risk estimation is based on qualitative approach [A.Ceric 2003]. In this research work a first qualitative risk estimation is implemented by a Montecarlo simulation forwarding a probabilistic approach, useful to measure which is the error in the estimations.
At the end, risk evaluation is the comparison process between risks exposure and the risk acceptability criteria to take decisions about the acceptability of risks and how to treat them to reduce the risk level. Of course, criteria are different based on the context and the strategy of the organization involved in the project.
Along all this process is important to consider just another phase that is the risk monitoring. It's very important to control the risk's tendencies and to make new choices about risk treatment.
Next chapter will present an integrated system of risk assessment applied to life cycle management, combining FMECA methodology and Montecarlo simulation.

2.3 Risk Analysis in Life Cycle Management

The studies presented in this paper show implementations of risk analysis tools to solve two different kinds of risks found in the life cycle management process:

- the first one is the risk associated to errors made using FMECA tool for prioritizing aging effects and their treatments (maintenance operations). So it will be possible to know and assess which is the retained risk also for unplanned maintenance operations (fig.2). To achieve this result it is necessary to implement a probability approach using Montecarlo simulations in risk analysis.
- the second one is the risk associated to errors made estimating time and costs of maintenance in maintenance schedule program. Also in this case a Montecarlo simulation is implemented to set up a maintenance plan with reliability information (fig.8)

The risk analysis method proposed to treat the first kind of errors comes out from collaboration between Polytechnic of Milan and CSTB (Centre Scientifique et Technique du Bâtiment – France) that in the last years have worked a lot on durability and life cycle management.

The common starting point of view is that FMEA and FMECA (Failure Mode Effect Analysis and Failure Mode Effect and Criticality Analysis) are the main tools to identify possible failures of building components and their effects during life cycle and to make a priority list of maintenance's operation to reduce the probability and the gravity of damns.

According to fig.2, the logical steps of risk identification using FMEA are:

- System analysis, divided in structural, functional and process analysis, in which the building components behaviour is studied;
- Qualitative failure modes analysis, in which are studied the components degradation modes, the causes of degradation and the consequences due to the degradation.
- Result presentation, that is the way to evaluate which are the most suitable maintenance operation to avoid the failure and so increase the durability of building components an the overall quality of life cycle (i.e. corrective maintenance, conditional maintenance, preventive maintenance)

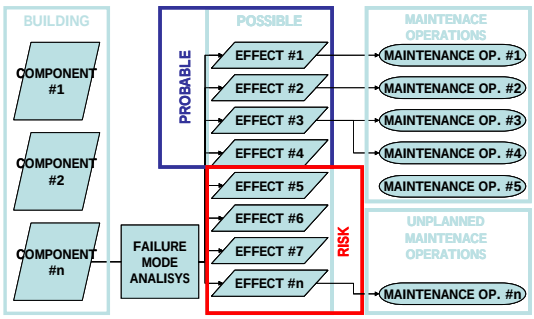

Figure 2. Risk identification using FMEA

The plain use of FMEA technique causes an important problem: every effect is measured estimating only the probability of the occurrences. This approach, in a risk analysis view, means to estimate only one of the two risk parameters necessary to calculate risk dimension. The negative effects of this procedure could be crucial. An

empirical law says that the less is the probability of an event the biggest is its gravity, and that the disasters are often the summarization of a lot of little probable events [Flanagan and Norman, 1993].
The aim is not to protect from all negative events, but to estimate related risk and control them during life cycle.

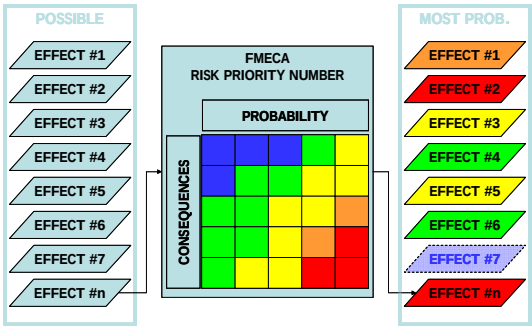

Figure 3. Risk analysis using FMECA

To solve this lack an implementation of FMEA tools was studied, named FMECA. The add value is represented by the implementation of a criticality analysis of the failure mode scenarios and their effects to obtain a risk list organized by priority based on risk dimension. So, both risk probability and risk gravity are measured and a risk priority value is attributed to the failure mode effect, simply multiplying the two previous parameters, as shown in fig.3.
In this way the list of possible effects becomes the list of most probable effects, and their treatments can be planned. In life cycle management it means to plan cost and time of maintenance operations.

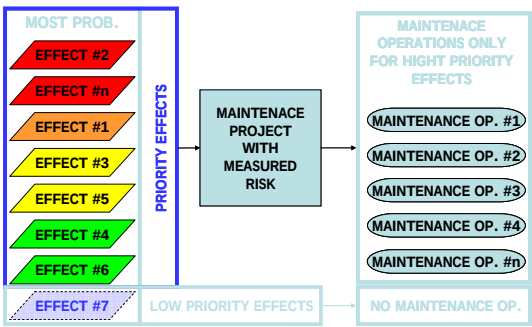

Figure 4. First level risk: errors in risk prioritization

As shown in fig.4 the output of criticality analysis implemented by FMECA is just a priority list of effects that should be treated in the life cycle, to guarantee the global durability of the building's components, but no measures of risk are presented: so, for example, risk 3 and risk 5 have the same priority and it means that is no possible to estimate the reliability of the risk estimation. Which one is better to consider as

first? Which is the error made during the estimation? How much is probable that a yellow risk will became a red one?
To improve the risk analysis, is important to measure each risk dimension considering the possibility of error made by the evaluator and improve a semi-probabilistic method.
The technique here proposed starts from a qualitative assessment of the probability and the gravity of events. In fact, for each dimension different classes that represent a different level of probability and gravity are proposed:

- Probability: form class 1 (very improbable) to class 5 (quite sure)
- Gravity: form class 1 (trifling) to class 5 (catastrophic)

For each class a standard numeric value is associated whose value is the same of the related class (from 1 to 5) and the evaluator, by a direct estimation, chooses the more suitable class for the two risk dimensions.
Though his decision can be supported by his own experience, historical data, and so on, it's always possible he is doing an error. So starting from the chosen class, a discrete distribution of probability is associated to all the dimension's classes (fig.5).

Probability	80.00%	10.00%	5.00%	2.50%	2.50%	100.00%
1	1	2	3	4	5	

Gravity	2.00%	8.00%	80.00%	8.00%	2.00%	100.00%
3	1	2	3	4	5	

Risk estimation

80%	5
85%	6
90%	8
95%	10

In a typical risk analysis the result of the risk measurement presented in figure 5 would be a risk equal to 3 (Probability 1 x Gravity 3). Instead, using the Montecarlo simulation it's possible to calculate the probability of error related to risk estimation (fig.6).
Today implementing a Montecarlo simulation is very easy (a lot of simple software can help to do it) and the benefits coming out are very significant. For the example proposed in figure 5 and 6, it's clear that a risk equal or less than 3 will be possible at 70%, but in other words it means that there is a 30% of possibility that the risk is higher: this information could be critical and is very important for the stakeholders during the risk evaluation.
The advantage is not only to have a risk measured, but also to know which is the attention level that the organization has to pay during life cycle management.

Figure 6. Percentile calculated by Montecarlo simulation

Besides, the knowledge of the variability of the risk estimation makes possible to set up a better monitoring system, that is the way to prevent the negative events or in the worst case to reduce their impacts.
After estimating risk and choosing the treatments, the next step is to schedule the maintenance program to build the economical and financial plan of the life cycle.
To do that it is necessary to estimate time and costs of every operation (the number has been already defined within the risk evaluation).
The risks linked to this phase are of two kinds: first of all the cost could be higher than the estimated cost; then the real moment of maintenance could be different from the period supposed in the plan. The financial consequences of these risks can be dangerous for the organization and for the durability of the building.

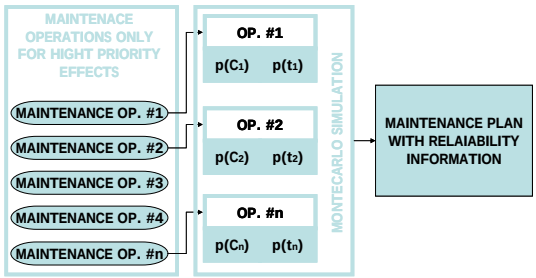

Figure 7. Semi-probabilistic approach for the maintenance time and cost scheduling

The idea is to move from a deterministic approach to a semi-probabilistic analysis and also in this case a Montecarlo simulation is the solution proposed.
First of all a deterministic assessment is made to estimate which is the most probable cost and time for the identified maintenance operation. Then other two values are defined both for cost and time: one that is the optimistic assessment and one that is the pessimistic value.
At the and by Montecarlo Simulation the uncertainty of time and cost is calculated for each maintenance operation planned. In this way a probabilistic relevance is

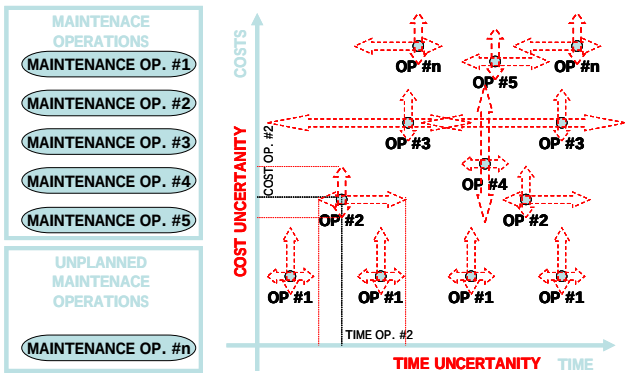

Figure 8. Cost and Time uncertainty in maintenance plan

given to the data loaded into the maintenance plan and the knowledge of the variability of time and cost let the organization to prepare the necessary financial resources for the maintenance operations avoiding ad surprises.

2.4 Case Study

A hotel building in the suburbs of Milan has been selected as the case study for this research. In particular, risk identification, estimation and evaluation has been made for the costs and time uncertainty in the maintenance plan made in the design stage of the building. Figure 9 shows results obtained in terms of reliability of costs forecast for the maintenance plan.
The information obtained by Montecarlo simulation can be use to take decision with a level of risk that is agreed by maintenance planner and the client.

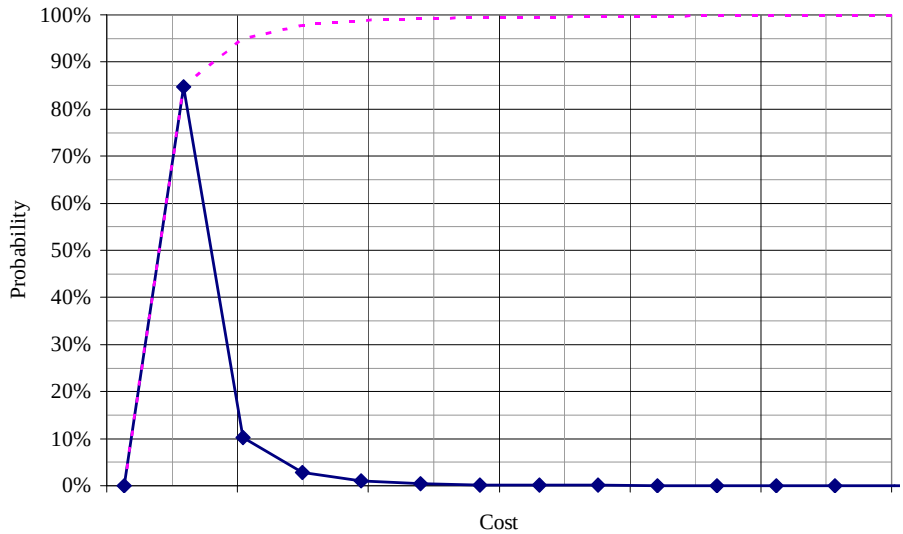

Figure 9. Costs probability of a maintenance plan calculated using Montecarlo simulation

3 CONCLUSIONS

Life cycle management is a risk business. Errors are likely to be done in the whole process and the presented research shows how to deal with to of the most likely. The questions are

- what if an unplanned maintenance operation is to be done? [i.e. what if an error is made in the FMECA process of prioritising effects?]
- what if time or/and costs forecast of a maintenance operation are wrong?

The paper shows how statistic can help practitioner to measure these errors and take more conscious decisions.

Service Life and Sustainable Design Methods: A Case Study

Johann Mc Duling [1]
Geoff Abbott [2]

T 51

ABSTRACT

The design life of hospitals normally varies between 50 to 60 years. This paper presents a case study of a major academic hospital that reached the end of its service life only 30 years after commissioning due to a combination of unsustainable design methods and inappropriate maintenance levels. Unsustainable design methods, such as long narrow multi-floor structures resulting in excessive walking distances and ineffective flow of patients and visitors, and insufficient structural depth and height, impaired the ability of the existing structure to accommodate changing demands of a modern health care environment, and the maintainability of services, such as sanitation, steam, ventilation and air-conditioning.

According to Ashworth [1996] building materials, components and technology may last for 100 years or more depending upon quality and standards, while engineering services have a life expectancy of about 15 years, and finishes and fittings frequently less than 10 years. Information technology hardware systems "are becoming outdated even after a period of only 3 years." This raises the question of a realistic design life for health care facilities. Should we not rather use a shorter design life to accommodate changing needs in modern healthcare technology and differences in life expectancy?

Inappropriate maintenance levels in addition to impaired maintainability of services due to unsustainable design methods caused premature deterioration to the extent that the facility's condition could no longer support a healing environment, resulting in a need to replace the hospital.

1 INTRODUCTION

This paper presents a case study of Tygerberg Hospital, a major academic hospital near Cape Town in South Africa, that reached the end of its service life only 30 years after commissioning due to a combination of unsustainable design methods and inappropriate maintenance levels. Tygerberg Hospital was conceptualised nearly 50 years ago and has been in operation for 32 years. During this time the community served and service required have changed as have health service delivery and medical training philosophy and practice, medical technology has developed substantially, and new technologies such as ICT have evolved. Unsustainable design methods, such as long narrow multi-floor structures resulting in excessive walking distances and ineffective flow of patients and visitors, and insufficient structural depth and height, impaired the ability of the existing structure to accommodate changing demands of a modern health care environment, and the maintainability of services, such as sanitation, steam, ventilation and air-conditioning. At the same time maintenance has been wholly inadequate and the condition of the buildings has deteriorated significantly. Many of the technical and engineering systems have also reached the end of their design life.

Tygerberg currently operates as an academic institution with 1 290 commissioned beds, some 600 fewer than the original design provided for when built in the early 1970's. The facility has some 74 buildings totalling some 312 000 m^2. Not all the buildings are currently used as hospital buildings. The main block is some 218 000m^2 and is 15 storeys high.

2 FACILITY ASSESSMENT

During 2005 the Council for Scientific and Industrial Research [CSIR] was commisioned to undertake a high level options review of Tygerberg Hospital aimed at identifying and quantifying the implications of redeveloping the facility from its current service to its planned use in terms of the 2010 Health Service Plan for the Western Cape. The study was confined to the administration block, the main hospital block, mortuary, oncology unit, boiler house, pump house and main electricity substation as well as the interlinking site engineering services reticulation.

The provision of health services at Tygerberg Hospital is influenced by the physical design of the facility, the current condition of the buildings and services infrastructure and the way in which the facility is currently being operated and maintained. The review covered, therefore, both an assessment of the existing structure in terms of its current use, condition, functionality and suitability as well as of the potential of the existing shell for redevelopment. As such the study provided the platform for the development of options for redevelopment.

A wide range of issues were identified in the study pertinent both to the development of options for the redevelopment of Tygerberg as well as important for the ongoing operation of the facility in the interim period while the selected strategy is being implemented. Should the existing facility be retained, the location of some departments will need to change as existing relationships between departments are not always ideal and many departments would need to be remodelled to a greater or lesser extent to accommodate more efficient planning, new service requirements and general upgrading.

A range of condition and non-compliance issues were highlighted by the assessment team as needing either critical or urgent attention. Critical issues included soil water discharge pipes and stacks and fire systems, while urgent issues included theatre air-conditioning, vacuum, potable water, lifts, cleaning and various hospital maintenance issues. Measures have been introduced by the Department to address these issues in the short to medium term during the redevelopment process. Some of these will impact on the redevelopment strategy and investment required.

2.1 Physical Assessment

The overall condition of the facility was found to have deteriorated further from the average 3,65 condition established in the 1995/96 National Health Facilities Audit to 3,02 on a 5 point condition assessment scale [5 being very good and 1 very bad] representing an increase in the maintenance backlog over the 10 year period of some ZAR335m [ZAR7 = US$1±]. This average figure hides a range of elements where the condition was found to be substantially worse while in a few areas the condition had improved due to limited recent repairs and upgrading [as in some wards]. While the overall shell of the building, with the exception of the roof, appeared to be in relatively good condition, of primary concern are a number of core systems and elements identified such as the soil water [sewage] system in the building, various mechanical systems including air-conditioning, medical gases and steam systems and some electrical systems such as lifts. The level of maintenance was found to be very low with a lack of planned or preventive maintenance.

The poor condition of key systems and components in the facility coupled to physical design constraints and ad-hoc changes made to the building in use, have led to the situation where the facility, in many respects, no longer meets required service delivery standards or legislated performance safety standards and has reached the end of its service life 20 years prematurely.

2.2 Functional Assessment

The current utilisation of Tygerberg Hospital, at 1 290 beds, is more than 35% below the original design capacity. With the planned utilisation expected to remain at about 1 300 beds, the existing facility measures nearly twice the area per bed than currently accepted as the norm, with significant negative functional and operational implications. There is no clear entrance or point of arrival, and the dual corridor legacy of the original functionally separated design and current scattered location of departments [such as the poor relationship between theatres and ICU's] lead to poor functioning, operating inefficiencies and pressure on staff and risk to patients. The functional layout of wards and ICU's are particularly poor, being constrained by the physical shape of the building and circulation. The design and current use does not allow good operational practice to be adhered to, resulting in high infection risk to patients and staff alike. Of particular concern is the use of the ICU's as thoroughfares from one side of the hospital to the other and various compromises in good theatre practice.

A number of issues were also identified in the assessment where there was concern regarding patient and staff safety through non-compliance with provisions of the Occupational Health and Safety Act [OHS] and the National Building Regulations [NBR]. Areas highlighted in the operational risk and regulatory compliance assessments include fire risk, materials handling, air-conditioning and ventilation systems, finishes, water supply and sanitising equipment and medical gases. Action, identified during the assessment, has been initiated to bring aspects of the facility into line with most requirements of the OHS Act and NBR. Some are being addressed at a management level but many more are fundamental in nature, such as fire compartmentation and shallow buildings unsuitable for modern hospital layouts, and will require major remodelling of the shell to resolve.

2.3 Financial Performance

It is estimated that the current equivalent cost to rebuild the hospital as it now stands is some ZAR1,92bn [including Value Added Tax and professional fees], more than 50% above the current benchmark cost of R1,24bn for a new facility. The estimated budget to reinstate the facility to an acceptable condition is ZAR788m or over 60% of the cost of a new facility. The actual annual current maintenance expenditure of ZAR35m is only 4,6% of the estimated current requirement.

The total hospital [including salaries, administration and medicine] and facility operating costs

[including utilities, steam, security, cleaning, building and equipment maintenance] are 32,5% and 4,8% respectively of the current equivalent construction cost. Facility operating costs are well below benchmark levels as building maintenance, cleaning and security are all well below estimated funding requirements. The balance between facility and service operating costs will change for those options where the total building area is reduced to actual requirements.

2.4 Transient, Alterable and Fundamental Issues

Issues identified during the assessment can be classed into one of three broad categories: transient, alterable or fundamental issues. Transient issues can generally be addressed through management intervention alone and include housekeeping, and some legislative compliance and safety issues, such as blocking of escape routes by stored equipment. Alterable issues generally require minor or major capital work and include issues that can be undertaken without significant, long term disruption to services and include issues such as redecorating or repair of finishes, and repair or replacement of engineering plant or equipment [e.g. air-conditioning, lifts and standby generators].

Fundamental issues affect the basic structure and systems and require major intervention and disruption to normal operation, usually involving major building work at high cost. These include issues such as layout, structure, and replacement of major engineering systems and networks. All three levels are evident at Tygerberg. Many of the problems, such as the shallow buildings and the physical spread of the overall structure [24 km of passages] are fundamental and intractable and can only be addressed through extensive demolition and remodelling of the shell at very high cost.

2.4.1 Design and Layout

Most new wards in modern hospitals have a far more compact layout than those at Tygerberg, see Figure 1 below. There are significant advantages to a compact design including shorter walking distances between patient beds and key work areas [nurses station, clean and dirty utility, etc], better observation of patients by staff, less overall area, better external wall to area ratios and therefore lower cost. A compact ward with a central nurses' station also allows more effective air-conditioning air flow with supply flow from the nurses' station outwards through patient and service rooms.

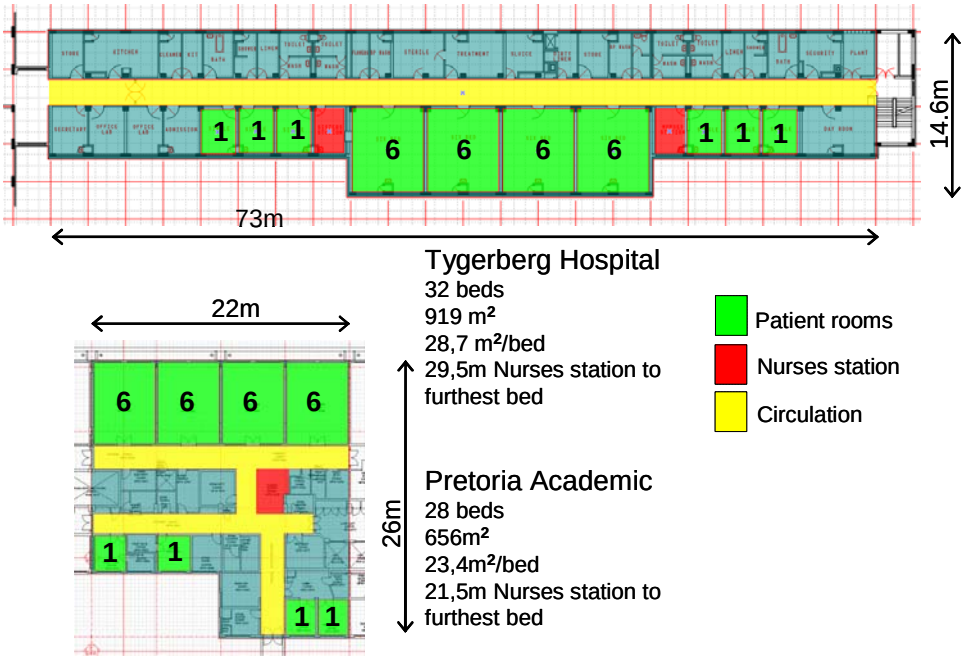

Figure 1: Ward shape comparison

The current elongated layout was designed originally for natural ventilation. Air-conditioning was added but is not working. The location of the plant rooms [at the furthest point from the entrance near the escape stair] is problematic as all maintenance and moving of soiled filters have to go along the length of the ward. The elongated ward required the separation and duplication of some support spaces including two nursing stations [ward secretary at entrance, sister's station and nurse's station along the length of the ward], two sluice rooms [including duplication of equipment], two linen rooms, and main kitchen and sub-kitchen. Control of the ward and observation of patients is problematic and security is a concern. Patients in single rooms towards the end of the wards can easily be forgotten. Many of the wards have their escape doors leading to the fire escape stairs locked for security reasons or open but not alarmed.

2.4.2 Replacement of Major Engineering Systems and Networks

The access to service ducts is from inside the building as shown in Figure 2 below. This makes maintenance and repairs extremely difficult. Removing blockages from sewer pipes is difficult resulting in spillages of waste, sometimes into wards, as shown in Figure 3 below. Replacing sewer pipes can only be addressed through extensive demolition and remodelling of the shell at very high cost. The same applied to the steam and airconditioning installations.

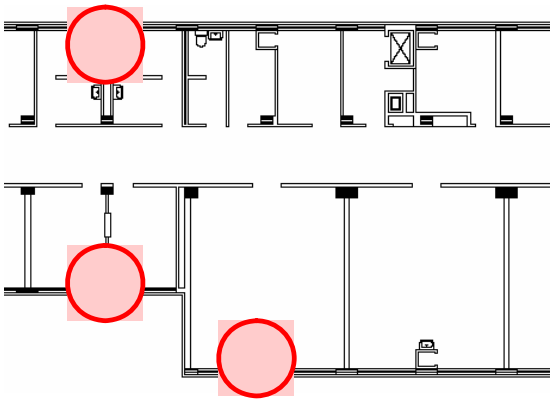

Figure 2: Location of Service Ducts

Figure 3: Duct to Service Duct, Inside Service Duct and External Wall outside Service Duct

2.4.3 Maintenance Levels

In Figure 4 below, the actual average condition of Tygerberg Hospital as assessed during the NHFA and 2005 CSIR assessment is compared to the anticipated change in average condition over time for various levels of maintenance, ranging from no maintenance to a very high level of maintenance. For a health care facility, such as Tygerberg Hospital, a high level of maintenance [the curve second from

the top] would be appropriate. From the graph it can be seen that the 1996 NHFA and 2005 CSIR Assessment average condition of Tygerberg Hospital falls on the low maintenance curve.

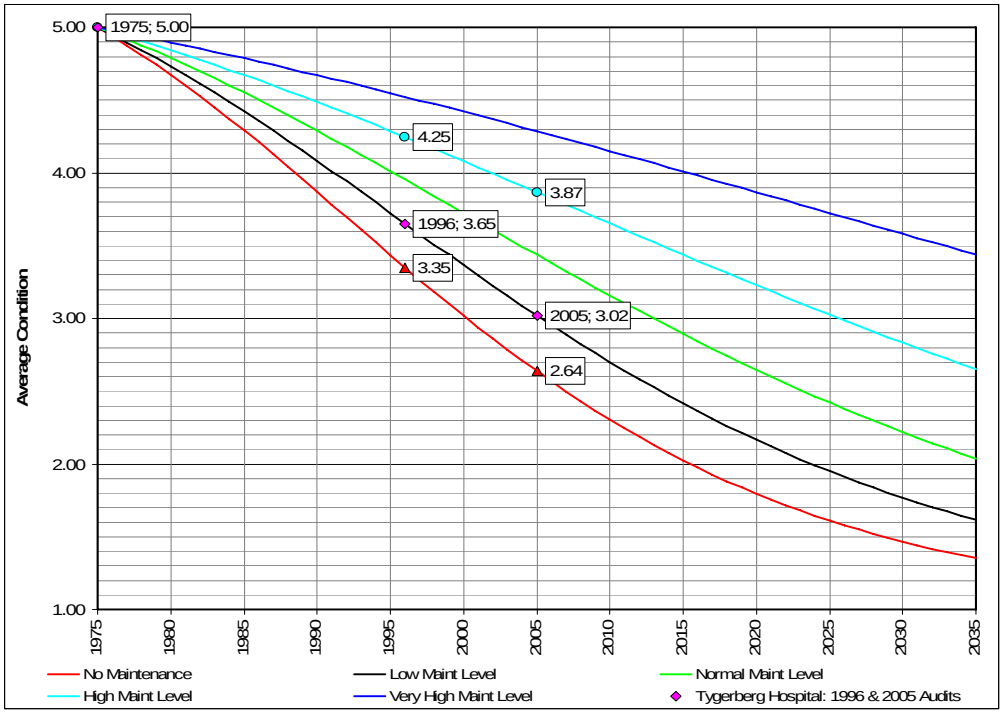

Figure 4. Anticipated Average Condition over Time vs Level of Maintenance [Mc Duling, 2006]

The anticipated average condition of Tygerberg Hospital should have been around 3.87 for a high level of maintenance and 2.64 for no maintenance. The consequences of the inappropriate level of maintenance amount to R428 million more required now than what should have been the case if the facility was properly maintained [high level of maintenance].

3 OPTIONS DEVELOPMENT AND APPRAISAL

In order to address the primary concerns identified in the assessment study, three broad redevelopment options, outlined below, were identified for further development, costing and evaluation. The results of the assessment and the options development study were presented at a workshop of key role players from the Hospital, the Medical Faculty and the Departments of Health and Public Works. The advantages and disadvantages of each option were reviewed and a high level of consensus reached that Option C, for a new facility, would provide the best solution.

3.1 Option A – Rehabilitation

This option involved the reuse of the existing hospital buildings with minimal alterations and upgrading, sufficient only to address areas of critical interventions identified in the assessment and to create separate level 2 and 3 management units. This option was not supported as, while the capital costs and relative speed of delivery are lower than other options, most of the inherent constraints, costs and inefficiencies of the existing shell would remain and, as the area will still be far more than required, operational costs would be far higher than other options, leading to substantially higher operational costs in total.

3.2 Option B – Remodelling

Option B involved the reuse of the existing shell with extensive remodelling to address key functional, condition and compliance constraints identified in the assessment. Entrances, circulation and layouts would be rationalised and many features of a modern hospital could be built into the design. While the solution would have offered a workable hospital within the existing shell and the net present value [consolidating capital and operating costs over a 10 year period] would be slightly less than for a new facility, the solution was not supported, as there was still a significant legacy cost to the remainder of the shell and the severe disruption to hospital operation, patients and academia during remodelling.

3.3 Option C - New Facility

Option C involves building an entirely new facility on the same site and either the demolition or reuse of the existing facility for a new function. While this solution has higher capital costs, operational costs will be the lowest of the three options and over a short period the solution will become far more economic than working with the existing facility. This solution was supported for further development as it offers the most effective financial and functional solution and has the major advantage in that all construction work will be separated from the running of the existing facility.

4 CONCLUSION

Tygerberg Hospital reached the end of its service life only 30 years after commissioning. The design life of hospitals normally varies between 50 to 60 years, which means between 40% and 50% of its design life has been lost.

Building materials, components and technology may last for 100 years or more depending upon quality and standards, while engineering services have a life expectancy of about 15 years, and finishes and fittings frequently less than 10 years.

This raises a number of questions around a realistic design life for health care facilities. Should a shorter design life not rather be used to accommodate changing needs in modern healthcare technology and differences in life expectancy? Can we really plan for 50 to 60 years when technology develops at a mind-boggling rate? Why plan and design for 50 to 60 years if after 30 years new healthcare needs render the facility unsuitable? Should we not rather use a shorter design life to accommodate changing needs in healthcare technology?

ABSTRACT

The EU project Smart-ECO brings together experienced organizations spanning the full range of stakeholders covering the area of sustainable building. These include universities, R&D organizations, companies developing, supplying and using innovative technologies, consultants, users, government and policy makers. Smart-ECO uses this core partnership together with a wider stakeholder group community to focus on global issues of sustainable building to identify and evaluate priorities for current and future RTD activities. Activities and policies are due to be mapped to identify gaps and to focus future efforts. Innovative technologies, as well as improvements of the construction process, and their introduction into the building sector will be considered in relation to sustainable development, life performance, ambient intelligence, and other relevant stakeholder concerns.

The project focuses on routes and means to enable the uptake of efficient technological and non-technological innovation that in turn enable the building and construction sector to meet the requirement for sustainable building. The current situation and the vision of a more sustainable built environment sets the frame for the appreciation of the long term effectiveness of Eco-buildings and innovative technologies, especially renewable energy systems. Together, the vision and relevant EC policies will serve as a reference framework for the analysis of life performance aspects of innovative technologies applied to realise more energy efficient and more sustainable buildings.

This paper presents and discusses the process of establishing a reliable vision for sustainable buildings and related performance requirements.

1 INTRODUCTION

Smart-ECO is the acronym for the EU-FP6-project "Sustainable Smart Eco-Buildings in the EU". The project started in October 2007 and is conducted by a project consortium consisting of 12 partners, led by the Center for Built Environment at Gävle University in Sweden.

Smart-ECO aims to evaluate technical and non-technical innovations relative to their contribution to a vision for sustainable building. Such innovations will only be successful if the potential to implement and apply the new solutions will be sufficiently promising. Consequently, combining these criteria, we will deem any innovation to have promise if it is satisfies the following:

- It contributes to the development that is in-line with the vision for sustainable building
- It fulfils the desired performance requirements that arise from such a vision
- It is perceived as being feasible by a wide range of stakeholders.

To start with, the vision for sustainable building needs to be identified, discussed and anchored with a relevant panel of stakeholders that is wide enough to represent all legitimate views on sustainable development in the building sector. As the building sector is so strongly interlinked with other sectors of the economy (i.e. the energy sector, transport, and labour development and deployment), the perspective applied when establishing the vision needs to be extensive and all-inclusive. The project vision aims to use the current status of sustainable construction within the EU (including the major outputs of previous related EU projects and thematic networks) as the starting point and to set out an ambitious yet realistic roadmap of development.

An extensive stakeholder group has been formed to contribute to the establishment of the vision and to serve as an anchor providing legitimacy to the reference points of the project. The starting point is represented by the current position and described by established practice, current policies, existing standards and EU-directives. An analysis of completed and ongoing research and development projects may provide an indication of the short- and mid-term drivers for development. Strategies and policies addressing other sectors, especially energy and transport, need to be considered as well, as they often address aspects that are relevant to the building sector.

A vision is usually a rather descriptive and qualitative presentation of the ambition. However, specific, measurable requirements and metrics are needed to quantify progress towards successful development of movement towards realising goals in the vision. The potential of technical and non-technical innovations to contribute to such developments can then be discussed and assessed against the requirements.

The later evaluation of innovation will necessarily apply these metrics, after discussion and agreement with the stakeholder group. The evaluation should not only consider the requirements derived from the vision, but should also address other stakeholder concerns. The stakeholder perspective is the core novelty of this approach, based on the project group's conviction that it is essential to successfully bring innovation into application. The implementation of such an evaluation routine itself can be interpreted as a non-technical innovation aiming at enhanced sustainability in the building sector. Likewise the application of assessment methodologies as part of the evaluation of building sector products and services can be perceived as innovative. The project therefore applies a cycle of self-evaluation involving assessment methodologies such as Environmental Life Cycle Assessment (LCA), Economic Life Cycle Assessment (Life Cycle Costing LCC), Service Life Planning (SLP), Life Cycle Management Systems (LMS) or the concept of Performance-Based Building (PBB).

2 THE INTERNATIONAL PLAYING FIELD

The recent United Nations Climate Change Conference in Bali, 3-14 December 2007 clearly brings the international discussions on climate change to the mind and its relevance to sustainability. While ongoing, the expected short term outcomes range to be somewhere between no agreement, continued discussions, or agreement to a reduction target for industrialized countries somewhere between 25 and 40% by 2020. The Kyoto conference and all subsequent conferences and protocols are an excellent example for the international process of policy setting, when international concerns need to be balanced with national and regional interests. However, it seems very likely that the political consensus is moving to embrace significant, concerted international action to address the challenge of a changing climate.

Sustainable Development is a much broader thematic complex, and an EU-project vision for sustainable building must necessarily be embedded in the interpretation of the concept of sustainable development to "sustainability in building construction" and to the regional situation and the regional potentials of the building and construction section in Europe. As an internationally harmonized background, a set of ISO standards is well advanced, and a further series of CEN standards is also under development; with its core content published and available to serve as a reference point (*see "International Standards on Durability and Sustainability of Buildings and Construction Works" by Sjöström, Trinius, Davies and Lair in these proceedings*). The ISO standards discussed in that paper are those directly applicable to the vision-requirements-innovation-evaluation process of the Smart-ECO project presented here, using the ISO standards presented in the companion paper.

Finally, addressing the building and construction sector also results in considering various international Agendas being of relevance, like for instance the Habitat Agenda, and the older but still very relevant CIB Agenda 21 on Sustainable construction.

3 THE EUROPEAN PLAYING FIELD

Giving itself the task to develop a vision for sustainable building in the EU, and to measure the contribution of innovation to that vision requires:

- The expression of the vision and the identification of clearly described measures expressing that vision (requirements)
- The identification of the current state as the "starting point", and the goal status against which we can measure progress towards the vision
- The identification of technical and non-technical innovations that need to be considered, discussed and evaluated in contributing to realising the vision.

Consequently, the current status of the construction sector and the business environment in terms of policies, directives, standards and legislation needs to be scrutinized and expressed to provide a initial starting basis for the Smart-ECO project. At the same time, it is clear that conditions vary throughout the European regions and countries, so that innovation with a promising potential in one region may fail in other regions. Applying what is common practice in one region may be perceived as highly innovative in another. Applying a "national" approach is not the aim of Smart-ECO, as it does not focus on policy setting. However, Smart-ECO is part of a "project cluster" together with other R&D projects, one of which, ECOBUILD, focuses on innovation and policies supporting innovation. Instead, Smart-ECO can adapt to regional differences and commonalities by relating the evaluation of potential impacts of innovation to clearly described characteristics of the built environment, the social environment and the economic environment within which the innovation needs to perform.

The European Construction Technology Platform (ECTP) aims to increase the sector's performance and competitiveness, by analysing the major challenges in terms of society, sustainability and

technological development. Concerning sustainability, the platform's first ambition was to raise awareness among stakeholders and to promote R&D activities bringing human concerns to the forefront (ECTP 2007). Again, these sector ambitions, put together in the Strategic Research Agenda (SRA) are a highly important existing driver, to which the Smart-ECO project should connect.

4 EU POLICIES AND DIRECTIVES

The European Commission communicates white papers, green papers and prepares policies, communications and guidelines, as well as Directives and Regulations in fields that are crucial to the building and construction sector. Besides Directives and Regulations directly aiming at the sector and its products, such as the Construction Products Directive CPD (Council Directive 89/106/EEC) and the Energy Performance of Buildings Directive EPBD (Directive 2002/91/EC), other Directives address sectors that are significant to the building sector, or address cross-sectorial concerns, such as the Council Directive to limit carbon dioxide emissions by improving energy efficiency (Council Directive 93/76/EEC). Specific functional components, such as e.g. boilers, may also be subject to product specific Directives (Council Directive 92/42/EEC), and to the Framework Directive for energy using products.

Following EC policies and Directives, various initiatives and projects may follow, the R&D Framework Programmes are aligned, and standardization and harmonization tasks may be initiated. These overall initiatives set the frames for business development and aim to create the means needed for the industries to develop into the desired direction.

5 TOWARDS A STAKEHOLDER SUPPORTED VISION

In order to apply a sustainability perspective to the appreciation of innovative technologies for the building and construction sector, a vision for sustainable development in construction needs to be established and anchored with requirements from the stakeholders. Determining the vision consists of three components:

- Analysis of the current European status for guiding principles and reference points, which can be drawn from EU policies and Directives, and from RTD and TN projects performed under FP5, FP6 and other initiatives.
- To determine the requirements of the stakeholders that support EU policies on sustainable building together with the indicators to assess the impact of the innovations
- To plan a development pathway for the EU building sector, to meet the vision of sustainable development and address parallel European interests concerning innovation, technology, quality of life, etc.

This vision needs to be developed and "owned" by the stakeholder community. Then it can be adopted to serve as the "guiding light" for the consideration of life performance aspects of adopting innovative technologies and process improvements to be more energy efficient and more sustainable. Ultimately, such a vision will be vital in enabling the assessment, promotion and dissemination of all the new concepts proposed by Smart-ECO as well as other FP5 and FP6 projects.

Elements that can contribute towards achieving a more sustainable construction sector, and their potential impact if successfully adopted, need to be identified. Smart-ECO will investigate the approaches and results of completed and ongoing international research projects, thematic networks, various EU and international policies and international standardisation activities (in ISO and CEN).

The vision developed for sustainable buildings and the associated metrics developed will form a reference point against which to estimate the potential contribution of the various technical and non

technical innovations which may contribute to it. Research and development projects usually contain an evaluation as well as a dissemination and implementation part, however the criteria for the evaluation is to be set from within the project's own frame. Without disregard to the validity of such evaluations, Smart-ECO will perform new wide-ranging evaluations using the developed and accepted vision as the setting to assess the contributions of the projects and their potential impact.

"Elements" considered can be technological innovations (e.g. PV systems, bio-mass, wind energy generators, solar thermal technologies, smart decision making, etc), methodologies for analysis and assessment (e.g. Life Cycle Assessment (LCA) and Life Cycle Costing (LCC), management concepts (e.g. Life Management Systems), standards (e.g. General Principles of Sustainability in Building Construction), recommendations (e.g. those gathered within the EC thematic network on Practical Recommendations for Sustainable Construction (PRESCO)) and tools (e.g. systems of indicators as proposed by the EC Thematic Network on Construction and City Related Sustainability Indicators (CRISP)).

For the vision to be useful it must be able to be used to determine "useable metrics" based on the requirements to estimate the impact potential of successful adoption of eco-building innovations. The metrics established for the various elements under consideration need to be able to objectively assess vastly differing innovations so that proper comparisons are possible. When it comes to the process aspects and the new approach for designing and planning a project, the same ambition applies, and for instance the results of the EC Thematic Network on Performance Based Building (PeBBu, 2005), and of the European Construction Research Network (e-Core, 2005) will be investigated in terms of assessment indicators identification.

Hence the innovations must be investigated, the metrics to be used in assessing their contribution to the vision defined, and a methodology to estimate the likely impact of the innovation formulated.

Smart-ECO will illustrate how technological and non-technological innovations that have the potential to contribute to the vision can be promoted in order to become successfully integrated into the construction sector. The project will show where and how existing elements can measurably support the vision, how far the building sector can develop towards the vision based on these elements, and indicate what further innovation is needed to meet the aims of the vision. Relevant stakeholders and multipliers (including education and training organisations) will be key targets to whom the project's results will be disseminated. This is a bidirectional dialogue rather than a dissemination of project results.

6 DISCUSSION AND PERSPECTIVES

The building and construction sector is facing significant challenges. Sustainability, Performance-based Building and Performance-based design and facility management processes are key items and strong priority themes describing international trends and drivers for research and development as well as for standardisation, policy setting and market initiatives.

International Standardisation as well as European Standardization develops standards addressing sustainability in building construction. The conceptual anchor is the concept of sustainable development, as laid out in the Brundtland report to the United Nations. With respect to further work of, for example, UNEP, the WTO, etc, the concerns of sustainable development have matured and now not only policies are being set in relation to sustainable development, but also businesses address these concerns. Indeed, it is arguable that the primary driver of the sustainability agenda is now the business community. Consequently, businesses need to, and want to, adopt and communicate sustainability-related issues. International standards aim to define a common basis against which information can be

communicated. With the first sets of standards available, the communication of information between businesses but also between businesses and consumers is being made easier.

Another, even more important, step is the creation of a market for information relating to sustainability. When market actors generate information about their environmental, economic and social "sustainability performance", they do not only want to be able to communicate such information externally, but to use such information in their decision-making within their business.

Building designers, investors, facility managers and users rely on information that is provided from the product chain, from product manufacturers and from service providers. Whenever a building is the object of for example, an environmental assessment, information about all its constituent parts, plus information about the building itself and its context is needed. At the same time, manufacturers and providers will often only generate the information where they see a larger scale of application.

Any decision-making that takes account of sustainability information will usually rely on the capability to express targets or goals for sustainability aspects of a service, product or building. Decision takers need to be able to express goals, to relate information to these goals and to make balanced judgments of decision alternatives. Such decision-making necessarily involves the consideration of the functionality and the performance of the object. ISO/FDIS 15392 states "sustainable development of buildings and other construction works brings about the required performance and functionality with minimum adverse environmental impact, while encouraging improvements in economic, social (and cultural) aspects at local, regional and global levels". With this, the concept of performance-based building and performance-based facility management becomes an integral part of sustainable building. The concept is open to involve the anticipated business-model move from cost-based construction through service-based construction to value-based construction (Haagenrud 2007), all depending on the concerns for which performance requirements can be expressed and handled in the decision making processes.

The management of sustainability-related information as well as the management of performance requirements gains a significant role when striving to bring the construction sector towards sustainability. The current habit of re-entering more or less the same information up to seven times (Haagenrud 2007) provides for errors and causes cost. The information communicated to decisions makers relative to sustainability aspects is substantial in quantity and complexity. Databases fed from relevant and reliable data sources, on the basis of an agreed data set, paired with communication formats and interpretation aids are elements of the route currently being pursued in R&D and standardisation activities. Object-based generation of information, related to the decision alternatives as well as to the decision context of decision takers is suggested to be a powerful support on the route from "required sustainability", through designed and constructed to "delivered sustainability". The challenge for ICT structures facilitating the information, is naturally the content and the knowledge provision, where the implementation of performance based standards for sustainable construction are the key to pursue a sustainable value-based construction sector (Haagenrud 2007 and *EU-project STAND-INN –Integration of standards for sustainable construction into business processes using IFC standards* in these proceedings).

The ultimate and again very significant milestone on the route to achieving a more sustainable built environment is to enable the building user to operate the building in a way that it can actually achieve its intended performance in practice. For the Smart-ECO project, we entitled this last milestone as "smartness" – claiming that a high performance building may still be a failure if the users, whether professionals or private, do not have the capability or the information required to operate the building as intended, or as foreseen when designed. Bordass and Leaman have published extensively on the problems of user interactions with buildings, most recently in Leaman and Bordass (2007) but also in Derbyshire et al (2001).

At this point, let us redirect our attention to the Smart-ECO project presented here. Reflecting the above, Smart-ECO aims to

- establish a vision for sustainable building
- translate that vision into requirements
- apply the requirements in terms of indicators in the evaluation of innovation
- communicate the potential contribution of innovation to towards the vision

Throughout this process, stakeholders representing the various demands and interests of the building and construction sector, including the users and policy makers, are given not only a significant influence as a reference panel, but are given an active role in the establishment of the reference terms, requirements and indicators of the project.

Durability in Technology Design

Jacopo Gaspari [1]

T 51

ABSTRACT

The achievement of a sustainable dimension in contemporary architecture is a challenge that engages both its design and materials, components, systems the building is made of. Nevertheless durability is, nowadays, more than a requirement in the design phases. As a consequence the concept on which the building is based is deeply connected with the expected lifespan. No sustainable requirements can be correctly evaluated without using an Extended Life Cycle Cost (ELCC) approach.

This research is based on the idea that part of a sustainable approach is aimed at a building lifetime in which its quality could be preserved. Starting from this point of view durability is intended as the skill of a building to maintain efficient and functional its features in the time.

Lifespan can be influenced by the technology used, the maintenance and rehabilitation activity, the random events. The problem has been examined from a technological point of view. Masonry, concrete, steel, wood technologies present different expected lifetime. The growing complexity of the contemporary project leads to new requirements related to durability and performances.

The design activity plays a central role in the contemporary building process. Some case studies are used to analyse a new possible trend in building conception. This trend identifies some “permanent” and “reversible” elements in the building. The first ones are those, like the primary structure, the service core, the technical spaces, whose role and performance in the construction can be considered the same for all the lifetime. The second ones are those, like a cladding system or a climate control device, that can be changed in order to obtain an higher level of performance. Consequently the design activity has to foresee two different levels of durability which correspond to a more adaptable and sustainable use of technologies and materials.

1 INTRODUCTION

Durability is a concept that has deeply changed its meaning during the time. Not really in its inner meaning that is still connected with a long period of time, but rather in defining the span of this time. In ancient times buildings were supposed to last for centuries, nowadays we design our buildings with a different approach. They have to reach their higher durability in relationship with the performance they've been built for. So durability is a matter of materials and components, but also of a design approach and of a technological choice. A cultural change is occurring in the world of building construction. Achieving a sustainable dimension in architecture, as part of a suitable sustainable future, has become a need, no more a desire of a limited part of the society. A sustainable construction is a challenge that is not only connected with the idea of an energy conscious building or a reduction of environmental costs during its realization, but also with the idea that the impact of building process conception would deeply influence both the design phases and the management ones.

In this topic, innovation technology, translated either in new concepts or applications, plays an important rule. A theoretical analysis of innovative contributions in building process using the Extended Life Cycle Cost (ELCC) method has been developed. This study aims to define new sustainable requirements and, basing on a comparative process of design methods and technologies used, to upgrade the assessment action with tasks related to design phases and management, maintenance and rehabilitation ones[1]

2 BUILDING PROCESS AND SERVICE LIFE

2.1 Durability and Quality in Technological Choice

When innovation is associated with the world of constructions its meaning is often linked with new materials or new systems.As Martin Pawley reminds [Pawley, 1990] some new materials and techniques have led to epochal changes in building construction, nevertheless another kind of innovation silently feeds evolution of buildings' world. It has been defined "the invisible technology" [Sinopoli, 1997] and it concerns both design and construction process. It has been called invisible because it isn't linked to the use of new materials or components, but it is the result of the relationship between the different "actors" involved in the building process. Their contributions start with the building conception, pass through its construction, management, use and end when the building has expired his time.

Durability involves all these phases and must be considered not only for what concerns the behaviour of materials and components during the lifetime of a building, but also when the building as a whole ends to work. A growing sensibility in contemporary building design is leading to foresee what it'd happen at the end of its lifetime, with the so called "deconstruction activity". This new task is strictly connected with the time a construction system is expected to preserve his quality. Quality is a concept which has been evolving during the time with the introduction of new requirements and functionalities involving sustainable strategies. For a technological system, durability can be intended as the skill of a building to maintain efficiently its quality, features and functions during the time [Manfron, 1995]. This can be deeply influenced by the materials used and by the construction methods.

To analyse the quality of a building as a whole means essentially to verify the technological solutions adopted in relationship with the expected lifespan [Manfron, 2005]. Technological choice is one of the most important elements which can influence lifespan. Masonry constructions, like most of historical buildings, may have an Expected Life Cycle ($E_{xp}LC$) of about 500 years, concrete and steel structures an $E_{xp}LC$ of about 300 years, balloon frame an $E_{xp}LC$ of 50-100 years, Hi-Tech is supposed to have an

[1] For this reason a research program that joints innovation technology, sustainable construction and assessment methods has been activated at IUAV University of Architecture in Venice. Part of this research is led in partnership with the PHD Technology School involving IUAV, Ferrara University of Architecture and Cesena University of Architecture.

E_{xp}LC of 50 years. These elements suggest how deep is the link between technological choice and durability and how the concept of durability can be different.

As an higher level of durability is not a direct consequence of an implementation of technological complexity, most part of this research concerns the assessment of recent technologies application, like assembled construction or Hi-Tech, trying to understand how they can influence the behaviour of the building with the passing of time. As a consequence the attention to the design activity has grown and the conception of the building has become the central point of the analysis.

2.2 Cost and Requirements in the Extended Life Cycle

The conception and the design weight strictly depend from the point of view the building process is examined. In preliminary phases, we are used to assess a project through costs evaluation which often involve only economic reasons. Otherwise, evaluating a project, environmental, social, cultural and energy costs, etc., must be considered too [Odum, 1997]. The Generalized Cost Equation (GCE) [Manfron, Siviero, 1998] summerizes costs as follows: $C_{gen}= C_c+C_m+C_{ma}+C_{re.}$ Where C_{gen} is generalized costs, C_c is construction costs, C_m is management costs, C_{ma} is maintenance costs, C_{re} is random events costs. All these factors can be specified in other sub-cost factors. Construction costs, for example, can be expressed as the addition of planning costs, site costs, design costs, building costs, etc.

These factors, typical of the preliminary phase of building process, involve mainly the promoter, the general contractor, the design team and the builder. All these "actors" share the interest to minimize, from an economic point of view, the so called Initial Costs (IC) which can be synthesized as follows:
IC = PC + FC + DC + BSC + CC + … Where PC are the planning costs, FC are the financing costs, DC are the design costs, BSC are the building site costs, CC are the construction costs. For all the actions connected to these cost factors a list of sustainable requirements can be set [Table1].

Table1. List of sustainable requirements set for the "actors" involved in the construction process.

Planned measures to minimize construction accidents
Planned measures to minimize construction time
Prefabrication/industrialization
Fast transport and packing
Reduction of the waste production during the construction and deconstruction phases
Reduction of the use of energy and raw materials
Simple and fast construction/deconstruction
Waste management on site

The above list represents only a part of sustainable requirements which can be associated with a building process. Many other elements can be added analysing the project from different points of view [De Capua, 2002]. A specific list of sustainable requirements concerning durability can be set up [Table2].

Table2. List of sustainable requirements concerning durability.

Reliability
Controllability
Maintenance
Reparability
Replaceability

To satisfy durability requirements is a matter of technological choice, material and components quality and use. As a consequence the design team has the responsibility to increase the quality of the project to reach a sustainable dimension of the building as a whole, but all the other "actors" involved have to share the additional costs (not only economic ones) that derive. Unfortunately the decisional power of

the different "actors" involved in the process is very different. Investors operate following economical goals which, for example, may be far from social interest. For this reason a cultural change in building design is occurring.

To have a sustainable vision of the process, the building behaviour must be analysed in its extended life cycle. When the building is completed, Lifespan Costs (LSC) involve owner, administrators and users, but some Long Term Costs (LTC) still have to be borne by society. To achieve a sustainable process means to minimize the Extended Life Cycle Cost equation [ELCC]. To reduce LTC means the growth of other factors, like design costs, in the Generalized Cost Equation (GCE).

3 DURABILITY AND INNOVATION TECHNOLOGY

3.1 Sustainable Design Methods

The reduction of LSC and LTC is strictly connected with the way the building has been thought. This probably means a more complex design activity (aimed to provide a higher level of performance to the building) rather than the use of a high level of technological solutions. LSC and LTC are expressions of how quality and durability have been considered at the moment of the building conception. A sustainable design is a project in which conscious choices are taken foreseeing a specific level of quality and durability for the building. These performances must be evaluated with an Extended Life Cycle Cost Analysis (ELCCA).

The choice of a specific technology or of a particular construction method can influence lifespan modifying the expected lifetime from 50 to 500 years. Nevertheless, when a technology has been chosen, some other factors can influence lifespan. Lifespan can be influenced by:

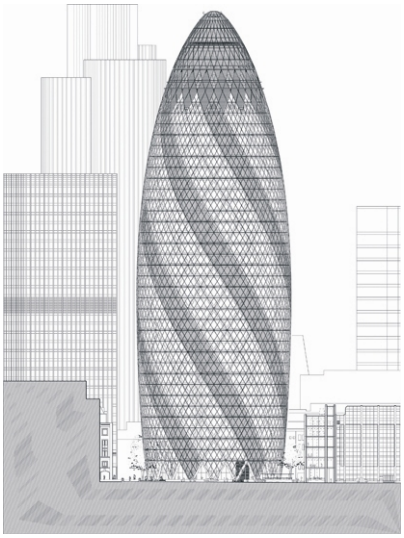
- Maintenance – which is not only connected to reliability, but also to the design concept, to the durability of materials and components and the way their joins have been done. In Hi-Tech and complex assembled buildings, maintenance costs include also the scheduled check activity on the components and the system behaviour.
- Rehabilitation – which allows, with the necessary transformation, to adapt the building to host new functions and to reach a longer lifespan.
- Random events – which represent all those catastrophic events like fires, earthquakes, collisions that can involve a building and modify its expected lifetime.

All these factors are closely linked to durability and each of them can also bring a level of transformation in the features of a building with a different corresponding influence in the Generalized Cost Equation. For these reasons the design phases are increasing their complexity and importance in establishing the durability of components, materials and technologies [Campioli, 1993]. When the Centre Pompidou was built, Hi-Tech solutions were considered innovative for the flexibility in the use of the inside spaces and also for the structural and technical choices, but the building wasn't supposed to bear a so deep change in energy consumption. The increasing of oil cost has brought to a different approach in thinking building conception and process.

Nowadays, in many international competitions design teams are asked to guarantee to their project a durability of, at least, 100 years without any extraordinary intervention. A new sensibility towards a sustainable approach is growing also in promoters and owners who ask to associate environmental features to architectural characters.

Contemporary buildings, e.g. the Swiss Re Tower in London by N. Foster, are thought to minimize energy loss, maintenance costs and especially running costs. This has led to another kind of innovation which regards, as in the Buckminster Fuller's projects, the idea of a synthesis between building design and technological performance.

In the Swiss Re Tower example, the reduction of running costs concerning climate control is obtained by a design conception which allows natural ventilation. Each floor-plate is rotated respect the one below, this allows to the space between the rating fingers of each floor to combine forming a spiral which help the climate control through a natural ventilation. This is reflected by the spiral design of the outside glass skin of the building [Fig.1]. The outside form is derived from a circular, radial plan which generates a profile that widens as it rises and then tapers towards its apex. The aerodynamic form has been explored in the wind-tunnel to test its behaviour in site conditions [Fig.2].



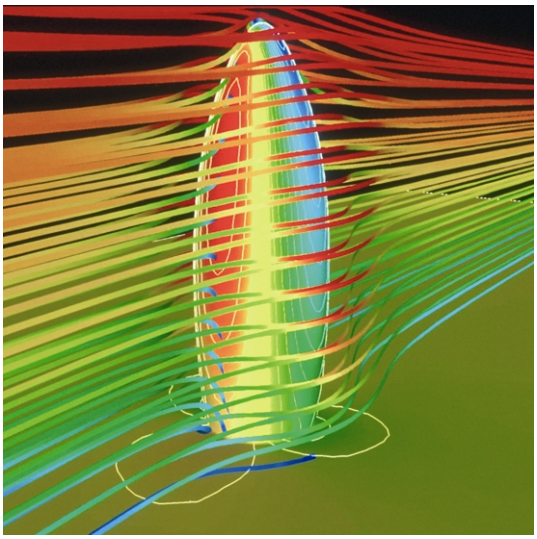


Figure 1. left: Swiss Re Tower, London, N. Foster – Schematic drawings of the spiral elements in the outside glass skin.
Figure 2. right: Swiss Re Tower, London, N. Foster – Diagram of aerodynamic behaviour explored with 3D models to simulate site conditions.

Many other important examples present a similar attention to sustainability and all of them are characterized by a high level of complexity in design phases. In contemporary design activity, part of assessment methods concern not only physical durability of materials (certification of components), but also durability as the skill of a building to survive to its original conception.

3.2 Layer of Durability

The achievement of a sustainable technology in the choice of a construction system is often associated with assembled structures or Hi-Tech solutions. This is connected with the reversible character of this technology and with the idea that the materials and the components used can be disassembled and recycled. Lifespan of this kind of buildings is expected in 100 years both for the deterioration of materials and the loss of performance in the technological system. In this case durability can be increased with a maintenance activity or a rehabilitation action with unavoidable consequences in the balance of Generalized Cost Equation.

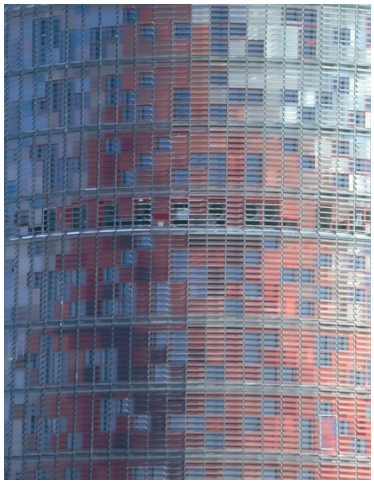
On the other side the use of irreversible technologies brings to a negative balance of environmental factors in the same equation. For this reason a great attention is given to adaptable and transformable solutions. A new design approach can be identified working on separate layers of durability in building conception. A hierarchical organization of structural, technical and functional elements can be set as an answer to some specific sustainable requirements. This analysis brings to two different kinds of durability.

A first group of elements belongs to a *layer*, that can be called *permanent*, which is thought to have a long life cycle period (about 500 years) without any meaningful change.

A second group of elements belongs to a *layer*, that can be called *reversible*, which is thought to have a shorter life cycle period (about 100 years) without any meaningful change but also thought to be transformed during the *permanent layer* life cycle.

The use of irreversible technologies to realize permanent elements that last for centuries allows to spread their environmental costs in the long period and to minimize energy consumption connected with these activities. In the meanwhile the use of reversible technologies in the same building allows to foresee an answer to the evolution in terms of functional and technical requirements. Agbar tower in Barcelona for example is characterized by a permanent structure and a reversible skin [Fig.3]. The outside skin seems to envelope the bearing elements.

The tower has been built with an external concrete structure and an internal core [Fig.4]. The steel substructure and the glass brise-soleil [Fig.5] which provide natural ventilation to all the façade, need a scheduled maintenance activity which will bring in the future to a substitution of the skin. At that moment environmental conditions might have had some changes and the technological solution for the skin will need to be updated.



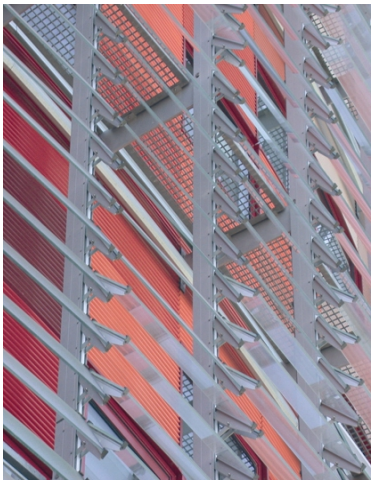


Figure 3. left: Agbar tower, Barcelona, J. Nouvel – View of the outside skin of the tower.
Figure 4. center: Agbar tower, Barcelona, J. Nouvel – A construction phase of the external concrete structure of the tower.
Figure 5. right: Agbar tower, Barcelona, J. Nouvel – Particular of the glass brise-soleil of the outside skin.

In the Agbar Tower example, the choice to have an external concrete structure guarantees to have a great degree of adaptability on each floor, but in the meanwhile forbids any change in terms of relationship with the outside environment. In the case of NET Center Tower in Padua, built with a central core and external steel structure [Fig.6], it's possible to image a different solution for the outside skin.
The glass façade with horizontal brise-soleil supported by a steel substructure [Fig.7-8] can be modified to create a different set of openings and voids in all the height of the tower.

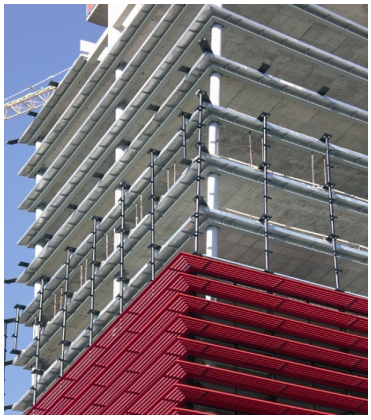

Figure 6. left: NET Center Tower, Padua, A. Galfetti – View of the central concrete core of the tower.
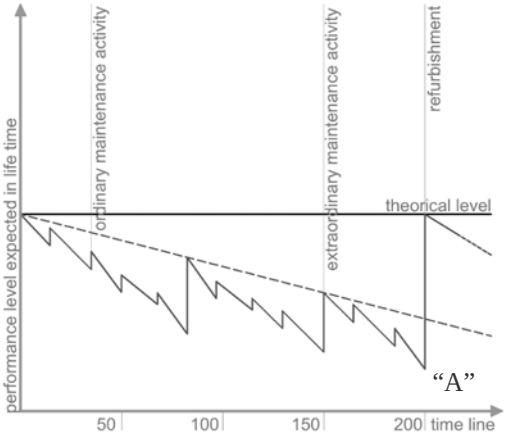
Figure 7. center: NET Center Tower, Padua, A. Galfetti – Detail of the steel supporting substructure.
Figure 8. right: NET Center Tower, Padua, A. Galfetti – The main steel structure, the substructure and the horizontal brise-soleil façade during a construction phase.

Adaptability is improving its importance and the chance to modify the section of different floors is considered as a new requirement in the design conception. In the NET Center case the concrete slabs don't allow a vertical adaptability which, on the contrary, a steel floor would have provided, but match a specific structural answer. As a matter of fact different layers of durability bring to different levels of transformation too. The chance to replace a reversible structure with another can increase the performance of the system, but it can also bring to a deep morphological change of the original conception of architecture. In this case too, the design of the building plays an essential role defining the degree of transformation and giving an architectural identity that can't be changed.

4 CONCLUSIONS

A design activity based on different layers of durability brings to a deep change in the behaviour of a building during the time. The typical behaviour of a traditional building can be represented by a graph [see figure 9] in which there is a progressive loss of performance during lifetime. This loss, represented by a split line ["A"], can be reduced by ordinary and extraordinary maintenance which can be translated in a vertical segment in the split line.



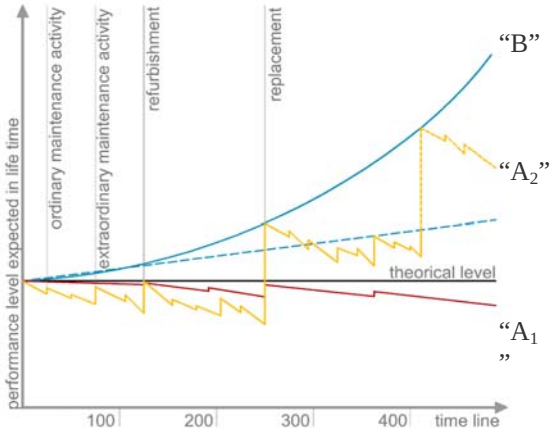


Figure 10.

Each action aims to increase the technological performances of the building, but it's unable to bring it back to its starting condition. This can only be obtained by a refurbishment action when the technological performance level is near to the end of expected lifetime. This action brings to a deep change in the building with costs that can be compared to a new building construction. This graph represents only the physiological obsolescence of the building not the obsolescence deriving from an increasing level of functional or technological requirements.

Nowadays this must be considered a strategic factor. In fact, the growth of requirements linked to energy reduction, adaptable spaces, environmental solutions, etc., cannot be represented by a linear trend, but rather by an exponential one [see figure 10, line "B"]. The design activity has to answer to a really different kind of requirements in the expected behaviour of the building during its lifetime. Building with a *permanent layer* [line "A_1"] and a *reversible layer* [line "A_2"] means to have two different split lines whose trend is really different. The first one is supposed to have a loss of performance during time interval of 150-200 years, the second one during time interval of 50-75 years. This brings to reduce costs of ordinary and extraordinary maintenance concerning the *permanent layer* while allows to invest in modyfing the *reversible layer* to match rising requirements. For what concerns the *reversible layer* ordinary and extraordinary maintenance actions are aimed to preserve technological efficiency not really to increase the performances of the building which can only be reached with a refurbishment action. When the starting technological choice is unable to answer to the growth of requirements, the reversible character of the layer allows to replace some technological solutions with more suitable other ones.

This method gives the chance to extend the expected lifetime of a building and to spread some costs in a longer period of time. Moreover it allows to answer to the contemporary question about adaptable and transformable spaces, but it can also bring to an unrecognizable architecture. When the distance between line "A_1" and "A_2" is high it means that a deep morphological change is occurring and the architectural identity of the building can be lost. For this reason any new design method has to aim at the preservation of architectural identity which represents the highest philosophical meaning of durability.

ABSTRACT

Tall buildings have always been built as totem: in fact, the skyscrapers acted a central role in the city of the early twentieth century and therefore they had to be fully recognizable from all the parts of the city. Their role changed along the last decades becoming in some cities of the world the only viable solution to face the growing price of the land. Skyscrapers are now spread almost everywhere and they are integrating a number of functions at the same time: offices, residences, hotels and public spaces; according to some studies, they seem to be one of the challenges for the sustainable city of the next century. In order to achieve this goal some mistakes have to be avoided. Today's skyscrapers are built as mere glass-boxes where the internal environment is only controlled by air conditioning. Often, they seem to be built without taking into account the constraints given by the setting: sunlight, wind, solar radiation, surroundings (other buildings, views, etc). Moreover, the needs of the users differ according to the purpose of their presence within the building: offices, hotels, residential floors or touristy places are placed one over the other "wrapped" within the same enclosure. Each typology of user requires very particular characteristic by the places he is living in: i.e. the need of light of a worker doesn't match with the light requirement of a person sleeping one story higher; also, the façade facing South doesn't have the same stressors than the one facing North, and so on. The actual way of producing building's enclosures creates discomforts in the users and increase the energy requirements of an high rise building.
This paper analyze the opportunities given by architecture and building technology to characterize the enclosure of a skyscraper in order to improve its performances and meet the requirements of sustainability needed by our culture. An example of regional setting of a skyscraper is provided.

1 INTRODUCTION

In modern cities, tall buildings have the role of pivots, around which the urban shape seems to be developed. Their capacity of marking the land and of declaring from far away the presence of a city makes skyscrapers icons of urban modernity and landmarks for the surrounding areas. The economical and cultural background of the American society of early '900 has to be analyzed in order to understand the role that skyscrapers had within a city.
When they firstly appeared, more than 100 years ago, tall buildings defined a brand new building typology. They were asked to declare, using the language of architecture, the power and the richness of the developer, who had reached that social position through his work and skills; this was the main force that influenced the design of a tall building. Nowadays the design process is still governed by this idea; according to the concept used for decades in the U.S., the skyscrapers are built as an urban uniqueness showing out proudness and sometimes event a brazen behavior. This idea creates figures that stand up over the surrounding areas as totem or obelisk. Since they become the target of everyone's sight they have to be fully recognizable from everywhere; thus, their fronts have an homogeneous design and it's hard to recognize a main façade or a back front.
Tall buildings are now changing their role; it's more and more common that universities, hotels, public administrations or residential enterprises become the tenants of a tall building. Despite the change of tenancies this building typology keeps on representing a landmark for the cities; thus, the symmetric silhouette is preserved in order to allow a full recognizability from every point of the city it is seen.

2 IMPORTANCE OF ARCHITECTURAL AND TECHNOLOGICAL CHARACTERIZATION OF THE ENVELOPE.

Since ever, the rules of the thumb of building practice teach to design a building taking into account the constraints and the advantages given by the site where it will be set. Vitruvio suggested the featuring that a building was supposed to have if it had to be build in the northern regions of the roman empire as well as the characteristics for building an house in the warmer climates. He also gave suggestions on the most suitable disposition of the internal spaces and "technological" advices for building the walls according to the characteristic of the outside weather. Those rules, that characterized 2000 years of building practice across the World, were forgotten when skyscrapers born.
As previously stated, the skyscraper is on obelisk; exactly like Egyptian obelisks are now in the capital cities of many Countries, the unbuilt projects of some skyscrapers can be relocated somewhere else and built in places that have sometimes urban and climatic characteristics very different from the site where they were firstly developed.
The symmetrical aspect of tall buildings often doesn't take into account:
- The sun path: it changes according to seasons and latitude.
- Dominant winds: each place often has a dominant wind that should influence the design.
- Urban context: the existence of other buildings can create problems as: shadows, air turbulence, privacy, outlook.

For instance, considering just the positive and negative effects of the sun, a symmetrical envelope is justified only nearby the Equator line: here the sun position at noon shines the North façade in June and the South one in December, while the East and West fronts are lighted every day at sunset and sunrise. At higher latitudes, this condition doesn't exist and one façade is never lit by the sun all the year long.

3 A NEW URBAN OPPORTUNITY: MULTI PURPOSE TALL BUILDING.

Tall buildings seem to be the main tool to fight the growth of metropolis in several regions of the world and they can provide a real opportunity for building more sustainable cities and conquer better living conditions. In order to fit the urban regulations and to fulfill the requirements of urban zoning, tall buildings are often having multiple uses proposed at a time. All the major cities in the world are experiencing a constant rise of land price that pushes more and more citizens to leave the internal

zones and to look for lower prices and better living conditions in suburbs and satellite cities. The separation of residential places from the working areas of the city has negative consequences both on the individual (the increase in time and cost to reach the office) and on collectivity (traffic, pollution, crashes). With the aim of limiting those stressors on the population several urban interventions are proposing various tenancy typologies included in the same building; sometimes the same building also hosts public functions or leisure areas. The presence of a multiplicity of uses within the same tall building should give the chance to define three-dimensional urban regulations: the surfaces available at height will be adopted as those at street level to provide the space required by the urban zoning policy. The urgency of new urban regulations is particularly clear in some cities of Asia, where the speculative market and the objective need of built spaces makes non-remunerative areas to desappear: gardens, leisure and sport areas, cultural and associative areas should then be placed on the upper floors.

4 PERFORMANCES REQUIRED BY USERS ACCORDING TO THE BUILDING'S PURPOSE OF USE.

As previously seen, it is more and more common to have two or more typologies of users within the same building. Each typology is characterized by some specific aspects that can be seen in table 1:

Table 1: Characteristics of use of the various typologies of users

Typology	Residential	Office	Hotel	Public
Day occupancy	Low	High	None	High
Night occupancy	Medium	None	Medium	None
Human activity	Low	High	Low	Medium
Human heat gains	Low	Medium/high	Low	High
Equipment h. g.	Low with except.	High	Low with except.	High
Moisture	Low with except.	Medium	Low with except	Medium

The requirements and expectations of those typologies of users are often different or sometimes even opposite. The architect can control those aspects since the very beginning of the design process. This is particularly true if one considers the characteristics of lighting, ventilation and shading expected from the envelope of the building, as shown in table 2:

Table 2: Performance required by users. Public spaces are omitted due to the variability of final use.

Typology	Residential	Office	Hotel
Light required	Medium	High	Low
Natural light	Everywhere	As much as possible	In every room
Size transparent surf.	Medium	High	Low
Darkening possibility	Necessary	Optional	Necessary
Operable windows	Necessary	Preferable	Preferable
Openings to outside	Everywhere	As much as possible	View from each room

5 LIMITS OF NOWADAYS DESIGN OF TALL BUILDINGS

The analysis of the characteristics of use and of the user's performance requirements clearly shows that is a nonsense to "wrap" within the same enclosure expectations and requirements that are so different. The architectonic uniformity (or even worse, the technological uniformity) of the envelope causes that each user typology suffers discomfort alternatively: particular attention should be paid at the environmental features of places occupied by people.
In table 3 are listed the main typologies of envelop adopted in tall building construction, and the benefits or disadvantages created in each typology of users.

Table 3: Pros and Cons of several envelope featuring according to user's requirements.

Envelope typology	Pros & Cons for: All	Residential	Office	Hotel
Fully glazed curtain wall	Cons: low thermal insulation. Low thermal inertia .	Cons: low privacy. Low furnishing possibilities. Bad darkening possibilities	Pros: high natural lighting.	Cons: bad darkening possibilities.
Double skin	Pros: improved energy efficiency. Cons: high cost.	Cons: low operability of windows. Difficult management of interspace both for right to use and for cleaning.		
Use of opaque materials	Pros: improved thermal inertia if heavy materials are adopted	Pros: internal ambient similar with traditional housing .	Cons: Lower lighting.	Pros: more comfortable ambient in the rooms.
Absence of operable windows	Pros: lower thermal loss due at leaking . Cons: Claustrophobia, sick building syndrome .	Cons: total discomfort.	Cons: Lower possibilities of controlling the micro environment.	
Permanent brise soleil or shading	Pros: better energy efficiency. Cons: possible noise when windy.	Cons: discomfort due to jail-feeling.	Pros: Better diffusion of light within the internal spaces.	Pros: Better diffusion of light within the internal spaces.
Existence of external balconies or backspaces of the façade	Pros: Better energy efficiency given by the shading effect	Pros: better comfort and improved quality of the built spaces.	Cons: lower penetration of natural light.	Cons: uselessness of the spaces.
Existence of terraces and courts in the sky	Pros: improved quality and value of the building. Cons: high cost for maintenance.	Pros: possibility of use for kid's play and leisure whenever those areas are not available at ground level.	Pros: creation of lobbies and leisure spaces that don't require climatic control.	Pros: creation of lobbies and leisure spaces that don't require climatic control.

6 TECHNOLOGICAL AND ARCHITECTONIC POSSIBILITIES TO MEET THE ENERGETIC PERFORMANCES EXPECTED FROM THE ENVELOPE.

The most effective answer for the issue of the energetic behavior of tall buildings is provided by the choices that can be taken from the very first step of the design process. There are three different approaches:
- "hidden" technological characterization: it is achieved through a technological differentiation of the building envelope conforming it to the performances required and using only invisible features like: selective glazing, different thickness of insulation layers, ventilated façades that have the external appearance of the other parts of the building and so on;
- "visible" technological characterization: it may include some external apparatus like brise soleils, balconies, recessed façades, double skin façades and so on. At European latitude the main issue is to avoid excessive solar heat gain: the best solution is to shade it before the rays enter the envelope. Controlling the size or typology of windows and the presence of balconies is one of the easiest way to protect the south façade from excessive light and solar gain. Also, in order to delay the heat transmission, it is important to provide the walls with a good thermal inertia.

- architectural features: Several buildings have been recently built with shapes that differ significantly from the glazed box we are used to. The goal is to enhance the natural ventilation and the solar shading by the design of the building's silhouette. Braking its volume into smaller parts improves the energy behavior of the building; the chances are: greater light penetration and improved natural ventilation, self-shading of the building, terraces and naturally chilled public places and so on.

7 MULTI PURPOSE TALL BUILDINGS: SUITABLE ENVELOPE CHARACTERIZATION

The design of a multi purpose tall buildings is always an hard task for the team involved, because it requires an enhanced coordination and a very complex decision-making process. Placing three different purpose of use within the same building requires to meet needs and requirements that can totally differ one from eachother. In fact, an office building requires an open plan design with wide spam beams (12 meters or more) in order to provide the maximum flexibility for the offices. Otherwise a residential building will have a thinner shape, in order to provide natural light and ventilation in all the areas of the apartments: the structure will have therefore shorter spams. The same is for hotels; furthermore it has to be considered that all the bedrooms of the hotel must have a view; therefore, the inner areas of the core will be used for public amenities, and a lot of the gross floor area will be non remunerative. Matching all these features in the same building requires to take choices that may vary from case to case. Generally, an horizontal subdivision of the functions is adopted:
- the lower floors will be used for offices, as they require high performances from the vertical circulation system and because they allow the use of wider floor areas;
- the middle floors will be used for residential units, therefore placed away from noise and air pollution coming from the street;
- on the higher floors (which can have a smaller floor surface) there are the hotels that can benefit a better view and a more efficient plan layout;
- the top floors are often used for public amenities (restaurants, sightseeing, etc) or extra-luxury apartments.

Considering the climatic stressors that affect a building, another subdivision of the functions seems to be more suitable: a vertical partition of the building. If we consider the benefits arising from a technological and architectonic characterization of the building's envelope we will understand that those match with the user's requirements of each purpose of use.

Considering those aspects we can find out that the most suitable orientation for residential units is the south façade: here they will benefit from balconies and have normal size windows shaded by the terraces of the upper floors. The act as a thermal buffer for the whole building. The office areas will be disposed with a "c" shape around the central service core and the residential units; therefore they are oriented East, North and West. The North side, entirely glazed, provides natural lighting but it preserves the heat loss using a double skin façade. The East and West sides, quite similar, are distinguished for the presence of terraces on the west side. Eventually, the hotel will be located on the East side; in fact, during the hot season, it can cool down in the evening before guest come for sleeping.
Table 4 shows the possibilities of such a different characterization of the envelope of a tall building. For each direction some environmental constraints are analyzed and a suitable technological solution for the envelop is provided.

Table 4: general principles for the technological featuring of the envelope for a proposed tall building in Paris, La Defence.

	North	East	South	West
Lighting	Soft, it is suggested to foster its penetration in the building.	Medium, early in the morning. It should be diffused within the building.	Strong. Its penetration should be avoided.	Medium, in the evening. It should be diffused within the building.
Solar Radiation	Low. In winter it is suggested to preserve the heat loss with appropriate technologies.	Medium, in the morning. At summer-time it has to be shaded in order to prevent the over-heating of the building. In winter it has to be used for pre-heating the spaces.	Hight. It has to be shaded. Also during the winter it can cause an overheating of the internal areas.	Hight, in the evening. It has to be shaded or its effect has to be delayed through thermal inertia of the enclosure. In winter it can help pre-heating the spaces to avoid excessive night cooling.
Wind	Low, cold in winter. To be controlled and kept out	Low, brings pollution from the city. It has to be kept out.	Low.	Strong. It is cold and humid in winter and therefore it has to be kept out. Cool and clean in summer, it should be used for natural ventilation.
Suitable envelope technology	Glazed Double skin with heat recovery system.	Glazed, with brisesoleil which control and diffuse the natural light. They have to be operable in order to let the solar radiation in the building in winter and avoid it in summer.	Opaque envelope, with an improved thermal inertia. It should include balconies and brisesoleil in order to shade the solar radiation. Small openings must be shaded or regressed from the perimeter.	Glazed envelope with brisesoleil. It is the most suitable side for green terraces and "courts in the sky". It should have wide operable windows to benefit the summer ventilation, It should have a good thermal inertia to delay the summer heating.

8 CONCLUSIONS

Multi purpose tall building represent an opportunity for creating more sustainable and livable cities. Limiting the energy requirements is becoming a prerogative for the feasibility of every human activity: buildings have to be designed keeping this in mind. Therefore it is required to design them, and every part of them, with the idea that the energy consumption is no more just an economic issue but is becoming a social and marketing discriminant. Tall buildings have experienced, since their first appearance, a multitude of major technological and stylistic improvements but they kept on conserving their totemic external symmetry. Giving up with this design anomaly will help in creating more comfortable skyscrapers that will more suitably match the user's requirements and will achieve major energy savings, especially in the summer months.
Multi purpose tall buildings, that are progressively taking a dominant role, especially in the group of super-tall towers, are a viable proposal to solve many problems of nowadays cities. Reducing the spread of the city and augmenting its density and social variability are among the most positive factors in favor of tall buildings and of multi purpose tall building particularly. However, architecture have to

start considering the tall building as a place to live or work in, not (or not only) as a sculptural totemic object. By considering the needs of the users that live within the building the design team could achieve a more differentiated and performing envelope, improving the energetic behavior as well.

Towards a Framework for Durability Design & Life Cycle Costing of Infrastructure Projects

O. O. Ugwu [1]
S. T . Ng [2]

T 52

ABSTRACT

This paper discusses a study that investigated organizational issues and requirements for improved durability design and life cycle assessment/costing as part of integrated sustainability audit in delivering infrastructure projects. The Hong Kong based study was conducted between 2003 and 2006. The research methods include; questionnaire survey of a cross section of Hong Kong construction professionals (consultants, contractors, clients, and other suppliers), analysis of the responses from the survey to elicit current state-of-practice and identify areas that require improvements, development of framework for durability design and life cycle costing within the broader context of improved sustainability audit, and case study project investigations. The study highlights significant issues that cumulatively impinge on durability design and life cycle costing at the proect level. Conclusions are drawn and recommendations given for the delivery of sustainable infrastructure projects, trugh integarted sustainability audit that subsumee durability and life cycle assessment.

1. INTRODUCTION & BCKGROUND TO STUDY

Both pubic and private sector clients are now placing increasing emphasis on the need to "design for durability". In this context the underlying objective is to ensure that construction defects and life cycle maintenance requirements are kept to minimum. Consequently designers are increasingly being charged with the responsibility to ensure that a design is durable. Achieving this design goal demands attention to construction process and other critical factors such as the interaction between a structure and its environment, which cumulatively impinge on quality and durability of the structure in use. For example in Hong Kong SAR, the government requires consultants to specify design life for all structures (HKSAR Highways Department 1997). Also in 2001, the HKSAR Construction Industry Review Committee gave several recommendations to improve the construction sector. Some of the recommendations focused on durability aspects of infrastructure delivery. The Tang Report recommendations include (CIRC 2001): (i) (giving) more considerations on the life cycle cost of a building, (ii) developing costing models and tools for the calculations of life cycle costs, (iii) developing a database on the life cycle costs and performance of materials and components, and (iv) developing a common set of accepted performance-based specifications for materials and components.

The main motivation for this paper is to understand current practice in *durability design* and life cycle costing, identify the issues that need to be addressed for improvement, and make contributions that address the identified based on the research findings.

The outline of the paper is as follows: Section 2 discusses the ontological diemension of durability design problem, while section 2 discusses the research objectives and methodology. The findings from indsutry survey are discussed in section 3. A framework for durability assessment and life cycle costing in the context infrastructure delivery, is dicussed in section 4. Finally section 5 draws concluons and gives recommedations based on the reserch findings.

2. RESEARCH OBJECTVES & METHODOLOGY

The main driving research question is: *how do various stakeholders and construction professionals perceive, define and address durability in infrastructure projext life cycle - design, construction, operation and maintenance?* The research questions enacpasulate the objectives. The objectives were: (i) to investigate current practice in durability design and assessment, and (ii) identify the duarability design knowledge sources as well as the the associated problems and difficulties in current practice, and (iii) propose a solution (e.g. a framework) based on (i) and (ii).

2.1 . Questionnaire Design & Emperical Survey

The study began with an extensive review of literature and desiging a quationaire surevy instrument that captured various aspecsts of durability and life cycle costing investigated. The questionaire had 5 main constructs that captured several details including: (i) demogarphic data of the respondnet and organisation, (ii) current approaches to durability design and process-related issues including clients briefing process, assessment in various project phases; and (iii) scope of the assessment. The questionnaire was sent to 60 industry profesionals working in different constructio organisations in HKSAR. A total of 37 completed questionnaires were returned after follow-up commincations with the organsiations and professionals the questionnaires were addressed to. This gives a response rate of **62%**. The next section gives analysis of the results. Table 1 shows the size of repsonding construction organsistions and the scope of porjects they undertake, while table 2 givs a summary of various responses to the constructs in the quationnaire.

2.2 . Analysis of Results

Table 1: Size of, and Scale of Projects undertaken by, responding organisations

3. DISCUSSION OF FINDINGS FROM INDUSTRY SURVEY

3.1 Types of Contractual Arrangements

Table 2c shows that 17 responding organizations (approx 46%) are involved in design and build projects. This is significant as it indicates that they have the necessary flexibility to design for durability providing there exist appropriate incentives and enabling environment that instills the culture of whole life costing in project design and construction, amongst others. The table also shows that the majority of the responding organizations (about 73%) are involved in the traditional Design-Bid-Build contractual arrangements.

3.2: Current State-of- Industry- Practice in HKSAR

3.2.1.Organizations' Identification and Definition of Service Life

However, it is observed from table 2b that only 8.33% of the responding organizations (3 out of 36) use a system such as documented guidelines to identify and/or include service life requirements in the project brief stage. This gap is also very significant considering that identification and inclusion of service life requirement at the briefing stage is a precursor to effective planning and designing for durability of the respective functional components of the infrastructure system. Furthermore table 2d cleary shows different definitions of *end of serive life*. 17.9% see the definition as 'end of economic life" while 25.6% and 41.0% respectively define it as 'obsolescene of use' and d'desgin life'. 10.3% (4 out of 37) look upon the cleint for definition. The result suggests that the concept of whole life costing or life cycle assessment is not well understood and commonly adopted.

3.2.2.Durability Assessment of Design and Construction

Table 2g summarizes the results on the scope of durability and life cycle assessment suggested by the respondents are shown below. The results do not indicate a clear a preference on the scope of durability and life cycle assessment. Almost allthe respondents (35 out of 36) agreed that the design service life should be checked against the requirements of the brief (Table 2k). However, only 3 (8.33%) of them use a system for specifying service life requirements in project briefs and then review whether the design is capable of meeting those requirement (Table 2b). In considering who bears the extra cost assocaited with durabiliy assessment, most respondents (30 out of 36) indicated that their organizations will accept increased briefing costs if its is offset by savings in operation and maintenance cost. Also a 30 out of 36 respondents agreed that their organizations will accept increased briefing and design cost if offset by savings in operation and maintenance cost (Tables 2l & 2m). The results suggest that clear demonstration of the benefits of life cycle assessment will increase industry awareness. This would facilitate the incorporation of durability and life cycle assessment in the the project briefing stage.

3.2.3.Current Approaches to Service Life in Construction & Design Knowledge Sources

Regarding the knowledge sources for durability design (Table 2i), more than half of the respondents used the British Standard design codes (BS5400, BS5950, and BS8110) and Structural Design Manual for Highways and Railways (published for use in HKSAR) in durability design. However, only 30% indicate that they use their in-house service life definition and design procedure and that 60% are not ware if there is in-house service life definition and design procedure in their organizations.

3.3 Benefit of Durability / Service Life Requirement

Despite the conflicting definitions of end-of service life (Table 2d), and the apparent absence of systems to identify and/or include service life requirements in 91.67% of the responding organizations (table 2b), the benefits of clear and unambiguous definition are quite obvious from the responses. The respondents identified the following top 5 benefits: (i) improved clarity o client's understanding (40.54%), (ii) Improved design process (35.14%), (iii) Reduced costs of over-specification (35.14%), (iv) planned maintenance scheduling (24.32%), and (v) Clear guidance and allocation of responsibilities (24.32%). Other high ranked benefits include Reduced costs associated with durability failure (18.92%), speed up decision making (18.92%) and improved risk management (13.51%).

Table 2k shows that, where durability is specified in the project brief, designs are (or more appropriately should be) checked against this specification. Hence to increase the uptake of durability assessment and life cycle assessment it must be led by the client through the briefing process. Finally there is a clear understanding of the benefits of inclusion of durability specification in the project brief and durability assessment of the construction. This shows that the drivers for uptake of durability and life cycle assessment methodologies are present. The next section discusses a framework that addresses the identified process-oriented (methodological) issues.

4. A FRAMEWORK FOR DURABILITY DESIGN & LIFE CYCLE ASSESSMENT

This section discusses a framework that addresses the issues and problems identified in the study as they impact durability design and whole life costing of infrastructure projects.

The framework incorporates different process-level activities. It begins with the Client's Project Briefing and requirements specification. At this stage durability issues related to durability should be clearly identified and outlined in very clear terms. At both the prelimnary and detailed design stages, references should made to appropraie knowledg soiurces inclding design standards, Element audist are perfoenr for the variopus functional elemsnt fop the projetc, and lifec cycle assessment is acrried out. The construction stage considers aspects related to (i) material such as sourcing and storage, (ii) construction process sequence inclusing worksmanship and (iii) quality related aspects of the construction. The operation and maintanance stage (O &M) considers inspection regime and the

frequency of inspectiuo to encure prooer maintainance. Figure 1 delineates the variois costings involved troughout the project life cycle.

In a broder context, the framwork shown in Figure 1, encapsulate the following methodological process steps for durability design and life cycle costing (Ugwu et al 2003):

i. Estimate the construction costs based on each of the possible design configuration options;
ii. Identify recurrent costs. These include relevant analyses of each structural element, along with the cost implications with respect to maintenance, inspection and repair;
iii. Assess risks throughout the life-cycle, including probabilities and potential impacts of each applicable risk factor; and project potential costs accordingly;
iv. Determine the operation cost and recurrent cost relationships;
v. Assess durability: which includes for example, establishing existing environmental parameters, evaluating their effects on concrete design and corrosion maintenance requirements and taking appropriate design decisions; and
vi. Compute the life cycle cost (in terms of the *net present values*) based on above design configurations, and the operation and maintenance requirements.

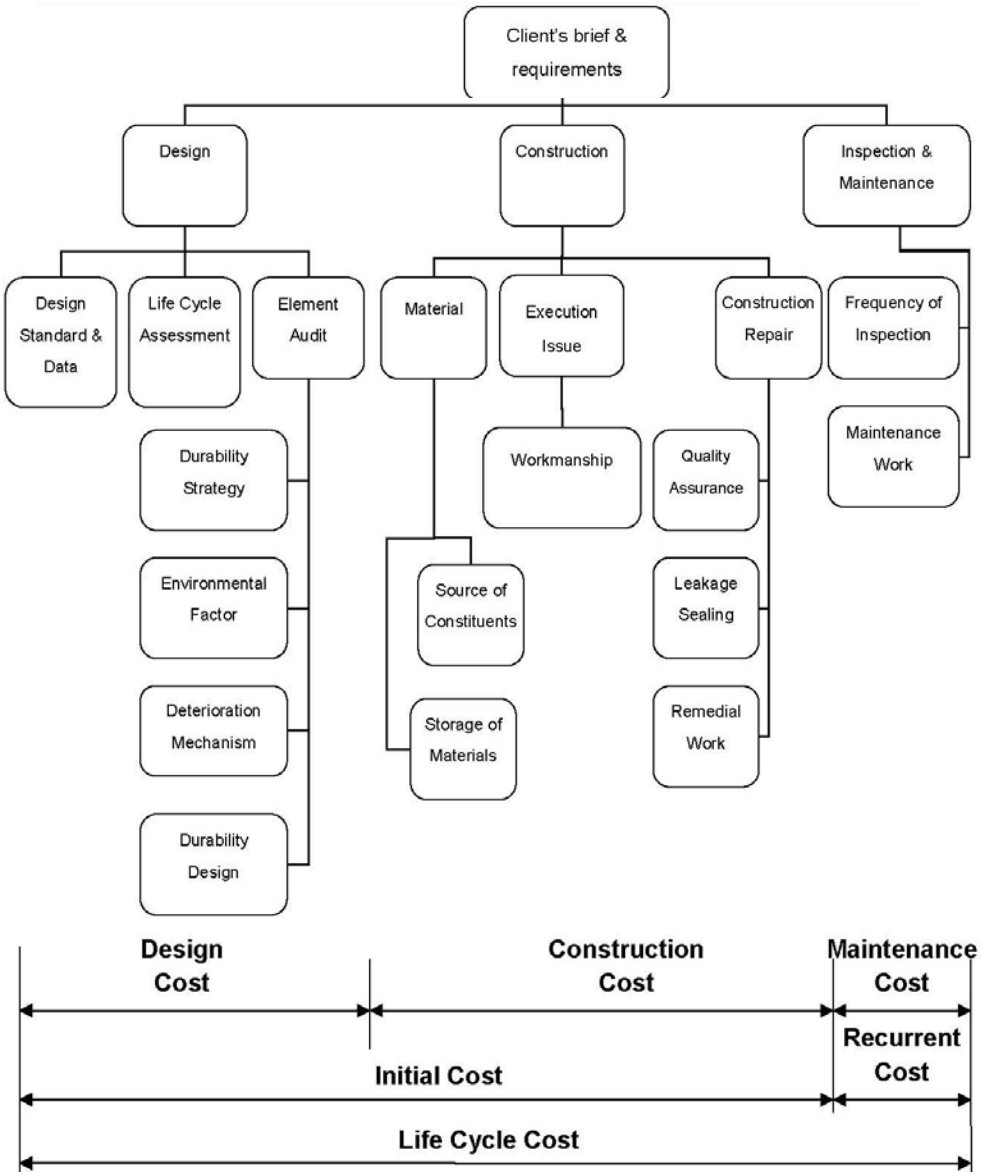

Figure 1: A Framework for Durability Assessment & Life Cycle Costing of Infrastructure Projects

(Ref: Source: Lam 2006 – Framework Adapted from *Ugwu et al 2003 & 2005* and modified for the study scope)

5. CONCLUSIONS & RECOMMENDATIONS

The study highlights significant issues that cumulatively impinge on durability design and life cycle costing at the proect level. The research discussed in the paper shows that some of these issues have *epistemological, process-oriented* and *pedagogical* dimensions. The epistemological dimensions relate to varying understanding and perceptions of durability and life cycle analysis concepts such as *design life* and *service life*. The aspects of ontology dimension investigated in this durbality design problem research focus on the basic level of human understanding, concept definition, and communication. A proper understanding of the contextual definition. interpretation and process-level implementation of durability is critical in achieving the objectives of designing for durability at the appropriate project interfaces (conceptual & detailed design stages). The importance and significance of this ontological dimension to the problem becomes more pronounced in the wider goal of delivering sustainable infrastructure projects. From a philosophical perspective, the ontology question has taken on epistemological dimension. In recent times the scope of ontological and epistemologcal arguement has expanded to the definition of sustainability and all its strategic-level abstract connotations that need deconstruction to design decision-making variables at project levels. Moreover, sustainability is very significantly impinged upon by the durability of constructed physical artifacts, and the impact of durabiity covers several aspects of the internationally accepted *tipple bottom line substantiality envelope*- economy, environment and society. As an illustration, durability addresses **economic** dimension (from point of view of initial cost as well as operation and maintenance – *Life Cycle Cost*), **environment** - *resource utilization* (from the conserved natural resources that are saved through adopting optimal designs that maximize use of resources including innovative materials, and material re-use during construction, as well as designing for de-construction), and **society** - *health and safety* (through the delivery of durable infrastructure systems that are safe while in use).

The process-oriented issues include client-designer communications and interactions during the project briefing process in order to delineate durability requirements in unambiguous terms. The paper propsed and discussed a framework that addresses the identified user requirements from the study. It is oberved that that an effective implementation of integrated *sustainability audit*, requires a paradim shift in educational curriculum to incoprate such a holistic approach at various interfaces in infrastructure delivery – conceptualisation, design, construction, operation & maintenance (a *pedagogical dimension*). The main educational challenge is to incorperate sustainbaility design and audit in the education of future constructyion professionals. So far this is not properly articulated in engineering and construction/project management courses although several professional organisations such as the ameerican sociery for Civil engineers (ASCE) and the Institution of Civil Engineers (ICE) UK, have started to address this in recent years. The findings and recommendations constitue useful lessons to construction researchers, educators and design professionals.

The Role of Using Durable Building Materials and Components in Reducing the Environmental Load of Buildings

Tülay Esin [1]
Nilay Coşgun [2]

T 52

ABSTRACT

Natural resource and energy consumption resulting from construction activities, emissions, construction and demolition wastes cause a great load on environmental values. The ecological characteristics of building materials and copmponents determine the ecological characteristics of the buildings, and accordingly their environmental loads. Durability is an important ecological characteristic for the building materials and components. In this study, the effects of the durable building materials and cpmponents towards reducing the environmental effects/loads of buildings are emphasized. In the scope of the study, durability and the potential for re-use possibilities is explicated in the context of the reasons for renewal of building materials and components by means of conducting a survey related to modifications done to existing houses. As a result of this study; it was discovered that modifications were done frequently mainly due to ageing and deterioration reasens, followed by modifications done due to aesthetic concerns. Only 25% of the modifications were done due to the ageing and deterioration of the buildings. Therefore the building material and components that not yet completed their usage life turn into waste. However, after checking the durability of such materials and components and making the necessary maintenance and repair, the possibility of re-use is considered as being quite high.

1 INTRODUCTION

Throughout their life cycle, buildings have negative effects on the environment due to many reasons. Natural resource and energy consumption resulting from construction activities, emissions, construction and demolition (C&D) wastes cause a great load on environmental values. The level of this load is related to the sustainable characteristics of the buildings.

Methods adopted towards the protection of natural resources and energy, and reducing waste, which all compose the base for sustainable development can also be implemented in the construction sector. The ecological characteristics of building materials and copmponents determine the ecological characteristics of the buildings, and accordingly their environmental loads. Durability is an important ecological characteristic for the building materials and components.

The reusability of building materials and components significantly reduces the environmental load of the buildings in which they are used. In this way natural resources and energy can be protected and pollution can be reduced. Building materials and components that are excluded from the scope of reuse and recycle are released to the environment as waste. This leads to environmental pollution which is amongst one of the most important environmental problems today. However, while reuse and recycling of materials prevents the formation of waste and pollution, it also allows for gaining new resources and reducing the environmental load. Reusability is related to the durability and usage life of the building materials and components against several effects.

In this study it is aimed to discuss the effects of the durability of building materials and components on reducing the environmental load of buildings. In this scope, the effects of the durability of building materials/components on reducing production of C&D waste and pollution is emphasized. It is known that buildings cause an important intensity of C&D waste during their life cycle. It is seen that a large quantity of C&D waste evolves particularly when modifications are done during usage phase. For this reason, in line with the aim specified, C&D waste that evolves the usage of buildings was chosen as the subject of the study.

2 DURABILITY OF BUILDINGS

Durability is one of the most important characteristic which defines the building materials and components and is expected to be permanent during the usage life of the building. Durability of building materials and components directly affects the durability of the building they are used in. The durability of building materials and components is related to their internal structure and their physical, chemical and mechanical characteristics. Durability can be reduced according to the faults and/or deficits done during the production and/or construction processes of the building and building materials. The building materials and components can be damaged due to the reasons such as detailing defects during the design phase , application defects and defects due to workmanship during the construction of the building. Accordingly the usage life of building can be shortened. External environmental conditions such as climatic factors and atmospheric emissions affect the durability of building materials negatively as well.

The durability performance expected from the building is directly related with the use of appropriate material. The selection of materials should be made according to the factors which affect the building materials on the basis of their usage position. Besides, it is important to state that different materials that are used together can interact and cause a reduction in durability. Using material with appropriate characteristic and standard at the construction is strongly associated with the material knowledge of the designer. The prevention of defects due to workmanship which effect the durability of the building and building materials negatively is possible by esuring detailing of design and efficient auditing. Providing sufficient attention to maintenance and repair during usage of the building is important in terms of the durability of building materials and the building's expansion of existence. Building

materials also have a definite life time and it is possible to expand this period via maintenance of building components at intervals changing according to building materials. The structure would be designed for the longest life +50 years. Exterior surfaces change about every 20 years. Wiring, plumbing, and other surfaces tend to wear out or go obsolete every 7 to 15 years. Interior walls and other components of the floor plan tend to change every few years in some buildings [Milani 2001].

3 ENVIRONMENTAL LOAD OF BUILDINGS – CONSTRUCTION AND DEMOLITION WASTE

Building life cycle is closely related to environmental impact. Buildings create a great burden on the environment during their existence because they utilize energy and natural resources and as a result of this, generate emissions and wastes. According to the data from Worldwatch Institute [Ngowi 2001]**;** building activities consume up to 40% of stone, gravel and sand, 25% of natural wood, 16% of water and 40% of energy used worlwide. Approximately 78% of carbon emissions come from fossil fuels that are burnt to make cement, and 60% of the water that runs through pipelines is consumed in cities [Eduardo 2007]. This situation causes some pollution and increases the deterioration of the environmental values. Waste production is accepted as one of the most important environmental problems of the 21st century. C&D wastes are defined as priority wastes in many countries due to their large volumes, quantities and complexities. Construction & demolition waste generates from:

- Building related waste; Construction, Demolition, Renovation,
- Roadway related waste,
- Bridge related waste,
- Landclearing & inert debris waste.

EPA (U.S.Environmental Protection Agency) estimates that in America 136 million tons of construction waste was generated in 1996 [EPA 1998]**.** It is stated that in Hong Kong 65% of the waste area was covered with C&D waste in 1994-95 [Stokoe *et al*. 1999]. This value is 35% in Canada [Cedar 2007]. According to EPA of Australia, 21% of all waste generated in Sydney is C&D waste [Gutovic *et al*. 2005].

There is no clear data in terms of C&D waste amounts in Turkey. It is stated that the average urban solid waste generation is 1.04 kg per capita/day or ~380 kg per capita/year in Turkey [Çevre ve Orman Bakanlığı 2006]. This value includes both the domestic waste and the C&D waste. According to the data from ISTAC (İstanbul Çevre Koruma ve Atık Maddeleri Değerlendirme San.ve Tic.A.Ş.), approximately one kilogram solid waste including C&D waste is generated per capita/day in Istanbul [ISTAÇ 2006].

As construction waste's have a larger volume than residential waste's, wide waste areas are essential since they put pressure on the existent landfill areas. When these wastes are released to the forests, rivers, streams or empty areas in an uncontrolled manner, they cause for erosion, the contamination of ground and surface water resources and the deterioration of natural areas [Construction Recycling Directory 2003]. The characteristics of solid changes and habitats are destroyed. Destructive contaminators spread out to the atmosphere by means of uncontrolled burning of paint, isolation materials and flammable materials. When these wastes are released to the environment uncontrollably they need to be cleaned and this is very costly both environmentally and cost economically.

4 THE ROLE OF USING DURABLE OF BUILDING MATERIALS AND COMPONENTS IN REDUCING THE ENVIRONMENTAL LOAD

C&D waste which causes economical and environmental load can be reduced through a rationalist management. However, the best method is to initially prevent waste generation. In this respect the

designer hold great responsibility. It is necessary that right decisions are taken towards preventing or reducing waste generation at the very beginning of design.

The selection of appropriate building materials and components is very important decision. It is also important to consider the durability and characteristics of reuse in the selection of building materials and components during the design phase. Because, the durability of building materials and components against variable factors is an important ecological characteristic which ensures the protection of resources and prevents waste generation. Such materials make important contributions to the reduction of environmental load as a result of their performances stated as follows;

- Building materials and components which have a high level of durability don't require much maintenance and repair during usage. This way, the reduction in the use of new materials ensures the protection of resources and pollution doesn't occur because waste that could be generated during maintenance and repair is prevented.
- Materials which have a high level of durability have a long life. For this reason, they don't need to be replaced for a long time and this detains the need for new raw materials and thus, the protection of the resource is ensured.
- Building materials and components that have a high level of durability can be reused after the building completes its life cycle or is changed before the building completes its life cycle. Thus, the need for new resources disappears or is delayed and therefore the protection of natural resources is ensured. As the materials are reused, there is no waste to throw away and therefore waste generation is prevented and pollution is reduced through reuse of them as new raw materials or sources.
- As such materials reduce the use of new resources and materials, the environmental effects (consumption of resources and water, emission etc.) that they have during their life cycle also disappears.
- Because they have long usage time, their total environmental effects gradually diminish since these effects are separated into long time periods.

5 SURVEY STUDY/ DETERMINATION OF DURABILITY AND REUSE POTENTIAL OF BUILDING MATERIALS AND COMPONENTS GENERATED AFTER MODIFICATIONS

Waste generation appears during various phases of the building's life cycle. It is observed that an important quantity of C&D waste is generated during various modifications done in the usage phase [Esin, Cosgun 2005]. EPA has reported that nearly 44% of the C&D waste results from the modifications activities in the buildings [EPA, 1998]. The long utilization time of the buildings effects in increasing this amount. In order to prevent waste generation it is important -in terms of environmental and economic aspects- to recover these C&D wastes generated in this process.

In the scope of this study, a survey conducted to determine the possible potential for re-using or re-cycling construction wastes generated by the modifications on the basis of their durability. Knowledge in regard to the reasons for modifications is important in terms of determining potential for the reuse of building materials and components. For this purpose, the modifications done in buildings, the reasons for modifications, which building materials and components are focused on during modification and how they are evaluated was researched.

A survey was conducted face to face with 90 building owners in Istanbul, the city chosen as a research area. According to the survey data results; Buildings varying from 60-200 m^2 are 1-20 years old. 80% of the survey participants are the building owners with middle income. 77% of the participants have done modifications in their buildings. 74% of them stated that they had modifications done (generally 5-6 years) after they moved into building.

It is seen that in the majority of the buildings various types of modifications have been done. The mostly preferred modification is the floor covering (61%). Followed by exterior door (43%), kitchen components (sink, counter, kitchen cupboard, etc.) (39%), window frames (36%), wall covering (33%), bath/WC components (bath-tub, wash-bowl, closet, bath cupboard) (31%), debris of wall demolish (23%), interior door (16%), ceiling covering (carton pierre, wainscot, etc.) (14%), heating system (13%), plumbing systems (11%) and electricity systems (10%) modifications [Figure 1].

It is found out that after the modifications, high percentage of building materials and components are thrown away. Accordingly, 58% of the material generated during the modification of floor covering is thrown away. 63% of exterior door, 59% of kitchen components, 60% of window frames, 70% of wall covering, 59% of bath/WC components, 82% of debris of wall demolish, 64% of interior door, 50% of plumbing systems, 55% of heating system materials are thrown away after modifications. 100% of the material generated during the replacement of ceiling covering and electricity systems are thrown away [Figure 1].

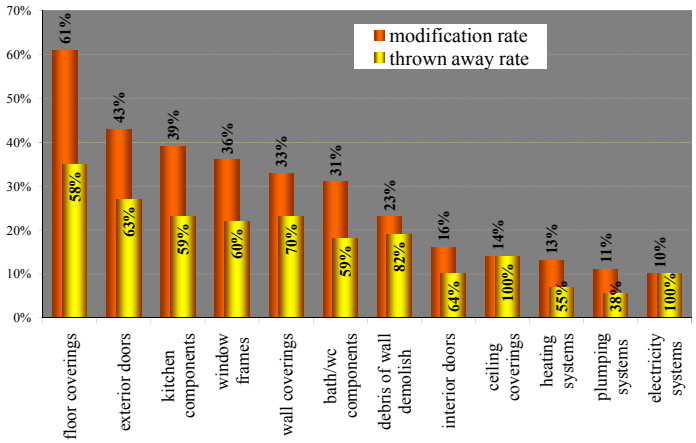

Figure 1. The rate of modifications done in buildings and the rate of materials thrown away after the modifications.

In regard to the modifications made, the participants of the survey ticked one or more reasons listed in the survey form as reasons for making modifications. Accordingly, modifications are done mainly due to ageing and deterioration (%25). Then it is followed by reasons of aesthetic (%19), amelioration in the material quality (%16), difficulty of usage (%10), insufficient space (%9), security (%8), amelioration in the workmanship quality (%6), demand of using fashionable material (%4) and respectively health reasons (%3). It is found out that the rate of modifications done due to the reasons excluding ageing and deterioration is much more (75%) [Figure 2].

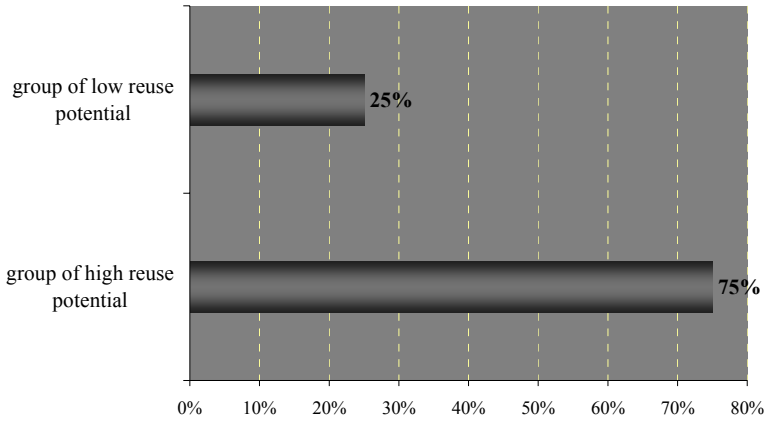

Figure 2- The rates of reuse potentials of modified building materials and components.

As a result of the cross-examination on how the building materials and components are utilized (thrown away, reused or not re-used) in the context of the alteration reasons are given in Figure 3. According to this, it is obseved that a majority of the generated materials for each modification reason are thrown away. It is determined that 65% of the building materials and components which changed due to reasons excluding ageing and deterioration and can be defined as "the group which have include high reuse potential" are thrown away [Figure 3]. Building materials and components which fit into the reuse group (sold, given to the modifier, given to somebody in need, kept in warehouse) are generally exterior and interior doors, kitchen cupboards and sanitary fixtures. The group defined as "stayed onsite" after modification are the wall, flooring and ceiling coverings that can not be removed.

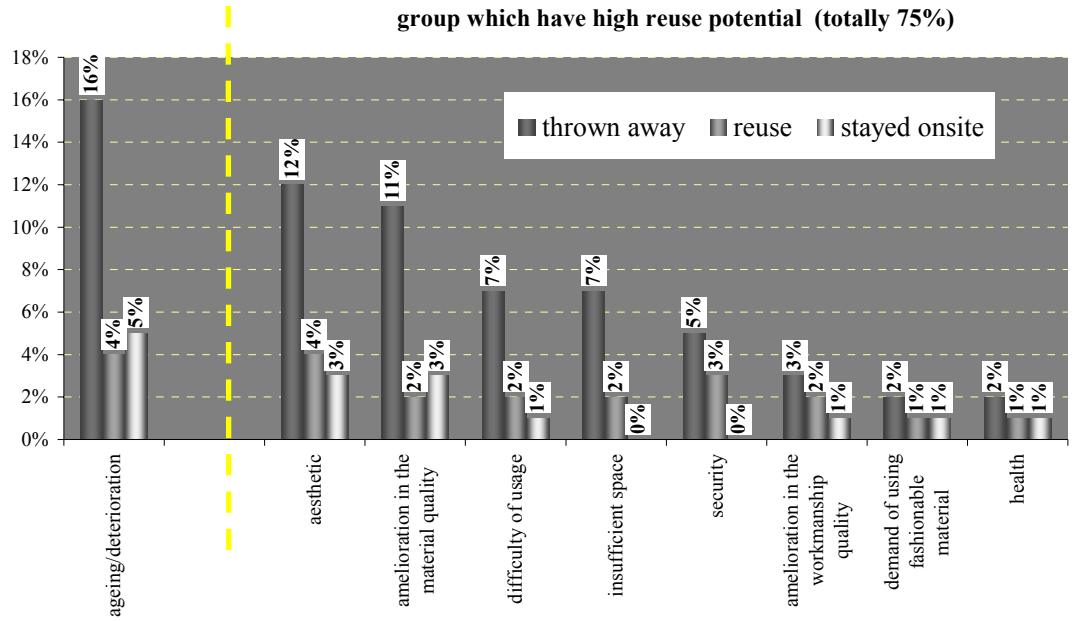

Figure 3- Reuse potentials of building materials and components in context of the reasons for modifications done in houses.

In the survey, a question was asked towards determining the environmental sensibilityof the participants which was related to "the issues in regard to giving importance to the selection of building

materials and components during modification". Figure 4 shows the results given by the participants to this question. According to this, while making modifications to their houses; it is observed that the users generally give importance to the durability and aesthetic outlook in the selection of building materials and components. Als it is observed that they don't give significance to the issue of using material that is non-harmful to the environment [Figure 4].

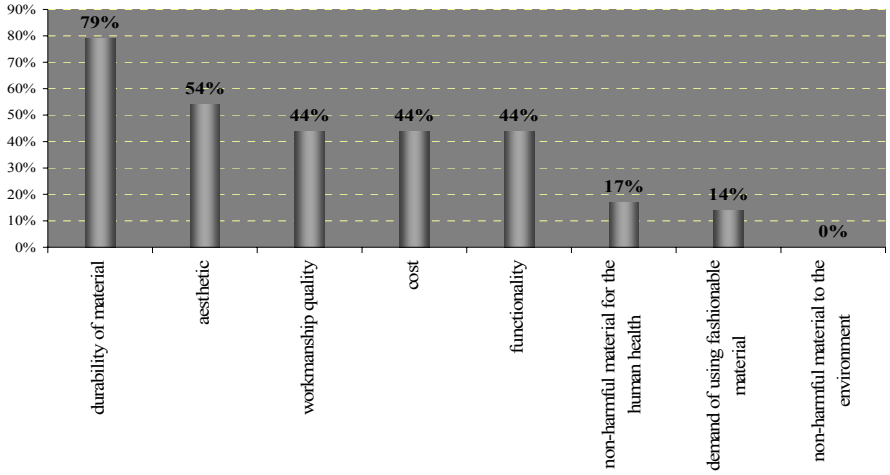

Figure 4- Issues given significance in the selection of building material and component during the modification

6 DISCUSSION AND CONCLUSION

Modification activities are done generaly due to ageing and deterioration. The second reason for modifications is due to the concerns of esthetic outlook. It is observed that the rate of building materials and components that are generated after modifications and that are thrown away is quite high [Figures 1, 3]. While the modification reasons are mainly due to ageing and deterioration, the materials and components which are replaced with new ones can hardly be reused. Thus they turn into waste materials. Some materials generated during modifications done due to the other reasons are modified before they complete their life cycle. Therefore their reuse potential is relatively high. 75% of the modifications are done due to reasons that exclude ageing and deterioration [Figures 2, 3]. Building materials and components that are modified due to reasons that exclude aging and deterioration can be reused (if they are durable) as they haven't completed their usage life. In particular it is understood that the majority of exterior and interior doors, kitchen components, sanitary fixtures and heating systems (radiators) are thrown away [Figure 1]. However, it is possible that such materials and components can be reused after their durability is controlled and the necessary maintenance and repair is done. As can be seen in 'Fig. 3', the majority of materials generated during modifications is due to the reasons that exclude ageing/deterioration are thrown away (~65%) and a very low rate of reuse possibilities (~23%).

The situation of the users in not giving signficance to using and selecting building materials that are "non-harmful to the environment" can be acknowledged as an indictor of the lack of environmental sensibility and awareness. However, the situation of the users' in giving importance to the "durability" characteristics in the selection of building materials is positive since it contributes to the reduction of environmental load [Figure 4].

In Turkey there are many modifications done due to aesthetic outlook concerns and thus building materials and components become waste before they complete their usage life. If these materials are durable they have the high potential for reuse. For this reason, by designing buildings according to the users' demands and expectations in a more satisfactory way, the modifications done before materials

complete their usage life and their turning into waste can be prevented. In meeting the users' expectation for long usage, the materials that have the characteristics of durability and reuse should be seleced. It is important to realize the necessary studies in order to inform and raise the awareness of the users.

The designers must have knowledge and awareness in regard to the selection and implementation of building materials that have the characteristic of durability. This is an important issue which should be stressed in training programs. The production of building materials and components which don't have durability and don't meet the standard should be prevented with the corporation of universities, industries and government. An efficient auditing system should be established by preparing laws and regulations on this issue. It is a fact that the environmental load of buildings will increase as building activities continues to rise. Giving importance to the durability in the selection of building materials and components for the sustainability of environmental values will contribute to the reduction of the environmental load of buildings.

Analysing Building Construction in Time, the ABC Research Matrix

Hielkje Zijlstra [1]

T 52

ABSTRACT

It is necessary to analyse the existing before changing it. That is the only way to regenerate buildings, parts of cities and urban landscapes with conscience. New applied research methods are needed to develop a sustainable environment including our heritage. In my research I concluded: Continuity + Changeability = Durability. Apart from studying relevant literature and other sources I studied seven buildings to develop a method for analysing these buildings.
Past, present and future are all relevant to the buildings. Three levels of analysis have been used to cover these phases. The objective of my research was to identify the qualities of buildings which are relevant when trying to shift from decay to preservation. The influence of construction engineering, the way we can learn from it now, and the way in which a building is able to accommodate change determine the chances of a building's long term survival – the outcome of the interaction of continuity and change.
My research method starts with the contextual aspects: commission; location; architect; typology and design process. The information obtained in the observation stage is reduced to the contextual information which affected the design, creation, existence and preservation/decay of the building. The later sections, which consider the building(s) itself in greater detail, are initially ordered by time: creation, existence, and preservation/decay. Within these, the elements of the building(s) are analysed at three levels: space (interior and exterior); structure (load-bearing elements and elements which determine the structure); matter (shaping the space through materials which affect light, colour, texture, surface, sound, impression, smell, size and weight); building services (climate control, comfort, maintenance and communications). In this way the ABC Research Matrix was created.
The ABC research method will be illustraded by the case study of the Rijksverzekeringsbank ((National Insurance Bank) in Amsterdam.

1 INTRODUCTION

In 2006 I finished my dissertation named: Building Construction in the Netherlands 1940-1970, Continuity + Changeability = Durability. This resulted in the research method: Analysing Building Construction in Time. This method was guided by the following themes: Observation - with an engineer's eye, Research analysis and Regenerative conclusions. It is a method to analyse the existing before changing it. That is the only way to regenerated buildings, parts of cities and urban landscapes with conscience. The main result of my research was this new research method. Also one of the conclusions of this research maintains that a new building typology will be needed to develop a sustainable environment including our heritage.

2 RESEARCH THEMES

Architecture is about more than just constructing buildings. Architecture adds meaning to buildings created by technology. In principle, buildings should be durable (in terms of time as well as finance) objects and therefore changeable, flexible. The lifespan of buildings, i.e. architectural objects, is inextricably linked with their ability to accommodate change. Being aware of this, learning from this, considering this when working on completely new design commissions or commissions concerning existing buildings (where technology will always be needed to implement the design) are all challenges associated with modern building practices which take a long-term view.

2.1 Observation - with an Engineer's Eye

I considered engineering and technology and the views of both architectural critics and practising architects about technology by studying the relevant literature and sources. Technology evolved after the Second World War as a result of the use of new materials, changes in legislation and standards, and the industrialisation of the construction process. Comments about the contribution, or lack thereof, of technical progress to a higher architectural quality were always personal visions primarily shaped by personal taste and habits. Architects developed from supervisors to architect-managers of the entire construction process. Time schedules became an important instrument and working together with structural engineering and building services consultants became steadily more important. The best results were developed on the basis of synergy between the different disciplines.

2.2 Research Analysis

When designing either completely new objects or objects to be incorporated into an existing structure it is important to learn from the past. Not to copy it, but to analyse it and apply the lessons learned while respecting the present context. We have to evaluate knowledge and methods and develop our own design method. This learning aspect is emphasised when a design commission concerns an existing building, but even a new build project always has a context. When dealing with an existing building that building provides the primary context and immediately becomes an element of the key points of the architect's brief. In my view, studying criticism, experiences and interviews, and thoroughly analysing the work of others is not adequately included in the education and training of architects as designers yet.

2.3 Regenerative Conclusions

Regeneration concerns changes which add a new period, a new generation, to the lifecycle of a building. Life means change and the past means that we progress in a spirit of tradition and memory. Furthermore, change cannot happen without continuity. Changes to buildings are affected by both financial and technical considerations. The existing adds a layer of history which can never be created in a true new build project. During the design and construction of the Trade Union Museum in

Amsterdam, housed in the building of the former Dutch Diamond Workers' Union (ANDB), I was introduced to issues related to National Monuments and making changes to such buildings. Fig. 1.
The examples by architects such as Piano, Foster and Herzog & de Meuron demonstrate that leading architects can produce excellent results when regenerating buildings [Powell 1999]. Figs 2 and 3.
The opinions aired by the original architects whose buildings are being changed make it eminently clear that some of them object to any changes to their buildings. Around 1950, architecture critics still felt that architecture amounted to an inviolable work of art. Optional changes were therefore considered an anathema. Architects also resisted changes to their work and event went to court to defend their copyright - it appeared that demolition was not prevented by this copyright but that changes to a building were.
Views about changes also changed themselves. In some cases the original architects are engaged to regenerate their own work. This requires them to take enough distance from "their building" to be able to accept it as a new commission. Of course, this is more likely to happen under legislation which allows listing after 30 years, than under the Dutch system where the period is 50 years.
'Refurbishment is the hard-headed business of making use of what is usable in the ageing building stock; the skilful adaptation of a building shell (which is valuable in its own right and not due to any historic mystique) to a new, or an updated, version of its existing use. The existing building, once refurbished, should be equally as efficient in its new role as a purpose-designed building would be, given the usual number of restraints which always impede the designer realising the ideal in new or refurbished merit and will, by its preservation, improve the amenity of the environment, so much the better.'[Marsh 1983].
To give regeneration a real opportunity, it is particularly important that those initiating projects are prepared to consider regeneration and do not automatically choose demolition. Bringing about this change in attitude is particularly relevant with respect to buildings dating from after 1940. There are definitely opportunities for such buildings in both the near and distant future.
Demolition amounts to a waste of energy and is neither durable nor sustainable, while reuse, changes in use and regeneration of buildings are.
Without a past there can be no future, and changes can only occur if there is continuity. The "creative re-use" advocated by Latham can produce a built environment stratified in time and therefore rich in appearance and the way it is experienced [Latham 2000]. Demolition is sometimes the best option and there is no need to preserve everything. However, a careful assessment which gives serious consideration to repurposing, reuse and regeneration provides many opportunities for creating a rich spectrum of buildings.

3 ANALYSING BUILDING CONSTRUCTION IN TIME

Past, present and future are all relevant to buildings. Three levels of analysis have been used to cover these phases. Where buildings are concerned, we have to look at creation, existence and preservation/decay. The objective of my research was to identify the qualities of a building which are relevant when trying to shift from decay to preservation. Main issues for redevelopment are: space and structure. The influence of construction engineering, the way we can learn from it now, and the way in which a building is able to accommodate change determine the chances of a building's long term survival – the outcome of the interaction of continuity and change. Research can provide data for careful and imaginative observation and analysis. The conclusions which can be drawn in this way may help us make discoveries to understand a building when either designing or redesigning it. Fig. 4. My research didn't only result in relevant conclusions, but also in a research method which will be applied to the subjects covered by the Faculty of Architecture of Delft University of Technology and could be used on international scale. It is a method to analyse the existing before changing it. That is the only way to regenerated buildings, parts of cities and urban landscapes with conscience. Analysing Building Construction in Time aims to discover the qualities of a building, rather than its value. Observation, the first stage of the research, aims to obtain information from the literature, the building

itself, archives and interviews with stakeholders. The second stage, analysis, includes structuring, analysing and interpreting the information. In the third stage, conclusions can then be drawn on the basis of the research themes discussed above. The information is structured in accordance with the research brief. In the long term, it will be possible to identify connections (concerning both buildings and building construction) between the results of Analysing Building Construction in Time, using the research themes defined by me. The information obtained in the observation stage is reduced to the contextual information which affected the design, creation, existence and preservation/decay of the building. Context is the title of the first section in which the contextual aspects are discussed: commission; location; architect; typology and design process. The later sections, which consider the building itself in greater detail, are initially ordered by time: arising, continuing and expiring. Within these, the elements of the building are analysed at three levels: space (interior and exterior); structure (load-bearing elements and elements which determine the structure); material (shaping the space through materials which affect light, colour, texture, surface, sound, impression, smell, size and weight); building services (climate control, comfort, maintenance and communications). In this way the actual research ABC Research Matrix was created. Fig. 5.

4 CASE STUDY: RIJKSVERZEKERINGSBANK AMSTERDAM 1935 – 1940

Architect D. (Dirk) Roosenburg (1887-1962) designed the Rijksverzekeringsbank (National Insurance Bank) building for the Plan Zuid (South Plan) in Amsterdam drawn up by H.P. (Hendrik) Berlage (1856-1934) who also made the first sketch design for the building in 1925.
The premises of the Rijksverzekeringsbank, the body responsible for the implementation of social security legislation in the Netherlands since 1901, were to be built at the site of the Kunstenaarshuis. At the time the commission for this building was being defined, Roosenburg worked at Berlage's office where he worked on Holland House in London which has some similarities with the later Rijksverzekeringsbank. In 1916 Roosenburg set up his own practice in The Hague, which now operates under the name LIAG.
The high-rise section of the Rijksverzekeringsbank intersects the site diagonally and was placed on top of a round building housing the archives. The ring shape was imposed by the 'adressograeph', the machine transporting the filing cards. The shipping department and plant rooms (accessible by truck) were located in the basements. Fig. 6.
The above-ground part had a prefabricated steel structure. The entrance to the office block was placed in the middle, the section at the front was wider than that at the back and the floor-to-floor height was 4.95 metres. The hydronic heating system installed in the ceilings could also be used for cooling. There was an innovative ventilation system installed, all in accordance with the overall design. Fig. 8.
Originally, the building was clad with ceramic tiles, in 1968 LIAG architects replaced these with smooth travertine cladding. Unfortunately this meant that the original texture and relief effect were lost. Based on insufficient research the decisions were made. All the architectural drawings, including those of the ceramic facade tiles, are archived at the NAi. Similarly, the roof terrace was replaced by a large plant room.
The building was extensively modified in 1993. The ring was demolished and then rebuilt with a car park underneath it. The ring also gained a floor level and was used as offices. The steel window frames were replaced by a reasonable alternative in aluminium. In the office section, a floor was

inserted in the double-height space at the front of the building and a new stairwell was built, intersecting the structure. The interior was furnished with precious woods, dark colours, suspended ceiling and high-pile carpet for a law firm which left the building after only five years. The service systems have been removed completely. They functioned very well, but described as 'out of date'. Ceilings were covered by suspended tiles, creating a space for new ducts of one and a half meter height. The next refurbishment was undertaken in 2002. However, the sense of light and openness of the past would never return. Fig. 7.
The technical options are those of just before the Second World War; the steel structure was partly prefabricated; the plant engineering was innovative; part of Berlage's Plan Zuid for Amsterdam. For this study, the building of the Rijksverzekeringsbank was analysed as offices and archives.
The Rijksverzekeringsbank was a technically impressive and beautiful building. It was an example for the technical possibilities just before the Second World War started. Its exterior was seriously affected by the 1968 refurbishment. If a more serious research should have made the reasons for the problems and the qualities should have been recognised. Later, too much money was thrown at it to remove the internal structure and it was pretentiously furnished, resulting in a complete negation of the building's original lightness and neutrality. In 2008 the building will be left again from the nowadays tenant, maybe an opportunity to get back to some of its original ideas that were an example of durable use of materials and services. The unique techniques could be analyzed by the ABC research method. Some of the conclusions out of the research are:
The height of the floors to 4.95 m, is one of the most important factors for possibilities in future change of buildings. As a starting point of the design of new buildings, in consideration of the regeneration of buildings, it is necessary to create an excess of measure in length, depth, height, tolerable load and infrastructure. The future is always unknown so it is better not to waste money on options for future modification as change is always unpredictable, but instead invest in space, dimensions, permissible loads and avoid the unnecessary use of elements which are specific to the building and difficult to reproduce. Examples to support this include the envisaged expansion of the Rijksverzekeringsbank with two floors which never happened, however the roof was fully occupied and the floor loads throughout the building allowed its use as archives.
The results of the ABC research of the facade of the Rijksverzekeringsbank proved that mistakes were made during refurbishments because the technical aspects of these buildings had not been studied in sufficient detail. Construction engineering research is an instrument to show what changes have been made so far and how the building was originally intended to look. Identifying these essences requires a study of the design history of the building. Decisions should not be taken lightly just because generous funding is available. [Zijlstra 2006].

5 CONCLUSIONS

The influence of Analyzing Building Construction in Time, the way we can learn from it now, and the way in which a building is able to accommodate change determine the chances of a building's long term survival – the outcome of the interaction of continuity and change. Research can provide data for careful and imaginative observation and analysis. The conclusions which can be drawn in this way may help us make discoveries to understand a building when either designing or redesigning it. A careful assessment which gives serious consideration to repurposing, reuse and regeneration provides many opportunities for creating a rich spectrum of buildings.
Past, present and future are all relevant to the buildings I have investigated so far and those which I will be investigating in future. I use three levels of analysis to cover these phases. Where buildings are concerned, we have to look at creation, existence and preservation/decay. The objective of my research is to identify the qualities of a building which are relevant when trying to shift from decay to preservation. Change and durability appear to be intimately linked to guarantee a degree of continuity of our built environment:

CONTINUITY + CHANGEABILITY = DURABILITY

Engineer-architects should not only be familiar with architecture (as the art and science of designing and constructing buildings) but also with building engineering (as the science of what is needed to construct buildings). However, architecture is about more than just constructing buildings. Like the case study of the Rijksverzekeringsbank in Amsterdam proved. Architecture adds meaning to buildings created by technology. In principle, buildings should be durable (= able to exist for a long time without significant deterioration in terms of time as well as finance) objects and therefore changeable, flexible. The lifespan of buildings, i.e. architectural objects, is inextricably linked with their ability to accommodate change. Being aware of this, learning from this, considering this when working on completely new design commissions or commissions concerning existing buildings (where technology will always be needed to implement the design) are all challenges associated with modern building practices which desires a long-term view to produce real durable buildings.

Life-Cycle Cost Analysis For The Residentıal Buildings

Esra Bostancıoğlu [1]

T52

ABSTRACT

Decreasing the housing cost – decreasing the life cycle costs that include initial investment costs along with the operating and maintenance & repair costs – will yield beneficial results both for the owners and/or users of the housing facility, and also for the economy of the country. If we consider the big share of housing sector within energy related expenditures, it becomes obvious that ensuring a decrease in the housing energy expenses will also substantially contribute in decreasing energy related expenditures of the country. Such studies and right decisions taken in the course of architectural design will lead to healthy, comfortable and sustainable buildings that consume less and less of limited and scarce resources and thus prevent environmental pollution. Upon understanding in which ratios the materials of building components affecting the initial investment, operating, maintenance & repair costs of the residential buildings would affect the costs as such; there will be preference to have quality and low cost residential buildings in the design phase. From investor's perspective, it will be possible to identify any cost-change rate or items that might be changed within a limited budget depending on the materials of a given building construction. From user's perspective, it will be possible to identify the rate of any potential decrease in the annual operating and maintenance & repair costs depending on the changing materials of building components. From the perspective of domestic economy, it will be possible to witness the potential rates of energy saving and less pollution of the environment thanks to the changing materials of building components.

This study aims at identifying the extent of any changes to occur in initial investment costs, operating costs and life-cycle costs as a result of a change made in the building envelope properties, which is also a factor affecting initial investment cost and operating cost of a building. Life cycle costs of two residential buildings have different structural systems (load bearing and reinforced concrete systems) are analyzed. To this end, building initial investment costs, operating costs and life-cycle costs have been identified and evaluated in line with the changes made in the materials used in the building components forming the building envelope including wall, roof and ground flooring.

KEYWORDS

Life cycle cost, İnitial investment cost, Operating cost, Energy saving.

INTRODUCTION

Housing construction in Turkey enjoys large shares within the construction sector and domestic investments. On the other hand, the housing need in our country prevails considerably in line with the increase of population. It is necessary to meet the **"quality and low-cost"** housing need of Turkey. Apart from addressing to the sheltering need of people, residential buildings should also offer comfort conditions to the users within their life-cycle. In connection with the increase in energy consumed by artificial subsystems, problems such as decline in energy resources in place, dependency on foreign countries for these resources, hazardous effects of gases emitted for energy consumption on the human health, increase in the air pollution and accordingly global warming have become significant in terms of providing comfort conditions. In the light of this information, it's necessary to construct and operate buildings, which meet required comfort conditions and ensures minimum energy consumption.

Decreasing the housing cost – decreasing the life cycle costs that include initial investment costs along with the operating and maintenance & repair costs – will yield beneficial results both for the owners and/or users of the housing facility, and also for the economy of the country. If we consider the big share of housing sector within energy related expenditures, it becomes obvious that ensuring a decrease in the housing energy expenses will also substantially contribute in decreasing energy related expenditures of the country. Such studies and right decisions taken in the course of architectural design will lead to healthy, comfortable and sustainable buildings that consume less and less of limited and scarce resources and thus prevent environmental pollution. Upon understanding in which ratios the factors affecting the initial investment, operating, maintenance & repair costs of the residential buildings would affect the costs as such; there will be preference to have quality and low cost residential buildings in the design phase. From investor's perspective, it will be possible to identify any cost-change rate or items that might be changed within a limited budget depending on the characteristics of a given building construction. From user's perspective, it will be possible to identify the rate of any potential decrease in the annual operating and maintenance & repair costs depending on the changing characteristics of building construction. From the perspective of domestic economy, it will be possible to witness the potential rates of energy saving and less pollution of the environment thanks to the changing characteristics of building construction.

This study aims at identifying the extent of any changes to occur in initial investment costs, operating costs and life-cycle costs as a result of a change made in the building envelope properties, which is also a factor affecting initial investment cost and operating cost of a building. To this end, building initial investment costs, operating costs and life-cycle costs have been identified and evaluated in line with the changes made in the materials used in the building components forming the building envelope including wall, roof and ground flooring.

2. COST CONCEPT AND LIFE-CYCLE COST

Building cost emerges in different phases of building construction process. Life-cycle cost of buildings is as much necessary as their initial investment costs. Buildings will also have costs during their utilization. Maintenance, repair and operating costs arising within the utility period amount to a significant line in the budget of house owners.

In terms of energy efficiency, an assessment of life-cycle costs to be conducted during the design, implementation, utilization or renovation phases of a building will contribute in taking right decisions about the design. With their acknowledged nature of continuity, the operating costs have a significant impact on the emergence of life-cycle costs along with the initial investment costs. Energy costs, which are also considered to be a part of the real operating costs, are the most important parameters to be controlled within the building life-cycle so as to ensure energy efficiency. The energy needed for heating and cooling, a major part of overall energy expenditures, can be controlled by means of building location, distance between buildings, building position, building form and building envelope

that provide climatic comfort conditions with a minimum heat loss. Similarly, the lightning energy can also be controlled. Since life-span of buildings is targeted to be reduced; initial investment costs, operating, maintenance-repair costs and renovation costs should be tackled altogether in the design phase.

By means of life-cycle cost, one can identify whether or not a project is going to be more cost-effective than its initial investment cost and under which circumstances maximum cost-effectiveness will be in place. Various projects can be compared for this purpose. Whenever a decision is to be made amongst various investment options, then the option having the minimum life-cycle cost is accepted as the most appropriate option. (Manioğlu, 16-17) (NBS Handbook 132, 14-20)

Design parameters affecting energy conservation are as follows: location, direction, building form, building envelope, thermophysical and optical properties, volume dimensions, settlement type, distance between buildings, natural ventilation system. (Berköz, Küçükdoğu v.d., 1995) The design parameters affecting the heating energy conservation in a given building are building form, building envelope, optical and thermophysical properties. Building envelope optical properties include absorption, conductivity and reflection coefficients against solar radiation; whereas thermophysical properties amount to total thermal conductivity coefficient (U (k)) and transparency ratio. All these properties are the determining factors for the heat quantity coming from the building envelope unit space, which is gained or lost by the effects of outside air temperature and solar radiation.

3. TWO DIFFERENT TYPES OF CONSTRUCTION SYSTEMS - LOAD BEARING AND REINFORCED CONCRETE FRAME SYSTEMS

Load bearing system is the one where various and relatively smaller construction materials including stone, brick, briquet blocks, wood, sun-dried brick and gasbeton are piled up one on the other to build a load-bearing wall by either standing on their own weight and or by using binder/adhesive materials. In such systems, it is allowed to leave spaces on load-bearing slot and exterior walls for doors and windows in line with the ratio and locations specified by the corresponding regulations. In those systems, walls are connecting to horizontal and vertical elements called bond beams and columns, which are based on pulling force.

In accordance with the provisions of "Regulation on the Buildings to be Constructed in Earthquake Zones" in effect in Turkey, the following unreinforced materials might be used on load-bearing walls: natural stone, solid brick in compliance with the Turkish Standards; bricks and block bricks having a void ratio not exceeding the maximum allowed void ratio for load-bearing wall material as specified by the Turkish Standards TS-2510 and TS EN 711-1, gasbeton construction materials and elements, lime - sandstone, solid concrete briquet block, sun-dried bricks or other similar masonry units. Natural stone bearing walls can only be built at the basement and ground floors of unreinforced buildings. Reinforced concrete bearing walls can only be built at the basement of load bearing buildings.

The minimum wall thickness rates -excluding plaster thickness- of bearing walls are illustrated in the Table 1 in relation to the number of building storeys. If there is no basement in place, then the minimum wall thickness rates of ground floor and upper floors will apply as indicated in the Table 1. Wall thickness rate of a permitted additional attic storey will be the wall thickness rate of its lower floor. (Resmi Gazete No:26100)

Table 1. Minimum thickness rates for bearing walls (Resmi Gazete No:26100)

Earthquake Zone	Permitted Storeys	Natural Stone (mm)	Concrete (mm)	Brick and gasbeton	Other (mm)
1, 2, 3 and 4	Basement	500	250	1	200
	Ground Floor	500	-	1	200
1, 2, 3 and 4	Basement	500	250	1,5	300
	Ground Floor	500	-	1	200
	First Floor	-	-	1	200

Reinforced Concrete Frame systems; are the ones where carrying elements such as columns and beams withstand the dynamic and static loads affecting buildings and where vertical loads are transferred to main system by means of columns. In such systems, all walls do only bear their own loads and impose the load to their underlying floor in any storey; floors then transfer their assumed loads to columns either by means of beams or directly. Not having a bearing character, walls in this system (except for the curtain walls) can be relocated or lifted in any storey; thus making space management flexible.

4. METHOD AND ACCEPTED CONCLUSIONS

- This study tackles building envelope properties, one of the efficient design parameters required for an energy efficient environment and for heating energy conservation in buildings. Building components forming a building envelope are walls, roof and the ground flooring. If materials used in walls, roof and flooring are to be changed, the initial investment costs and operating costs of a building will be different. This study is based on the existing standards and regulations in our country; therefore the unit prices of the Ministry of Public Works (Akçalı, Ü., 2007) and the materials that can be used in walls, floorings and roofs as specified in TS 825 (TS 825, 1998) have been identified in the first place. Since ground flooring is linked to the construction system and since wood rafter framing roof is approved, insulation materials and their thickness rates have been differentiated in those building components. It is determined that 4 cm of extrude polystyrene foam may be used in ground floor furnishing systems, and that fiberglass (6, 8, 10 cm fiberglass) of different thicknesses may be used on the roof as insulator. It is assumed that carrier brick and gasbeton shall be used in reinforced concrete system; and brick with vertical holes and gasbeton shall be used in concrete skeleton system as wall body material. For both systems, it is assumed that materials with identical thickness values are used in exterior walls. (19 cm brick, 19 cm aerated concrete) Different alternatives are created with the use of extrude polystyrene foam and rock wool in different thicknesses as wall insulator. Since it is a more convenient system in places that are used for a prolonged period, such as housings, and condensation possibility is less as a result of steam diffusion, it is assumed that insulators are applied externally on walls. Project alternatives generated by differentiating body and insulation materials in construction compounds are displayed in Table 2.
- Life-cycle cost consists of initial investment costs, operating costs and maintenance-repair costs. However, initial investment costs along with heating costs - having the largest share within the costs incurred in a building life-cycle - have been considered as operating costs in this study when identifying the life-cycle costs. Other costs have not been taken into scope.
- Initial investment costs of residential buildings - stand-alone buildings with two storeys covering a total of 148 m2- to be constructed by means of load bearing and reinforced concrete frame systems are calculated. The Ministry of Public Works unit price rates, a measurement standard adopted and used in Turkey, have been used in the calculation of initial investment costs (Akçalı, Ü., 2007). Unit Price Analysis has been conducted for the wall insulation materials with different thickness ratio, which are not covered by the Ministry of Public Works unit price list. The initial investments costs calculated also cover the costs

relating to civil works.

- It is aimed that projects also provide required climatic comfort conditions for users. Therefore, it is investigated whether the shell design conducted in all of the evaluated projects conform to specifications of TS 825, and whether it is less than restricted heat energy requirement. Also, it is checked whether there is any condensation in wall alternatives in the projects conducted. all project alternatives evaluated in Table 2 provide the required thermal comfort as per TS 825, and no condensation occurs in wall alternatives. Determination of operating costs of project alternatives is based on annual heating cost calculation. In order to be able to calculate annual heating costs, "TS 825 Heat Requirement Calculations" computer program is used. (www.izoder.org) Through this computer program, annual heat requirement values ($Q_{yıl}$) are calculated for all of the project alternatives. Annual fuel quantity is calculated through the following formula:

  $$By = \frac{Q_{yıl}\,(kWh) \times 1{,}3}{2 \times H_u\,(kWh/m^3) \times \eta_k} \quad (m^3/yıl)$$

  By: Annual fuel quantity (m^3/yıl)
  $Q_{yıl}$: Annual heat requirement of building (kWh)
  H_u: Fuel heating value (kWh/m^3) = 10,38 (kWh/m^3) for natural gas.
  η_k: Boiler efficiency= 0,85-0,92 for natural gas. (Anon., 2002)

  It is assumed that natural gas is consumed in all project alternatives, and annual heating expenditures of project alternatives are determined in accordance with natural gas prices in Istanbul in 2007.
- And when determining lifecycle cost, initial investment costs and operating costs are taken as basis. Buildings are evaluated considering their lifecycle as 60 years.

5. ASSESSMENT

As illustrated by the Table 2, when the initial investment costs of residential buildings - constructed through load bearing system having different building envelope alternatives - are assessed; the alternative in which a wall body material of 19 cm vertical perforated brick is jacketed with exterior 4 cm XPS and in which a 10 cm fiberglass is used in attic has been identified as the most cost-effective alternative in terms of initial investment costs. When it comes to annual heating energy quantities; the alternative in which a wall body material of gasbeton is jacketed with an XPS having maximum thickness and in which a 10 cm fiberglass is used in attic is considered to be the best alternative having the minimum annual heating energy quantity. When alternatives in which 19 cm gasbeton is jacketed with 8 cm XPS and with 8 cm rock wool are to be compared, extruded polystyrene foam alternative has proved to cause less heat loss. As regards the initial investment costs; the alternative in which gasbeton wall is jacketed with 2,5 cm XPS and in which 10 cm fiberglass is used for attic has turned out to have the lowest initial investment cost as compared to the other alternatives using gasbeton body material.

As illustrated by the Table 2, when the initial investment costs of residential buildings - to be constructed through reinforced concrete frame system having different building envelope alternatives - are assessed ; the alternative in which a wall body material of 19 cm horizontal perforated brick is jacketed with exterior 5 cm XPS and in which a 8 cm fiberglass is used in attic has been identified as the most cost-effective alternative in terms of initial investment costs. When it comes to annual heating energy quantities; the alternative in which a wall body material of gasbeton is jacketed with an rock wool having maximum thickness and in which a 10 cm fiberglass is used in attic is considered to be the best alternative with the lowest annual heating energy quantity.

The alternative in which a wall body material of 19 cm brick is jacketed with exterior 8 cm XPS and in which 10 cm fiberglass is used for attic, is the most cost-effective alternative in terms of the life-cycle

cost as compared to the alternatives to be constructed through load bearing system. The alternative in which a body wall material of 19 cm brick is jacketed with external 8 cm XPS and in which 10 cm fiberglass is used for attic, is the most cost-effective alternative as compared to the other alternatives to be constructed through reinforced concrete frame system.

Table 2. Initial investment, operating and life cycle costs of the residential buildings which are with constructed with load bearing system and reinforced concrete frame system.

6. CONCLUSIONS

As a result even though brick is the most cost-effective wall body material in terms of initial investment costs; gasbeton is the most cost-effective alternative in terms of annual operating costs for reinforced concrete frame and load bearing systems. Brick is also the most cost-effective alternative in terms of life-cycle costs for both systems.

When two residential buildings to be constructed through load bearing system and reinforced concrete frame system with the same features and same envelope properties (wall, roof and ground flooring) are to be compared, residential building to be constructed with load bearing system will found to be more cost-effective when compared to the residential building to be constructed with reinforced concrete frame system both in terms of initial investment and of operating costs, thus being more effective option in terms of life-cycle costs. As illustrated by the Tables 2, alternatives to be constructed with load bearing system has 4,23- 8,49% lower initial investment costs, 1,18- 4,60% lower operating costs and 3,51- 6,53% lower life-cycle costs as compared to the alternatives to be built with reinforced concrete frame system.

ABSTRACT

Timber traditional houses can pose a significant image of Malaysian built environment heritage. It is then crucial for professional to undertake the responsibility in ensuring the timber houses still in a fair condition. In judging the building condition, it is good to have a more concrete evaluation, so that the reliable recommendation can be made within short period of time. The Prioritize Ranking System which is still in the process of developing is deem fit for this purpose. The streamline methodology of the system is using the numerical coding for the survey pro forma. From the prioritize ranking, the data is then used as to foresee the condition of the house; either dilapidated, fair or good. For the pilot project, the system is tested to the small-scale timber traditional house namely Telapak Naning. The finding of the survey is found true in reflecting the current state of the house. The limitation of the research is regarding the reliability of the system; how does it suit in measuring the timber defects of traditional houses. Since then, the future research suggested is more concern on the reliability aspect, with more and more timber traditional houses should be surveyed using this proposed system.

1 INTRODUCTION

Malaysia, in aiming towards Vision 2020 as a develop country; still have large numbers of timber traditional houses which scattered in the suburban and rural area throughout the country. Some of them age, perhaps a few decades; and a number of them have reached a century. Become old and 'antique' across time, it is indeed requires the evaluation of maintenance, for the purpose of repair and replacement, could be; as to function up to the standard as well as providing safety for the occupants. In addition to that, these traditional houses also have a very significant potential in being gazetted as national heritage. Therefore we have to put an effort in realising this potential, or otherwise it will just be a conservation paradigm.

Moving forward the direction, this research gives focus in establishing the certain criteria to be used in evaluating the timber defects for traditional houses. To date, there is very little in number of published research focusing specifically on rating these traditional houses. Syed Zainal [1995] through Badan Warisan Malaysia provides some valuable criteria in assessing the building that should be classify as national heritage. But then, it is more to town building as well as colonial types. With the intention to link the said gap, this research concentrates on the idea of providing the criteria to be used when evaluating the timber defects via a building condition survey work. Apart from descriptive survey, this research tries to develop the Priority Ranking System, with the use of more numerical data for coding and analysing purposes.

Therefore, this paper discussed the said numerical-building-condition-survey based namely 'Timber Defects Prioritizing Ranking System'. The central approach of the system is to rank the timber defects that are found in one particular building. This will provide some guidance for the owner/care-taker in planning their repair (or replacement) work to be undertaken. After all, it will contemplate the current condition of the house, whether it is fit for occupancy or not. The discussion starts with the brief introduction of the timber house, literary discussion of the system as well as research approach, plus the survey pro forma adapted. It will then follow by the data analysis and discussion of finding, before end up with concluding remarks and future research to be done.

2.BRIEF DESCRIPTON OF TELAPAK NANING

Telapak Naning located at Kampung Sungai Jerneh, Brisu, Malacca, Malaysia, being among the oldest house within the vicinity. Telapak Naning has its own historical significance value. It takes about one hour and half by driving from the capital city of Kuala Lumpur, with estimated travel distance around 170 kilometres. Fig. 1(a) shows an image of Telapak Naning and background information in brief respectively. Telapak Naning was built in the year of 1800 as an arrogance of traditional Malay residential building by the great ancestors of Tuan Haji Nayan Karin. This 206 years house comprises many spaces for resting and welcoming guests (verandah), family occasion (huge main hall) and sleeping (bedroom).

(a) The exterior of Telapak Naning **(b)** The original portion of Telapak Naning

Figure 1(a) & 1(b): The house of Telapak Naning *Source*: Fieldwork (2007).

In 1967, the custodian of the house built an annex building to provide shelter for his younger sister. He had also made some replacement to the few building materials. The original portion of Telapak Naning can be seen in Fig. 1(b). Now, the house is not occupied at most of the time. The younger sister of Haji Nayan has been responsible to look after the house since her house is built as an annex to Telapak Naning. The house is raised on stilt which built from timber. According to Hj Nayan, only one big tree was used during the construction. This tree is cut into pieces to adapt the traditional structure of the house, namely column, raised floor, wall framing and roof truss. The joining of the structure is majority based on the type of tongue-and-groof and mortise-and-tenon.

In term of heritage or legacy setting, the special features of Telapak Naning predominantly affects by the historical value (as claimed by the custodian) of the house, which had been used by the Naning warrior named Dol Said as a place to rest, somewhere around 200 years back. This manifestation claimed to be true as it had been mentioned by national digest magazine in Malaysia, Mastika [2006] which stated that this house is a symbol of bravery and independence. As for further clarification, it should be confirmed by the Department of Museum, State of Malacca regarding the historical story line of the house. Until now, the house is proclaim to have some sort of supernatural element, in which it is said to give some sign if there will be anything likely to be happened to the family, or even to the area or *kampong*.

3.THE SYSTEM AND RESEARCH APPROACH

Remarks : October 2006 / Clear weather / Visual and Preliminary Inspection/ Detail Examination			
Scope of Condition Survey (Telapak Naning)	Covers: Exterior Public and Semi-private • Verandah • Living Rooms	Limitations	Excluded: Private Area (Bedroom) Attic Space Annex Building

Figure 2: Scope and limitations of condition surveys on site.

This survey used two (2) power tools, namely Protimeter SurveyMaster MM and Ventilation Meter and the scope of survey as per Fig. 2. The Protimeter is used for identifying the surface and internal moisture content of the timber element. Ventilation Meter is to identify the surrounding temperature and air velocity inside the house. The data from Protimeter is then refer to the simple diagnosis chart as depicted in Table 1, to determine whether the timber member have either condensation defect, rising dampness or no defect at all. For Velocity Meter, data gathered is for recording purpose only.

Figure of Condition Survey Checklist For Timber Defects

No.	Const. Element	Design & Construction	Building Survey: Defect Diagnosis – Causes	Building Survey: Defect Diagnosis – Types	Building Survey: Defect Prognosis	Building Survey: Proposed Remedial	Prioritise Ranking (Refer TOR) a	b	c	d	e	P.SM: Measure Mode	P.SM: Search Mode	Remarks

Guidelines:

1 "Causes" code: 1 Insects; 2 Fungal; 3 Weathering; 4 Mechanical Failure

2 "Types" code: 1 Termites-Subterranean; 2 Termites-Drywood; 3 Termites-Others; 4 Beetles; 5 Other insect; 6 Wet rot (brown); 7 Wet rot (white); 8 Dry rot; 9 Soft rot; 10 Blue stain; 11 Other rot

3 Prioritise Ranking: a Physical Condition; b Fabric Effect; c User Effect; d Potential Risk; e Risk Effect

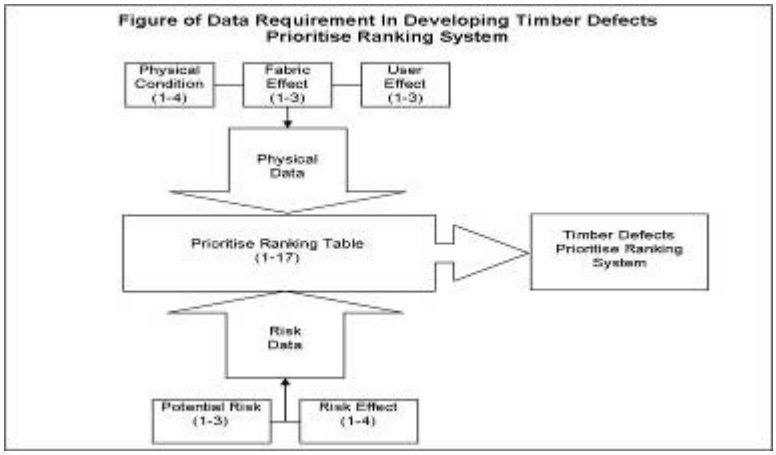
4 P.SM (Protimeter SurveyMaster SM) [Measure=Surface; Search=Below] L = Low ; H = High

Figure 3: Condition Survey Checklist for Timber Defects
Source : This research (2007).

Table 1: Simple Diagnosis Chart for Protimeter SurveyMaster MM
Source : Protimeter (---)

Measure Mode	Search Mode	Interpretation and Comment
Low Reading	Low Reading	Dry surface, dry below the surface – safe
Low Reading	High Reading	Dry surface, damp below the surface. Investigate further using Deep Wall Probes in Measure Mode
High Reading	Low Reading	Damp surface, dry below the surface – probable condensation
High Reading	High Reading	Damp surface, damp below the surface. Trouble. Investigate further with Deep Wall Probes.

Data collection is mostly in the form of numerical coding. By referring to Fig. 3, the latter section of survey pro forma indicates the information required for calculating the sum of timber defects in determining its priority. Two types of data have to be collected, which are the physical data and risk data as per Fig. 4.



Physical data:
Current condition of the building at the time survey conducted.

Risk data:
The potential hazard that might be occurred to the building

The physical data and risk data is sub-divide into 5 categories, with 3 types and 2 types respectively

Figure 4: Data Requirement In Developing Timber Defects Prioritise Ranking System
Source : Modified from Pitt (1997).

Data is sum-up as to get the ranking of defects priority. Towards the end, one particular building that being surveyed is rated out of 3 conditions in term of structural stability, namely Condition 1: Dilapidated; Condition 2: Fair and Condition 3: Good. The linguistic value and average marks of these 3 conditions is given in Table 3.

Table 2: Term of Reference For Timber Defects Prioritise Ranking System
Source : This research (2007)

No.	Type of Data	Scale Value	Chronology Value	Linguistic Value
a	Physical Condition	0	Repair or replacement is needed within the period of 1 month	Element/structure not function at all
		1	Repair or replacement is needed within the period of 1-6 month(s)	Serious defect, can not function to an acceptable standard
		2	Repair or replacement is needed within the period of 6-12 months	Functional sound, but need an urgency repair or replacement
		3	Repair or replacement is needed within the period of 1-2 year(s)	Structurally function, only minor defects
		4	No need for repair or replacement	Free from any visible defects
b	Fabric Effect	1	Significant effect	If one particular element/structure is malfunction, what is the possible effect to the other element/structure member
		2	Have effect	
		3	Minor or no effect at all	
c	User Effect	1	Significant effect	If one particular element/structure is malfunction, what is the possible effect to the other element/structure member
		2	Have effect	
		3	Minor or no effect at all	
d	Potential Risk	1	Most possible	Risk particularly to structural damage, which in turn lead to death or injury (if the scale value is 3, the "risk effect" should have the score value of "4")
		2	Possible	
		3	Not possible	
e	Risk Effect	1	Death or serious injury	Risk particularly to structural damage, which in turn lead to death or injury
		2	Injury	
		3	Minor injury	
		4	No risk associated	

Table 3: Condition Assessment of the Building
Source : This research (2007)

Condition	Linguistic Value	Average Total Marks
Condition 1: Dilapidated	✓ Not safe for occupancy	04-05
Condition 2: Fair	✓ Sign of defect in secondary structural member (not give effect to the building stability) ✓ Need repair or replacement	06-10
Condition 3: Good	✓ Main structural member is strong and stable ✓ Defects which influence aesthetic value only	11-17

4.ANALYSIS AND DISCUSSION OF FINDINGS

By the time survey is conducted, the ventilation meter indicates the surrounding temperature is 27 degree Celsius, with the air velocity of 2.5 m/s. This shows the possibility of low moisture content and providing the dry surface for the whole site. Proceed with the analysis, the result of condition survey is shown in Table 4. According to the number of appearances, rotting is the highest number of occurrence, followed by termites attack and beetles. Therefore, insect attacks and fungal infestation remain as the main causes of timber defects, since more than half of the number of defects recorded fall within these two categories of causes. The location of defects is mostly found in the exterior part of the house. The defects can be seen in Fig. 5.

(a) **(b)** **(c)** **(d)**

Figure 5 (a), (b), (c) and **(d):** Defects which occurred at the surface of the timber at the site.

For the analysis of timber defect prioritise ranking, the lowest total marks is 5, whereas the highest score recorded is 16. The indication for marking system is the priority should be given to the lowest score. In this condition survey, the element of roof beam at staircase area is found to have the serious defects cause by fungal infestation, with the type of defect is dry rot. The score for this defected roof beam is 5 with the occurrence number is 1. The second serious defect with total mark of 10 is still cause by the fungal infestation, and located behind the area of defected roof beam. Total mark of 16 is recorded as the highest with prioritise ranking number 6; and 4 number of defects occurrence. The defects which classified as the least priority defects are caused mostly by the insect attacks.

The result of moisture content for defected timber element is depicted in Table 4, which shown under column of P.SM. A particular attention should be given to H (high) score, regardless whether the score is under measure mode or surface mode. Based on the survey result, the dampness defects could be raising dampness, since the characteristic of the reading is dry at the surface and damp below the surface. Thus eliminates the possibility of condensation defects. The roof beam which is the serious defects among 12 has the reading of low and high for the surface and below surface measurement

respectively. As to confirm whether raising dampness is occur, a further testing should be done using Deep Wall Probes, which is not carried out since the custodian did not allow for any destructive testing.

After prioritising each and every single timber defects found, it is important to deliberate about the overall condition assessment of the house; whether it is dilapidated, fair or good. Furthermore, this finding is much more useful for the occupants of the house for the sake of safety. According to the rated score of 5 types of data in determining timber defects prioritise ranking system; this research has extended the calculation in getting the total average marks for rating of condition assessment. The analysis reveals the average score is 13, thus indicates the condition of good (as refer to classification in Table 3). The level of severity for each timber defects is determined by the calculation of severity index.

Two types of data is required, namely the frequency and the average score of risk effect for each particular defect. The frequency is determined when the survey completed by referring to the number of defects occurrence in "defect diagnosis-types section" (as per Table 4). At first, the frequency is translated into percentage form. Then, the average score of risk effect is matched with the cross-reference table to get the accumulate multiplier. The accumulate multiplier is used as weight-age for average score of risk effect, with 0.25 is assign for each score. The formulation of severity index is shown below. In interpreting the result, the highest percentage indicates the most severe defect.

Severity Index *= Frequency (%) x Accumulate Multiplier of Risk Effect*

Beetles	4	3	25.00	4	0.25	6.25	14.29
Wet rot (brown)	6	3	25.00	2	0.75	18.75	42.86
Dry rot	8	3	25.00	3	0.50	12.50	28.57
TOTAL		12	100.00			43.75	100.00

* cross-reference

Risk Effect	Score	Multiplier	Accumulate Multiplier
	1	0.25	1.00
	2	0.25	0.75
	3	0.25	0.50
	4	0.25	0.25

From this finding, suffice to mention that all timber defects found in Telapak Naning is classified as not very much severe, since no severity index above 50% is recorded. Termites attack found to be the lowest index (below 10%) and considered not severe to the house. The finding of severity index is then confirmed and supported the score of condition assessment, which good with no severe defects found. From the research conducted, the main finding can be drawn as below:-

a. Element to be repaired (in order of priority) – details to be refer from Table 4 and 5

1) Roof beam;
2) Ceiling joist
3) Fascia board;
4) Either floor (timber joist) or ceiling board;
5) Floor joist (header); and
6) Either beam, window, column or wall board

b. Overall Condition Assessment – Condition 3: Good

c. Severity Index – Wet rot (brown) with almost 43%

5 CONCLUSION

Telapak Naning gives significant remarks to Kampong Sungai Brisu, Malacca, Malaysia. This small-scale house at one time ago is used by the Naning warrior and its team as a rest house during Naning War. Now, the house is left unoccupied (except for special occasion) since the annex building is build by the custodian siblings. The special feature of this house is regarding its historical value. Major renovation which carried out around 1967 gives quite a lot of changes, especially for finishing materials. This is found to be the main cause in which the occurrence of timber defects in term of numbers is very minimal to the house nowadays.

Building condition survey reveals that the house is still in a good condition and classified as good. For maintenance purpose, the custodian should give priority for replacement of the roof beam element at the staircase area (the lean-to-roof structure). In term of severity level, frankly to quote that no element had seriously damaged. This is because all the timber defects are recorded to be below of 50% severity index. Keep in mind that only one portion of the house namely roof beam at the staircase area that need to be replace urgently, otherwise the severity level reflects the number of defects occurrence for the whole structure. The limitation of the research is the reliability of the system developed for the purpose of rating criterion namely Timber Defects Prioritise Ranking System. Telapak Naning form as pilot project for the system and it is likely to be found that the findings reflect the current state of the house. More and more building should be surveyed using this system in evaluating the system reliability. Therefore further research to be done is to carry out a building condition survey work, particularly to the timber traditional houses.

ACKNOWLEDGEMENT

The authors would like to acknowledge the parties that help in preparing the paper, in one way or another, especially to Tuan Haji Nayan Karin, the custodian of Telapak Naning and University Malaya, Malaysia for funding this research under fundamental research grant no. FP058/2005D. Last but not least, to all families members whom had give endlessly supports and encouragements.

Condition Assessment of Façade Rendering through in-Situ Testing

Inês Flores-Colen[1]
Jorge de Brito[2]
Vasco P. de Freitas[3]

T 71

ABSTRACT

Condition assessment of rendering façades should compare required performance level with supplied performance level, on a practical and unambiguous basis, in order to help the serviceability assessment and maintenance planning of rendering during the post-occupancy stage. The application of rendering on-site performance assessment has been difficult due to several reasons: design solutions are mostly prescriptive instead of based on performance assessment criteria; technical data provided by the manufacturers is insufficient or descriptive; and legal requirements (EN 998-1) are not enough to evaluate its global performance. Therefore, condition assessments have been restricted to visual inspections, without quantitative parameters through testing techniques.

This paper presents a methodology that can be used in condition assessment (supplied in-service performance) of rendering façades through in-situ testing. This ongoing research (within the PhD study of the first author) intends to identify some rendering properties (related to surface condition, mechanical strength and water resistance) that can be measured through on-site suitable and expedient techniques, and compared with standard hardened rendering properties or integrated into reference in-service performance profiles (IPP). Finally, performance criteria of mechanical strength is discussed through an experimental campaign that compares open porosity, apparent dry bulk density, compressive strength, adhesion strength, apparent ultrasonic pulse velocity and dynamic elastic modulus for different types of mainly cement-based renders (sound samples), used in common Portuguese buildings.

1 INTRODUCTION

Façade rendering is a common cladding system in Portugal. According to 2001 national statistics, rendering represents 61.6% of 2,561,227 Portuguese buildings built between 1946 and 2001 (81% of all Portuguese buildings), followed by architectural concrete (21.3%), stone (11.3%), ceramics (5.5%), and others (0.8%). Render mortars used in Portuguese recent buildings are of two types: cement and sand mortars in two or three layers, mixed in-situ (current renders), and factory-made mortars, made of cement, sand, admixtures and additives in a single layer (ready-mixed renders), in which the finishing layer is either the render itself ("one-coat mortars") or other materials (e.g. a paint). The use of ready-mixed mortars started in the 90's in Portugal and it has increased. In 2005, about 30 manufacturers produced 1.2 million tons of ready-mixed mortars, with a total amount about 90 million euros. In 2006-2015, the reduction of mortars made on site is expected to increase the production of ready-mixed mortars until around 2.5 million tons.

Condition Assessments are required throughout the life cycle of the building façade, and are an important tool to improve the knowledge of in-service conditions and helping the inspectors in maintenance planning. A condition survey is defined by RCIS [1997] as "the collection of data about the condition of a building, estate or portfolio; assessing how that condition compares to a pre-determined standard, to identify any actions necessary to achieve that standard now, and maintain it there over a specific time horizon, the purpose being to support management decision making". Conditioned-based maintenance by performing inspection assessments has been for some time a useful tool for reducing life cycle costs and finding more efficient ways of using maintenance budgets [Hertlein 1999], and it is also an appropriate maintenance strategy for elements whose condition can be suitably monitored.

In this context, condition assessment of rendering façades should compare the required performance level (properties that have been specified at the design stage) with the supplied performance level, in order to help the serviceability assessment. The application of rendering on-site performance assessment has been difficult. The lack of performance information provided by the manufacturers, the complexity of the building process, and the difficult relationship between users and products requirements, have led, in the majority of the cases, to in-field assessment based only on visual observation of defects / anomalies, instead of quantitative performance requirements analysis.

2 RENDERING CONDITION ASSESSMENT

Rendering condition assessment, based on technical in-service assessment, must define the problem, collect available data, characterize existing anomalies [Flores-Colen *et al* 2008] and their probable causes, evaluate in-service performance (fulfilment of the functions established at design), check whether user's demands are being fulfilled and, finally, define corrective, preventive or monitoring maintenance actions. The comparison of required performance level (the minimum performance level that must be provided at a certain moment in time) with supplied performance level (the maximum performance which can be provided by a building component at a certain moment in time) over time can be made if both supply and demand for components are expressed in the same way. Fig. 1 shows the proposed relationship between demand and supply sides, when a rendered façade condition assessment is made through visual observations, in-situ and lab testing. The relationship of these two conceptual languages is based on the context of Conceptual Framework for the Whole Life Cycle of Facilities [Szigeti & Davis 2005].

The required hardened properties rendering mortar (required performance criteria) are established by European standard EN 998-1 [CEN 2003] (rendering mortars based on inorganic binders use on walls with different fields of use and exposure conditions), and complemented by other technical issues (see Fig. 1). These properties are assessed through laboratory tests using standard apparatus and specimens.

According to Hermans [1995], the supplied performance level has to be determined on-site (it is affected not only by design decisions, but also by construction process, material characteristics, its shape and location in façade) and contains a set of performance levels belonging to various performance categories at a certain moment. This author also compares deterioration with performance "the term deterioration is connected to the change of the characteristics, instead of to the change of the performance level itself". Therefore, it is important to recognize that some cases of reduction of properties do not affect critical aspects of performance.

In-situ assessment of rendering in-service performance has been usually restricted to a visual appraisal without systematic methodologies in the majority the cases, which has led to a deficient diagnosis and consequent implementation of inadequate maintenance interventions. The usual absence of records of intervention (historic of the building) and means of access in the buildings aggravate this situation through an accumulation of errors.

Most field inspections of buildings that include an assessment of the performance of materials and components are descriptive. From literature, recent empirical studies have been developed to assess mainly degradation of common rendering façades through visual observation (symptomatic analysis) such as the application of a physical and visual five ranking (each level describes visual or functional loss of performance) for claddings [Shohet *et al* 2002] or a single deterioration indicator for render façade (OLD - overall degradation level) that is obtained through the average weighted sum of all defects, according to their condition level [Gaspar & de Brito 2005].

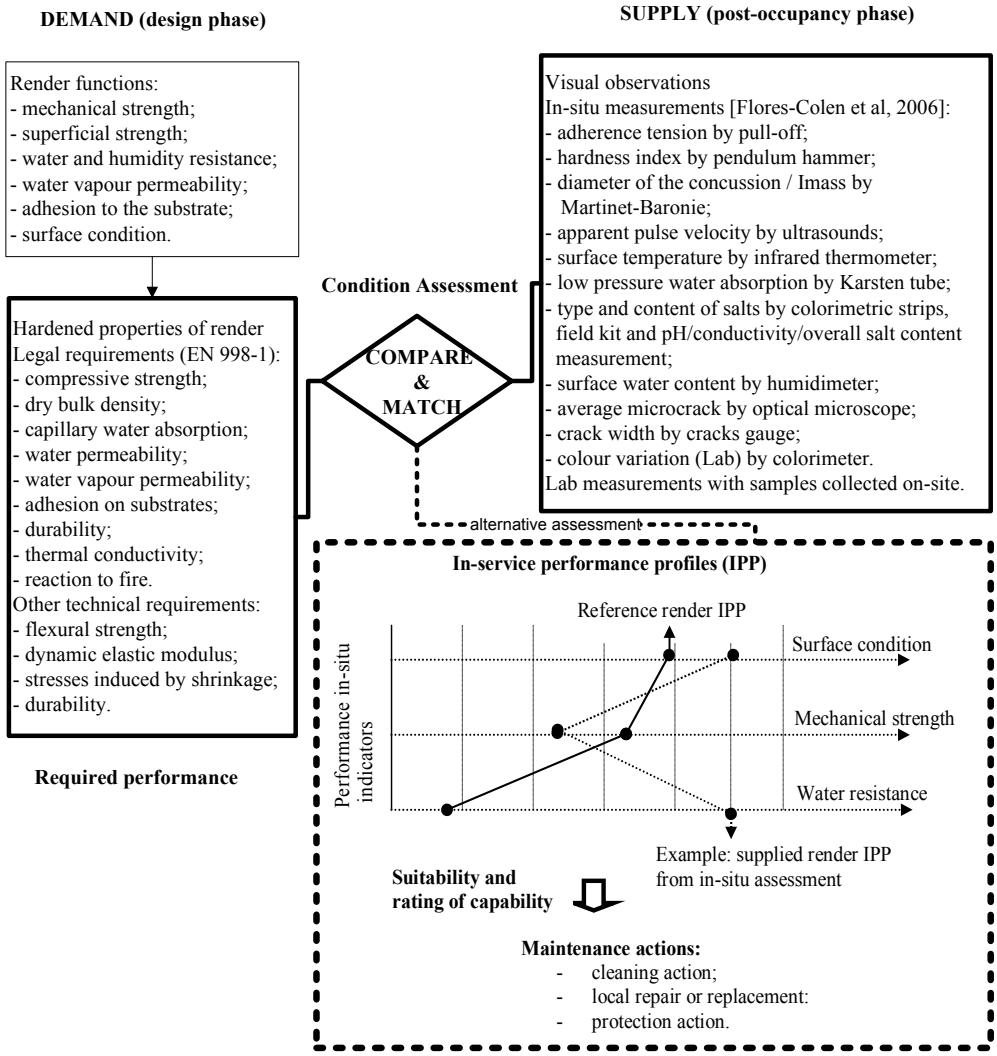

Figure 1. The methodology for rendering condition assessment.

Figure 1 shows in the supply column the in-situ techniques that have been used in field assessment [Flores-Colen *et al* 2006]. It can be concluded that these in-situ techniques (except for adherence tension by pull-off test) do not provide a direct correlation with the performance requirements for rendering in European standard EN 998-1 or other technical documents; most of these criteria result from laboratory tests. Therefore, it is important for conditioned-maintenance planning that in-situ characterization of each render includes relevant properties that are measurable on-site, complementing (or correlating with) standard performance requirements.

An alternative assessment is proposed (see Fig.1) using in-service performance profiles (IPP) that include in-service performance indicators and reference values of properties measured on-site (reference IPP). Three performance categories are proposed: surface condition, mechanical strength and water resistance. Conditioned maintenance should be applied when the supplied in-service performance level (at least in one of the three previous categories) is not acceptable, through cleaning, repair, replacement and protection actions.

3 INDICATORS OF MECHANICAL STRENGHT - EXPERIMENTAL CAMPAIGN

3.1 Testing Program and Results

In this paper, some indicators of mechanical strength are discussed in terms of in-service performance assessment. Therefore, an initial set of laboratory tests was performed in order to help the interpretation of in-situ technique results. This experimental campaign included the production of standard samples (3 samples for each property to be studied, with dimensions of 4 x 4 x 16 cm^3 or 2.5 x 2.5 x 28.5 cm^3 in the dynamic elastic modulus determination), and also of 9 small-scale models (1.5 cm of render + brick substrate, with dimensions of 49 x 19 cm^2), as shown in Fig. 2. These models were produced with different render mortars, taking into account the types that are currently used in rendering of brick cavity-wall façades:

- pre-mixed mortars (compositions specified by the manufacturer), that are applied in a single coat, without finishing (designated by one-coat renders - PM), with heavy finishing - PP (e.g. ceramic tilling) or light finishing (e.g. paint - PL);
- made on-site mortars (with cement and/or lime binders) that normally applied as multi-coat systems (but not in these tests), PC with cement binder and PB with lime and cement binders.

Figure 2. Standard prisms of rendering mortar (left), and small-scale models (centre and right).

Table 1 shows the average of three or five values for the following hardened rendering properties: apparent dry bulk density (ρ_A), compressive strength (R_C), dynamic elastic modulus (E_d), open porosity (P_{open}), adhesion strength (f_A) and apparent ultrasonic pulse velocity ($V_{apparent}$). The first three were determined by standard testing (see Table 1). The remaining properties were obtained by techniques that can be applied on-site (in this testing program those tests occurred on the surface of small-scale models or on small samples collected from those models).

The adhesion strength (f_A) is determined by the tensile extraction test (pull-off), Fig. 3, on the left, according to the EN 10 155-12 [CEN 2000], taking into account the recommendation MDT.D.3 of RILEM [2004] to evaluate in-situ adherence. The test program included five tensile extraction tests on the small-scale models for each product, using square metallic test piece with dimensions 5 x 5 cm^2.

The device that was used measured the force necessary to extract the disk. The pulling-off resistance was calculated by the equation 1.1. The types of the rupture (cohesive or adhesive) were also observed.

After pull-off test and adequate preparation (remove the metallic piece and remaining glue), three samples were submitted a compressive tests (Fig. 3, at the center). The other samples were used on open porosity determination (Fig. 3, on the right).

$$f_A\left(N/mm^2\right)=\frac{F_u}{A_{square}} \quad \text{.....Eq.1.1}$$

where: F_u (rupture force, in N), A_{square} (area of a square test piece, in mm^2).

Figure 3. Pull-off test (left), compressive strength test with small samples (centre), and samples for open porosity determination (right).

The open or apparent porosity (P_{open}) expresses the percentage of the relationship of the volume of open pores in the test specimen to its exterior volume, and can be measured by microscopy and intrusion techniques. The simplest indirect porosity measurement is total pore volume determination by vacuum saturation, where only pores that are interconnected are measured. This technique does not give any information about size and shape of the pores [Thomson *et al* 2004].

In this testing program the open porosity (P_{open}) was measured by immersion in water (Archimedes' principle), according to the equation 1.2 from ASTM C 830 [2006], but with the following adaptations: four samples with dimensions 2.5 x 2.5 x 2.5 cm^3 (cut from the samples that were obtained in the adhesion tests on the models) and process of saturation (samples were measured after having been subjected for 2 days to a correspondent pressure of 10 cm water column followed by a higher pressure of 88 cm water column for at least 7 days), using a pressure pump (Fig. 4, on the left). This procedure was set to guarantee that water penetrates in all open pores, even the ones that could be partially occluded, giving probably values close to the absolute porosity [Fernandes *et al* 2005].

Figure 4. Pressure pump (left), determination of suspended weight (centre), and transit time measurement on the surface of the model (right).

$$P_{open}(\%) = \frac{W - D}{W - S} * 100 \quad \text{.....Eq.1.2}$$

where: W (saturated weight, when two consecutive weightings do not differ by more than ±0.05 g), D (dry weight, in the oven at a temperature of 70 ºC), and S (suspended weight, after saturation and while suspended in water, Fig. 4 at the centre).

The apparent ultrasonic pulse velocity ($V_{apparent}$) was calculated by using ultra-sound equipment PUNDIT that generates low frequency ultrasonic pulses and measures the time taken for them to travel from one transducer to the other through the material tested (Fig. 4 on the right). The transducers were placed on five points on the surface of the render (indirect or surface transmission) with a distance between them of 100 mm. The apparent ultrasonic pulse velocity was determined from equation 1.3.

$$V_{apparent}(km/s) = \frac{d}{T} \quad \text{.....Eq.1.3}$$

where: d (path length between transducers, in mm) and T (transit time, in μs).

3.2 Discussion of Tests Results

The results have shown that the open porosity of small samples (using Archimedes principle technique and higher pressure in saturation process) can be used as an on-site indicator of render type, and of hardened standard properties (compressive strength $R_{exp}^2 = 0.9808$ and dynamic elastic modulus, $R_{log}^2 = 0.9174$, see Fig. 5). With these results, rendering façade of common buildings (mainly cement-based renders) should be divided into two groups. The first one includes the majority of pre-mixed mortars (one-coat renders without finishing or to receive light finishing), like PM and PL mortars. In this group of mortars it is to be expected (in small samples collected on site) values of open porosity higher than 20%, compressive strength lower than 5 MPa (categories CSI, CSII or CSIII according to EN 998-1), and dynamic elastic modulus lower than 10 000 MPa (according to LNEC 427/05 [Veiga 2005], ready-mixed mortars should have $E_d \leq 10\,000$ MPa to limit the cracking susceptibility). The second group includes all made on-site renders and some ready-mixed mortars (mostly to receive heavy finishing), and the expected values are open porosity lower than 20%, compressive strength (CSIII or CSIV according to EN 998-1) higher than 5 MPa, and dynamic elastic modulus higher than 10 000 MPa (for example, wall with high exposure to impact loads).

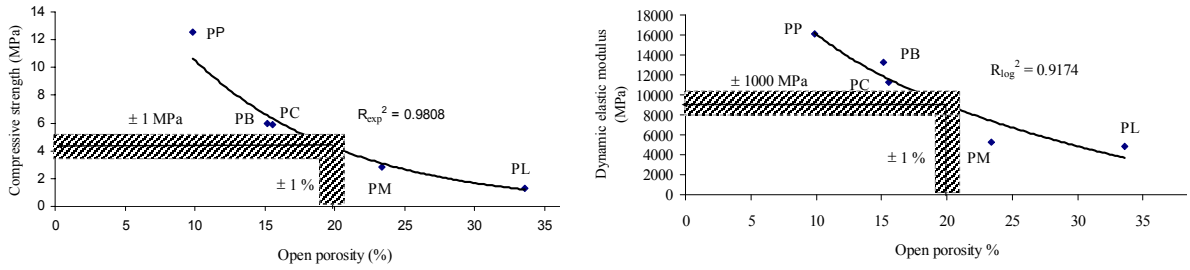

Figure 5. Relationship between open porosity and compressive strength (left) and dynamic elastic modulus (right) from test results.

According to other authors the porosity of cement-based mortars is low when compared with lime-based mortars, with reference values of 20 to 25% [Begonha 2001]. Another study has obtained a wide range of porosity from 10 to 35% in cement-based mortars and using water saturation [Goueygou *et al* 2003]. Also that compressive strength is a function of the porosity and the type of binder [Thomson *et al*, 2004], however the study of pore size distribution is important to understand in detailed mechanical properties of air-entrained cement-based mortars, like PM type; in general, only voids of diameters smaller than 50 nm enhance both compressive and flexural strength [Wieloch & Klemm, 2005].

The porosity is related with the compacity of render. The results have also shown the relationship between open porosity and apparent dry bulk density with $R_{linear}^2 = 0.7247$, with for example for first group: $P_{open} < 20\% \Rightarrow \rho_A < 1500$ kg/m^3. The results have also shown that the pull-off test can be an useful on-site technique, because its results can be compared with standard values (according to EN 998-1 and LNEC 427/05, it should be $f_A \geq 0.3$ MPa or a cohesive fracture pattern); it also can be used as an indicator of compressive strength of the render (the increase of compressive strength of in-situ samples when compared with standard samples can be due to application procedure changes, Fig. 6, on the left).

The results have also shown a good correlation between apparent ultrasonic pulse velocity and dynamic elastic modulus ($R^2 = 0.8804$, with $V_{apparent} < 3.5$ km/s $\Rightarrow E_d < 10\,000$ MPa for the first group of mortars, see Fig. 6 on the right), despite using indirect method (surface transmission). From literature, the ultrasonic waves are directly influenced by its elastic parameters (relation of shear velocities and Young's modulus for homogeneous material), and elastic modulus depend on porosity, therefore pulse velocity decreases with porosity increase [Goueygou *et al* 2003]; this tendency was observed with relation $R^2 = 0.6759$ between $V_{apparent}$ and P_{open}.

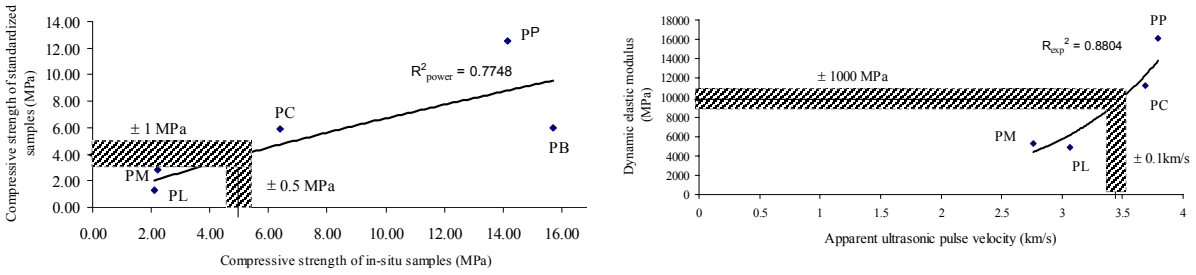

Figure 6. Relationship between compressive strength of in-situ and standardized samples (left), and apparent ultrasonic pulse velocity and dynamic elastic modulus (right) from test results.

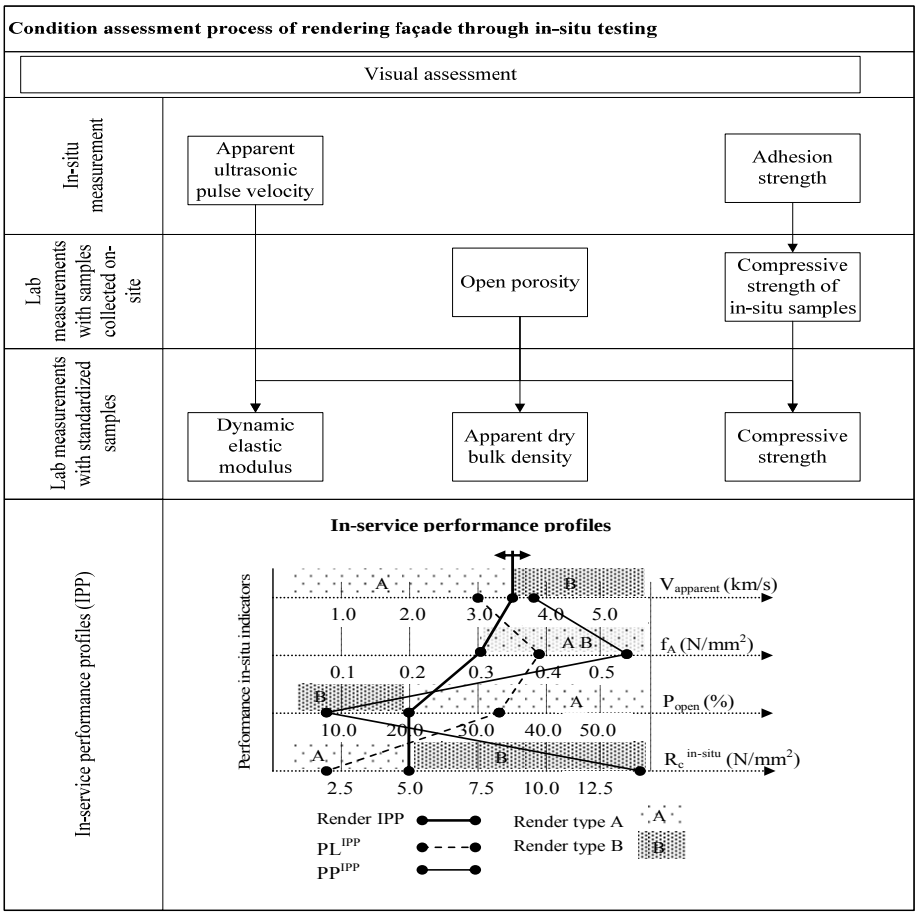

Figure 7. Condition assessment of rendering through hierarchy on-site mechanical strength indicators.

5 CONCLUSIONS

This paper is focused on in-service performance assessment within rendering condition assessment, in order to help conditioned-maintenance during its service life. The experimental campaign on sound samples allowed the specification of mechanical strength indicators that are measurable through in-situ expedient techniques or in laboratory with samples collected on-site, in terms of apparent ultrasonic pulse velocity, adhesion strength, open porosity and compressive strength (see Fig.7), despite the high variability of the material under study. Results have also shown that the extrapolation of standard hardened properties (dynamic elastic modulus, apparent dry bulk density and compressive strength) from previous on-site properties, and their comparison with required performance can be made. It can also be concluded that the use of an in-service performance profile (IPP) in serviceability assessment is possible with the identification of a reference IPP that considers two groups of renders (A and B), taking reference values (as shown in Fig. 7, in this example, the ready-mixed mortars PL belongs to group A and PP to group B). This profile allows the integrated study of more than one on-site property and therefore it can increase the reliability of the assessment. Finally, it is concluded that there is a potential to follow this methodology (with expedient techniques instead of more advanced techniques that can increase costs and time consuming of inspections) of rendering condition assessment, even though its reliability can only be acquired through wider and longer experimental campaigns. The actual performance in-situ during early age of rendering façade is yet to be fully understood (an important step to maintenance planning), therefore, more studies and further research should be conducted in sound and damaged samples.

ABSTRACT

The aim of this paper is to explore the durability aspect of a realkalisation treatment using impressed current. To that purpose, a series of small slabs of poor quality reinforced concrete were cast and artificially carbonated. A first set of electrochemical experiments were then performed, including rest potential, linear polarization and impedance measurements. Afterwards, carbonated slabs were realkalised using an impressed current of 1 A/m² of steel following the CEN/TS 14038-1 specification [1]. The efficiency of the treatment was determined 15 days, 10 weeks, 6 months and 12 months after realkalisation through different electrochemical measurements and analytical characterizations.
The rest potentials and corrosion currents results indicate a slight decrease of the corrosion activity after treatment although the passive state of the reinforcement encountered in uncarbonated concrete was not recovered. The efficiency of the treatment is clearly demonstrated with the phenolphthalein test just after treatment with the pink coloration around the rebars, but, the colour is not so obvious after 12 months. SEM and Micro-Raman analysis indicate an evolution of the rust products from active to passive, thus confirming the decrease of corrosion activity. Concerning the impact of the treatment on the cement matrix, a noticeable enrichment in potassium concentration was encountered on the treated surface. But the mechanical performances of the concrete do not seem to be affected.

1 INTRODUCTION

Good quality concrete protects steel reinforcement. Chemical protection is provided by the concrete's high alkalinity and physical protection by the concrete cover acting as a barrier which impedes the access of aggressive species. Nevertheless, the corrosion of steel in concrete is becoming the most common cause of failure in concrete structures. The corrosion can be due either to the presence of chlorides at the steel level or by the carbonation of the concrete cover. Concerning the latter, the natural ageing carbonation process leads to a consumption of portlandite inducing a decrease of the pH. Then, the concrete cover is no longer protective and active corrosion can take place [1-3]. Since the rust products as a result of corrosion have a 2-4 times bigger volume than that of steel, it causes volume expansion developing tensile stresses in concrete, which ultimately result in cracking and spalling of the concrete cover. Before its spalling, reinforced concrete structures affected by carbonation may be cured by two realkalisation techniques using either impressed current or sacrificial anodes [3]. In these techniques, rebars play the role of cathodes and an anode is temporarily applied onto the concrete surface. Electrical conductivity is assessed by an alkaline electrolyte contained in a cellulose pad. Realkalisation treatments are supposed to both generate hydroxyl ions around the rebars by hydrolysis and induce a migration of alkaline ions from the electrolyte to the concrete cover. A few studies [5-16] deal with the efficiency of the realkalisation treatment but very few explored the durability aspect [16-17].
The aim of this paper is to evaluate the efficiency and the durability performances of a realkalisation technique using impressed current applied to carbonated reinforced using electrochemical measurements (rest potential, linear polarization and impedance) and analytical characterizations (phenolphthalein, Micro-Raman Spectroscopy, Scanning Electron Microscopy combined with EDS, alkaline concentration profiles and mechanical tests).

2 EXPERIMENTAL

2.1.Specimens

Seven 300x300x50 mm reinforced concrete slabs were cast using Portland cement (CEM I, 275 kg/m^3) and a 0.7 water to cement ratio according to the EN 1766 Standard. The reinforcement consisted in three parallel steel rebars (Fe235, 6 mm in diameter and 400 mm in length) embedded in a 22 mm concrete cover. On these rebars, a 200 mm zone was delimited in the centre using epoxy resin (Fig. 1).

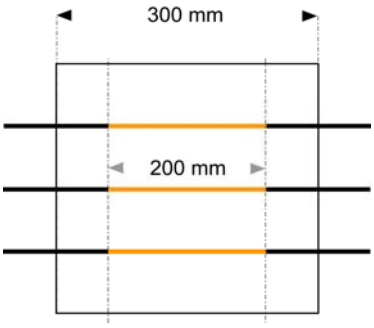

Figure 1. Diagram of the reinforced concrete slabs

After curing, one slab was conserved as a sound reference specimen and the other six were preconditioned for a month (45 °C, 60 %RH) and then carbonated for two months (22 °C, 50 %CO_2, 60 %RH). Prior to the study, all the slabs were stored in water in order to prevent the carbonation of the sound concrete slab.

2.2.Treatment Realkalisation Using Impressed Current

The realkalisation treatment using impressed current was applied on 4 reinforced concrete slabs (Table 1). The three rebars of each slab were connected together as the cathode. An anode (steel, grid of 5x5 mm meshing, 2 mm diameter) was placed on the top surface of each slab, embedded in a cellulose pad impregnated with a potassium carbonate-based (Ka_2CO_3) electrolyte. The pad was kept wet by spraying electrolyte during the treatment, on a daily basis. The four slabs were put in series, with the anode and the cathode connected to an electrical supplier with an imposed current density of 1A/m² of steel. The temperature and the current generated by the electrical supplier were monitored with a Sefram datalogger during the treatment. In order to reach the 200 A.h/m² efficiency threshold given in the European Specification [1], a current density of 1 A/m^2 of steel was imposed for 8.5 days. At the beginning of the treatment, the necessary voltage to deliver the correct current was about 18 V for the four slabs.

Table 1. Slab references

Slab references	Treatments
1-S	None (sound concrete reference slab)
2-C	Carbonation (carbonated concrete reference slab)
3-C	Carbonation
4-R, 5-R, 6-R and 7-R	Carbonation and realkalisation

2.3.Characterizations

2.3.1 Electrochemical measurements

Non-destructive electrochemical measurements were used to estimate the corrosion state of the steel rebars embedded in concrete. As such measurements depend so much on temperature and humidity, a specific preparation of the slabs was required in order to obtain reproducible data : thus, the measurements were performed at 20°C, on a slab that had been totally immersed in water for 24 hours the day before.

The electrochemical system was composed of three electrodes, the working electrode being the steel rebar, the reference electrode being a calomel saturated with KCl ($E°_{(NHE)}$=242mV), the counter electrode being a titanium/platinum based grid and the chosen electrolyte being water. The measurements were conducted with a portable potentiostat PARSTAT PAR2263 on 9 sites (sites 1, 2 and 3 for rebar 1 ; 4, 5, and 6 for rebar 2 and 7, 8 and 9 for rebar 3) of the slab surface as illustrated in Fig.2.

Figure 2. The electrochemical system

Three types of electrochemical measurements were performed. First of all, the potential monitoring gave the rest potential value after 10 minutes. Second of all, the slope (1/(Re+Rp)) of the linear polarization resistance measurement (± 10 mV around the rest potential and a sweep rate of 2.5 mV/min) was determined. Third of all, the impedance technique (± 10 mV around the rest potential, 39 mHz < frequency < 100 kHz) was used to assess the concrete cover and the electrolyte resistance (Re). Finally, corrosion currents (taking into account the ohmic drop and the polarised surface; and expressed in µA/cm²) were calculated according to equation (1).

$i_{corr}=26.10^{-3}/(Rp.S)$ (1)
with Rp the polarisation resistance and S the considered steel surface.

2.3.2 Analytical characterizations

Complementary analytical characterizations (Table 2) were performed, mainly on the carbonated concrete reference slab 3-C and on the treated slab 7-R, in order to both evaluate the efficiency of the realkalisation treatment and detect eventual side effects such as transformations of the cement matrix. The sampling locations are given in Fig. 3.

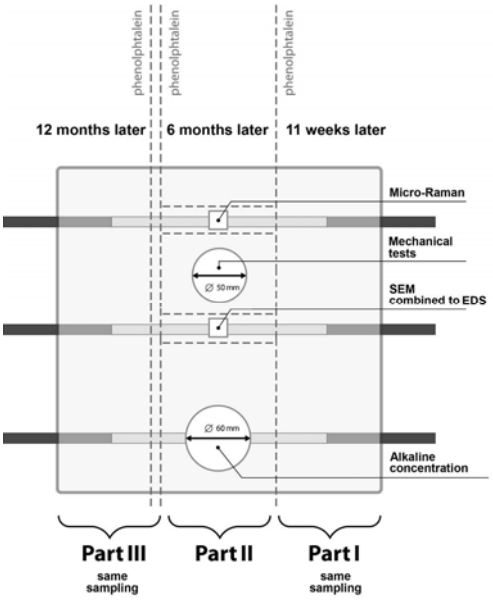

Figure 3. Sampling locations for analytical characterizations

Table 2. List of analytical characterizations

Analytical characterizations	Samples	Expected information
Phenolphthalein test *(Colour indicator)*	Freshly sawed surface	pH evolution
Micro-Raman Spectroscopy	Freshly broken surface	Rust identification
SEM combined to EDS *(JEOL JSM-5600)*	Freshly broken surface	Transformations of cement matrix and rust
Alkaline concentration profiles *(Atomic absorption spectroscopy)*	Powders at different depths	Penetration of alkaline ions in concrete
Elastic modulus (E_{dyn}) *(Ultrasonic measurement)*	Cores (50 mm in diameter and 50 mm in height)	Evolution of mechanical properties
Compressive strength (Rc)	Cores (50 mm in diameter and 50 mm in height)	Evolution of mechanical properties

3.RESULTS AND DISCUSSION

3.1.Electrochemical Measurements

A set of electrochemical measurements was performed before, 15 days, 10 weeks, 6 months and 12 months after the realkalisation treatment in order to evaluate its efficiency and durability.

3.1.1.Rest Potentials

Before the realkalisation treatment (Fig. 4), the rest potentials are respectively around -100 mV for the sound concrete slab (slab 1-S) and mainly between –300 and -550 mV for the five carbonated slabs (2, 4, 5, 6 and 7). ASTM C876 [19] indicates that the corrosion probability of rebars embedded in concrete is less than 10% when the rest potential is above -120 mV (SCE) and it is more than 90% when the rest potential is below -276 mV (SCE). This standard has been quite discussed lately, due to a discrepancy between the thresholds above mentioned and the real state of corrosion encountered for steel reinforcement embedded for example in chloride contaminated concrete (where very low potential values can be measured due to the salinity of the concrete more than to a real corrosion of the rebars). Therefore, the results are more commonly interpreted considering potential gradients instead of absolute values. Nevertheless, as far as the slab were cast using ordinary Portland cement and carbonated, the thresholds can still be considered as relevant.

Thus, the rebars in the sound concrete are probably passive whereas an active corrosion probably takes place on the rebars in the carbonated concrete. It is to be noticed that although the fabrication, the curing, the accelerated carbonation and the measurement protocol were strictly the same for the five carbonated slabs, their electrochemical rest potential response showed a variation of about 250 mV.

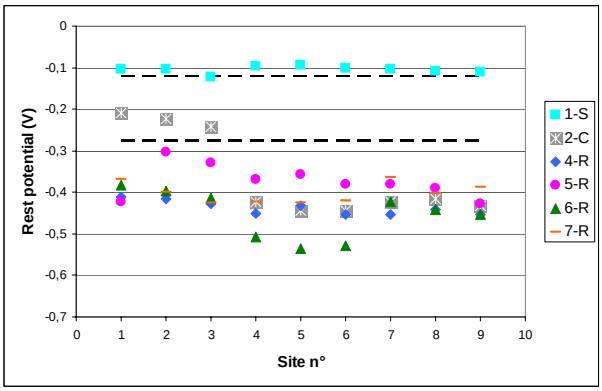

Figure 4: Rest potentials for the sound, carbonated references and the carbonated slabs before the realkalisation treatment

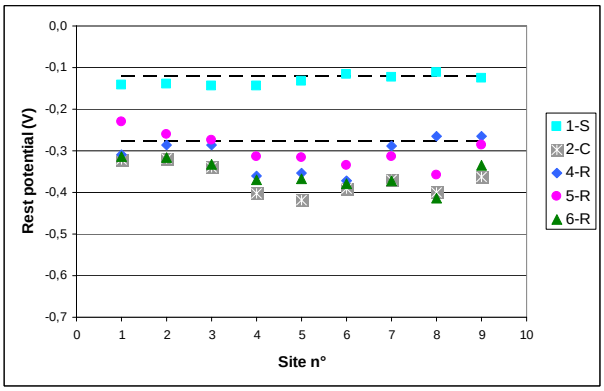

Figure 5: Rest potentials for the sound carbonated references and the carbonated slabs 10 weeks after the realkalisation treatment.

Just after treatment, the rest potentials have shifted to values of about –1.2 V indicating that the rebars have been polarized. This polarization effect has to be monitored to confirm that the treatment has been done correctly. After about 2 weeks, the polarisation effect is no longer observed except maybe for rebar 3 of the four treated slabs.

Ten weeks after treatment (Fig. 5), the rest potentials of the non treated slabs are respectively between –150 and –100 mV for the sound concrete reference (slab 1-S) and between –400 and –300 mV for the carbonated concrete reference (slab 2-C). These rest potentials shifted slightly towards more negative values. On the contrary, the rest potentials for treated slabs 4, 5 and 6 shifted towards more positive values and are more homogeneous

(-300 mV ± 100 mV) than the initial ones. This rather indicates a slowdown of the corrosion probability after the realkalisation treatment.

Twelve months after treatment (Fig. 6), the rest potentials of the untreated slabs are respectively between –200 and –100 mV for the sound concrete reference (slab 1-S) and almost equal to –450 mV for the carbonated concrete reference (slab 2-C). Thus, these rest potentials continue to decrease slightly. Concerning the treated slabs, the rest potential values are almost the same as those obtained after 10 weeks (more or less 50 mV).

As an example, the evolution of the rest potential measurements for treated slab 6-R, versus time (before treatment, 15 days, 10 weeks, 6 months and 12 months after treatment) is illustrated in Fig. 7. After treatment, the rest potential values are always higher than the initial ones indicating an efficiency of the realkalisation treatment (except for rebar 3, 15 days after treatment which can be due to a non depolarisation of the steel). The rest potentials increase with time starting from before treatment to 15

days after, to 10 weeks after and to 6 months after but then slightly decrease for those obtained after 12 months.
More electrochemical measurements are needed to verify the durability of the realkalisation treatment for a longer time.

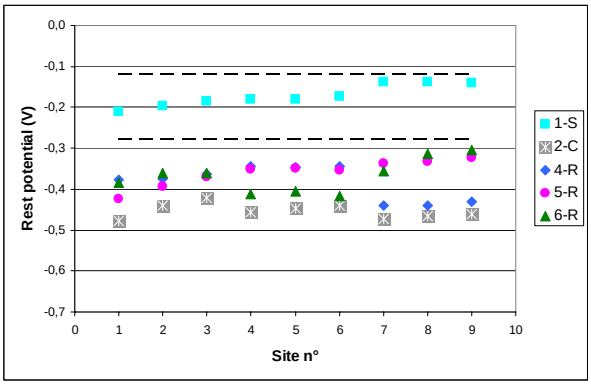

Figure 6: Rest potentials for the sound carbonated references and the carbonated slabs 12 months after the realkalisation treatment.

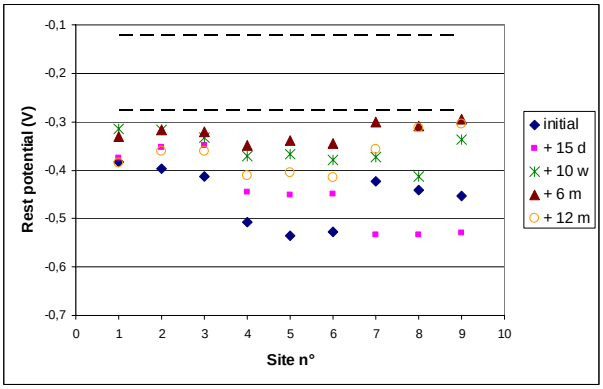

Figure 7: Evolution of the rest potentials for treated slab 6-R.

3.1.2 Corrosion currents

The corrosion currents of the sound concrete reference (slab 1-S), the carbonated concrete reference (slab 2-C) and the treated slabs (4-R, 5-R, 6-R and 7-R) are illustrated in Fig. 8 (before treatment), Fig. 9 (10 weeks after treatment) and Fig. 10 (12 months after treatment).
According to RILEM studies [21], 4 ranges of corrosion activity can be distinguished from negligible, to weak, to moderate and up to high, the corresponding thresholds being 0.1, 0.5 and 1 µA/cm².

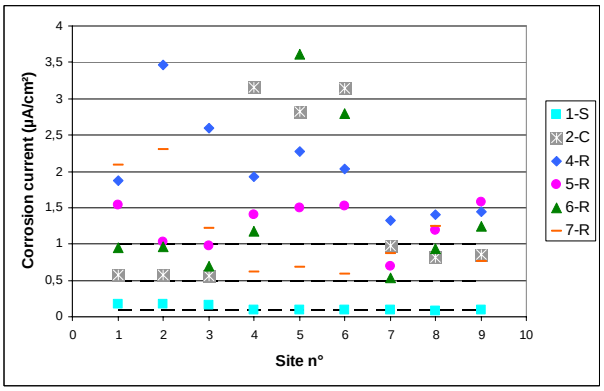

Figure 8: Corrosion currents for the sound carbonated references and the carbonated slabs before the realkalisation treatment.

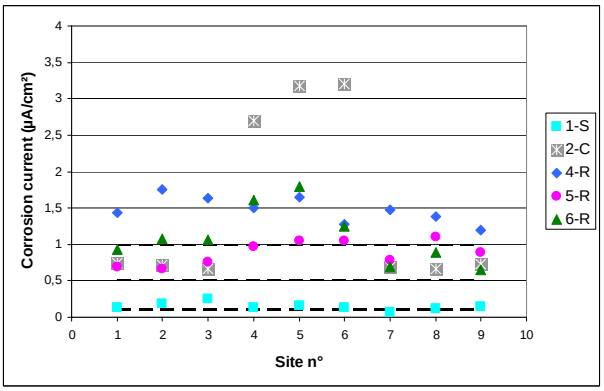

Figure 9: Corrosion currents for the sound carbonated references and the carbonated slabs 10 weeks after the realkalisation treatment.

Before the realkalisation treatment, the corrosion activity of the rebars in the sound concrete reference (slab 1-S) is negligible to weak as the average corrosion current value for the slab is equal to 0.12 (± 0.04) µA/cm². But the five carbonated slabs show a corrosion current ranging from 0.5 to 3.6 µA/cm², indicating a moderate to high corrosion activity of the rebars. Here again, the corrosion current response is quite large although the fabrication, the curing, the accelerated carbonation and the measurement protocol have been exactly the same for the five slabs. With time, the corrosion currents for the sound concrete reference slab 1-S remain low (0.15 ± 0.05 µA/cm², 0.18 ± 0.06 µA/cm² and 0.12 ± 0.05 µA/cm² respectively for 10 weeks, 6 months and 12 months after treatment).
Concerning the carbonated concrete reference slab 2-C, the corrosion currents of rebars 1 and 3 remain almost constant with time while those for rebar 2 decrease (the average value for rebar 2 is 3.02 ± 0.23

µA/cm², 2.11 ± 0.21 µA/cm² and 1.55 ± 0.12 µA/cm² respectively for 10 weeks, 6 months and 12 months after treatment).

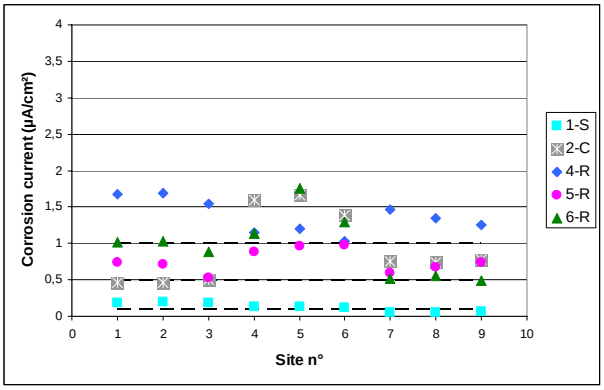

Figure 10: Corrosion currents for the sound carbonated references and the carbonated slabs 12 months after the realkalisation treatment.

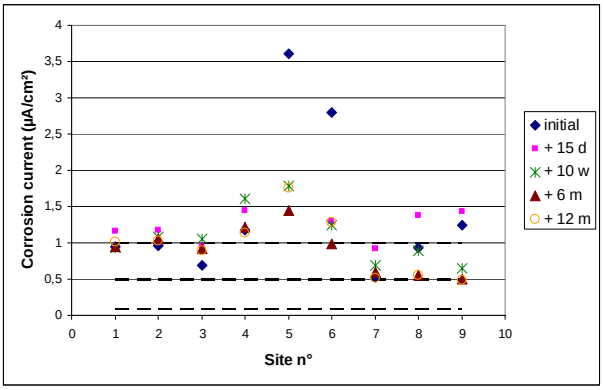

Figure 11: Evolution of the corrosion currents for treated slab 6-R.

After treatment, the realkalised slabs show lower corrosion currents with time and 12 months after treatment the corrosion current range is from 0.49 to 1.76 µA/cm².
As an example, the evolution of the corrosion current measurements for treated slab 6-R, versus time (before treatment, 15 days, 10 weeks, 6 months and 12 months after treatment) is illustrated in Fig. 11. For rebar 1, there is no clear tendency of the corrosion currents. For rebar 2, the corrosion currents drastically decrease after treatment. Finally, for rebar 3, where the corrosion currents before treatment were in the range moderate to high, they are in the range of weak corrosion activity 12 months after treatment. The values obtained 15 days after treatment are higher than the initial ones and can be explained as rebar 3 is not completely depolarized.
It is to be noticed that this corrosion current decrease tendency, which could be considered as an efficiency indicator for the realkalisation treatment, is more noticeable for rebars showing a high initial corrosion activity. In some cases, the corrosion activity decreased to a lower range but the negligible range encountered for the sound concrete slab was never reached. So the corrosion process is probably slowed down but not stopped.

3.1.3 Comments on electrochemical characterizations

The increase tendency of potentials and the decrease tendency of corrosion currents for the treated slabs seem to indicate that the realkalisation treatment reduces corrosion activity with time.
Concerning the durability aspect of the realkalisation treatment, no conclusion can be drawn from these results. Therefore, all the slabs are now ageing naturally and a complementary set of electrochemical characterizations is scheduled in order to explore this last issue.

3.2.Analytical Characterizations

3.2.1 Phenolphthalein test

Phenolphthalein is a colour indicator that turns pink when pH is above 9 and remains colourless for lower pH values. It was sprayed on freshly broken concrete surface before the realkalisation treatment, 15 days, 6 months and 12 months after the treatment (Fig. 12).
Before treatment, the phenolphthalein test revealed a complete carbonation of the concrete which remained colourless (as expected after the artificial carbonation ageing).
Just after realkalisation, the efficiency of the treatment is demonstrated by the presence of a pink zone, around the rebars, indicating a pH increase above 9. Nevertheless, the durability of the realkalisation is questionable as the change in colour is less and less obvious after 6 months and 12 months. The same type of results was obtained, on reinforced concrete containing either slag or sulphates [8, 14, 16]. Moreover, the phenolphthalein indicator only indicates if the pH value is higher or lower than 9-10.

Some authors such as, Yeih suggest that 9 is not enough to ensure the repassivation of the rebars and recommend a pH value of 11 that can be evaluated either with rainbow indicator [15] or thymolphthalein [8].

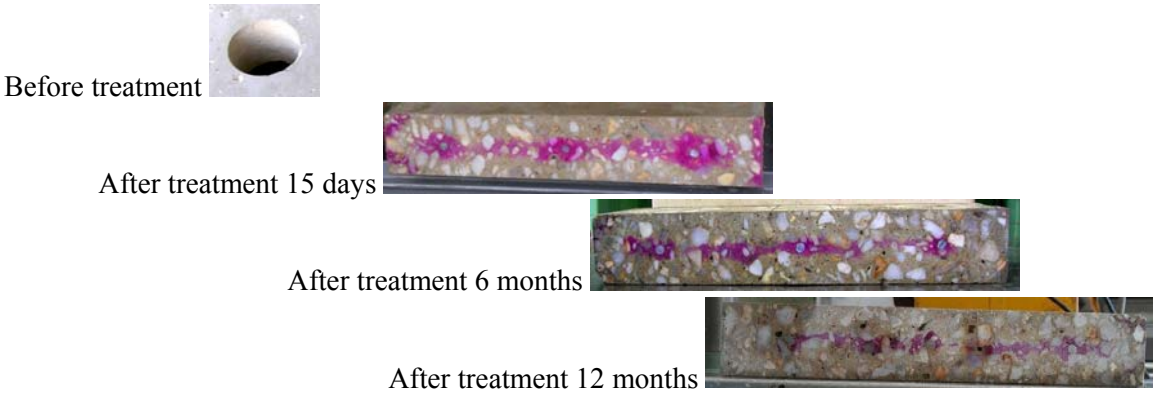

Figure 12: The phenolphthalein tests before, 15 days, 6 months and 12 months after the realkalisation treatment.

3.2.2 Micro-Raman Spectroscopy

Rebars embedded in concrete were also observed using Micro-Raman Spectroscopy to assess the nature of the rust. The presence of green rust and goethite (α-FeOOH) was detected on the carbonated control specimen indicating an active corrosion of the rebars. Six months after treatment, stable ferric products (magnetite and hematite) were detected. It could be supposed that green rust and goethite were transformed to a dense magnetite layer after the treatment (as shown in Equation 2).

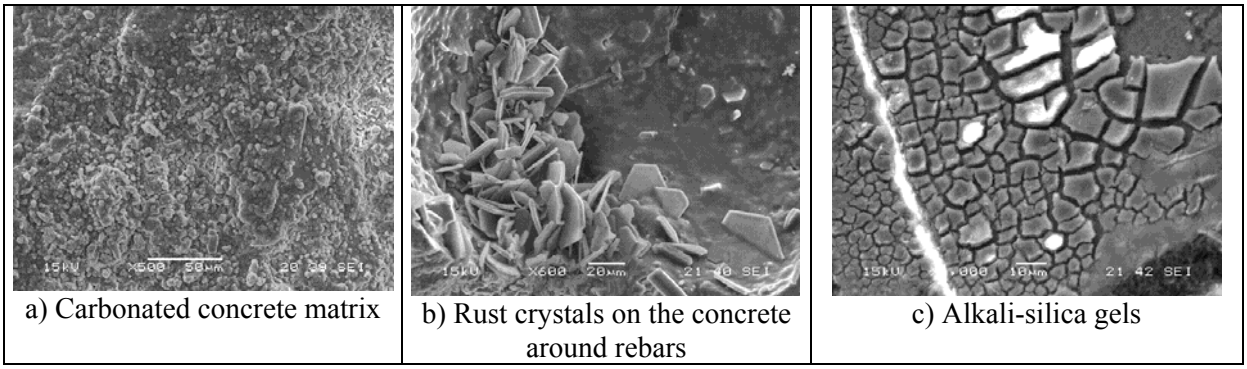
$$6FeOOH + 2e^- \rightarrow 2Fe_3O_4 + 2H_2O + 2OH^- \quad (2)$$

This equation highlights the FeOOH reduction at the magnetite-oxyhydroxide interfaces, as suggested by Stratmann [22].

3.2.3 SEM combined to EDS

Both treated and untreated samples were observed with SEM combined to EDS 6 months and 12 months after the realkalisation treatment.

The SEM observation of the carbonated concrete control first corroborates the carbonation of the matrix, portlandite being replaced by calcium carbonate (Fig. 13a). In addition, a large presence of rust crystals (Fig. 13b) was observed on the concrete around the rebars which indicates an active corrosion process. Finally, alkali-silica gels were identified close to the rebars (Fig. 13c). This latter observation is rather unexpected as the aggregates were chosen as non alkali-silica reactive (unless the long storage time in water before the study could have favoured such a phenomenon).



a) Carbonated concrete matrix

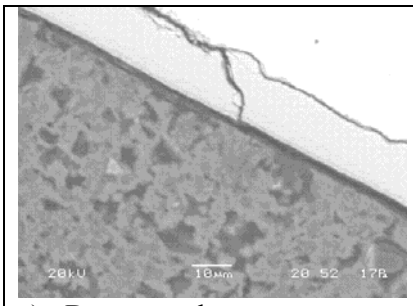
b) Rust crystals on the concrete around rebars

c) Alkali-silica gels

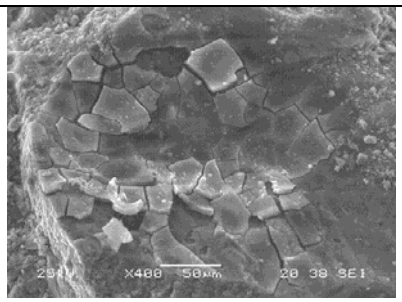
Figure 13. SEM observations of the carbonated concrete control slab (3).

Six months after treatment, no obvious transformation of the cement matrix was observed. Though a few rust crystals were still visible scattered in the concrete, a compact and dense rust layer was

observed (Fig. 14a) that could be a magnetite layer as previously seen through Micro-Raman Spectroscopy.
Alkali-silica gels were also observed on the realkalised concrete 12 months after treatment (Fig. 14b). As the nature of the gels in carbonated or realkalised concrete is almost identical (potassium-silica species), these gels can hardly be attributed to the realkalisation treatment. Complementary observations are ongoing to better understand this gel formation.



a) Dense and compact rust layer observed between rebars and concrete after 12 months



b) Alkali-silica gels

Figure 14. SEM observations of the realkalised concrete slab (7).

3.2.4 Alkaline concentration profiles

In order to obtain a potassium concentration profile, the cores were sliced in 10 pieces (5 mm thick), half of which were titrated by atomic absorption spectroscopy (Fig. 15).
For the carbonated concrete reference slab, a constant potassium concentration (about 0.13 %) was detected whatever the depth (at the 20mm-rebar depth, no powder was collected but it can be assumed that the potassium content is equivalent).
Eleven weeks after treatment, a great increase in potassium ion concentrations was detected. On the top surface of the slab, the potassium concentration (0.38%) was 3 times higher than that of the control specimen. On the rebar level (depth 25 mm), it was the same as that of the control specimen. Finally, on the bottom surface of the slab, the potassium concentration (0.32%) was 2.5 times higher than that of the control specimen.
During the realkalisation treatment, the potassium ions contained in the electrolyte placed on the top surface of the slab are supposed to penetrate into the concrete to the rebar level through two processes : capillary absorption and electrical migration. The results are in agreement with this assumption. However, the capillary contribution seems the most important as can be seen on the slab bottom surface (the electrolyte ran down the slab) where there is no electrical field.
But, it has to be noted that the potassium content does not provide direct indication on steel repassivation nor on the pH value around the rebars.

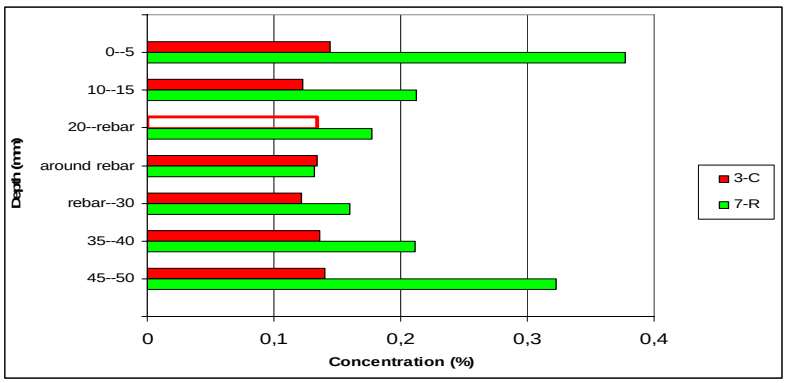


Figure 15. Potassium concentration profile before and 11 weeks after treatment.

In order to assess the durability of the treatment, complementary alkaline concentrations are scheduled. A diffusion process leading to a re-distribution of the potassium ions might be encountered.

3.2.5 Mechanical tests

Mechanical measurements (dynamic modulus of elasticity and compressive strength) were conducted on cylinders (diameter 50 mm, height 50 mm) respectively cored in the carbonated concrete control slab 3-C and in the realkalised slab 7-R.
The results are summarized in Table 3. Compared to the control specimen, there is no clear evolution either of dynamic modulus of elasticity or of compressive strength in time.

Table 3. Evolution of dynamic modulus of elasticity and compressive strength

	Slab 3-C (Carbonated control)	Slab 7-R
		After 11 weeks
E_{dyn} (GPa)	34.2	34.8
Compressive strength (MPa)	60.8	58.4

5. CONCLUSIONS AND OUTLOOK

The purpose of this study was to evaluate both the efficiency and the durability of realkalisation using impressed current. Therefore, a series of tests was performed on poor quality concrete slabs artificially carbonated, before and after an 8.5-day realkalisation treatment.
Concerning the efficiency just after treatment, promising results were obtained : alkaline titration revealed a significant penetration of potassium ions, and phenolphthalein tests just after treatment showed a clear pink coloration around the rebars indicative of a pH recovery induced by the realkalisation treatment.
Electrochemical characterizations, even if the results were difficult to analyse, showed an increase tendency of potential and a decrease tendency of corrosion currents, indicating a slowdown of the corrosion activity. The evolution of the nature of the corrosion products observed by Micro-Raman spectroscopy confirmed this phenomenon.
Regarding potential side effects, no evolution of the mechanical properties was noticed, and SEM combined with EDS did not reveal any significant transformation of the cement matrix.
Finally, dealing with durability, 12 months after treatment phenolphthalein tests and electrochemical characterizations still seem to indicate an efficiency. However, as the change in colour observed in the phenolphthalein tests concerned smaller areas with time, further work on pH evaluation is necessary and durability needs to be confirmed after longer periods. Therefore, the slabs are now exposed to natural ageing and characterizations will be continued.

ACKNOWLEDGEMENTS

The authors wish to thank the Renofors Company for their technical contribution to this study, supported by the Ministry of Sustainable Development and the Ministry of Culture in France.

ABSTRACT

During its service life, concrete undergoes several deteriorating mechanisms which affect its performance and strength. Diagnosis of the cause(s) of deterioration is(are) important in order to arrive at the correct repair and rehabilitation method. The first step in the diagnosis of concrete deterioration is visual inspection. In this paper, diagnosis of concrete deterioration by the use of an interactive software is introduced. This software can be a useful guide for engineers during their inspection of deteriorated and cracked concrete. As a first step in the preparation of the software, five different deterioration factors (corrosion of steel reinforcement, sulphate attack, alkali silicate reaction, freeze and thaw and plastic shrinkage) have been studied in detail. The symptoms of deterioration of these factors have been studied and later have been incorporated in a computer program. The user can arrive at the cause of deterioration by responding to direct simple questions which appears on the screen. Furthermore, the program can provide photos of similar cases to those introduced by the user. By simple comparison of the actual case and the photo provided, the user can assure the diagnosis of the case under consideration.

1 INTRODUCTION

Cracks in concrete, which have many causes, can affect appearance only or may also indicate significant structural distress or a lack of durability [ACI 224.1R]. Also, cracks may represent the total extent of the damage, or they may point to problems of greater magnitude. Their significance depends on the type of structure, as well as the nature of the cracking.

The cracks that appear in concrete structures are either structural (which usually occur due to excessive loads) or nonstructural, which are due to the presence of concrete in certain environments. Nonstructural cracks occur due to physical, chemical, mechanical or biological effects on plain or reinforced concrete. While the specific causes of cracking are manifold, cracks are normally caused by stresses that develop in concrete due to the restraint of volumetric change or to loads which are applied to the structure [ACI 224R]. Cracks can expose reinforcing steel to oxygen and moisture and make the steel more susceptible to corrosion.

The main physical factors that cause concrete cracking are freeze and thaw effect, shrinkage of concrete (plastic and drying shrinkage), movement of concrete against restraints and temperature effects (uniform or differential). The main chemical effects are alkali-silicate reaction, sulfate attack, seawater effect, acid attack and corrosion of reinforcing steel. The main mechanical factors are wear and abrasion. Biodeterioration occurs when concrete is in an environment suitable for the growth of microorganisms, such as the sulfate reducing bacteria, the sulfur oxidizing bacteria and the iron oxidizing bacteria [Qasrawi 2006, Qasrawi 2005]. Each type of deterioration is characterized by its cracks and symptoms which reveilles its identity. For example, alkali-silicate reaction is characterized by its map cracking which appear after more than five years of construction only in damp areas and extends throughout the whole body of affected concrete [Neville and Brooks 2004]. Hence, diagnosis of concrete deterioration starts with the study of cracks. The study should include shape, length, width, direction, extent and distribution of the crack. Furthermore, other factors, such as the time of occurrence of cracks and the presence of colored chemicals on the surface of concrete, are considered critical in the diagnosis.

Since repair of structures is critical in maintaining the integrity and durability of concrete structures, proper repair of cracks depends on correct diagnosis and later on selecting the repair procedures. Of course, incorrect diagnosis will result in improper repair and hence further cracking and deterioration. According to [ACI 224.1R] successful long-term repair procedures must attack the causes of the cracks as well as the cracks themselves. Only expert engineers are able to diagnose correctly the cause of cracking. Therefore, it is important to guide engineers and help them diagnose correctly the main cause.

According to Moodi and Knapton [2003], the use of information technology in construction is becoming increasingly sophisticated, with virtual reality, knowledge-based systems, database management systems, objected-oriented approaches, and neural networks among the latest technological advances now available for performing condition surveys, consistent and quantitative condition assessment, and database management. Database management systems are important in those engineering computing applications where the volume of data is very large and where several users and programs must share the same data. Engineering computing applications are making increasing use of database management systems to provide these capabilities [Ullman 1988; REMR 1996; Betts and Smith 1999].

Several attempts have been used in order to use the information technology and the computer capabilities in the diagnosis of concrete deterioration. Some of the attempts are described in the following paragraphs.

Kaetzel and Clifton [1991] presented a survey of thirteen expert/knowledge based systems applications and development methods related to concrete pavements and structures. These systems can be considered as initial steps in the development of expert systems diagnosis of concrete.
Chan [1996] presented a study in order to develop a prototype knowledge based expert system (called RCDES) for civil engineering applications in the knowledge domain of diagnosis of deterioration and other problems in reinforced concrete structures. The research emphasized on providing a broad view of diagnosis of reinforced concrete structures by capturing the knowledge of human experts and using a modular approach. Traditionally, the process of diagnosis is carried out by human experts/specialists and the use of computerized systems exhibiting artificial intelligence to provide a systematic and efficient diagnosis process.

Jepsen [2002] designed and used a neural network to investigate the influence of different parameters on the salt frost resistance of concrete.

Iyoda et al [2003] presented a study where they made a concept of a database of deteriorated concrete bridges in metropolitan area of Japan. They included database, which includes some information such as locations of bridges, year of construction and degree of deterioration. They also included many photos and the results of non-destructive tests such as digital still camera and thermal camera. In order to inspect the deteriorated concrete bridges, they used “the inspection software for deteriorated concrete structures” which has been produced by IIS, Japan. By the use of this software, they could recognize the cause and degree of deterioration to a certain degree of accuracy

Moodi and Knapton [2003] have developed a repair of concrete database which has been introduced as REPCON that deals with the diagnosis, evaluation, maintenance, and repair of concrete structures. The REPCON Management System has been designed to be an effective support tool for experts whose data can be evaluated and tested to ensure that the evolving database retains its integrity. The work explains how a computerized database management system can allow an initial database to evolve and become a forum for exchanging ideas in the field of concrete repair, and how the new methodology of data/user evaluation could have wide implication in many knowledge-rich areas of expertise.

Lücken and Stangenberg [2003] developed an expert system for an assessment strategy for deteriorating concrete bridges, which included in-situ inspections, evaluation of inspection results and condition assessment of the bridges.

Kanada et al [2003] developed an inspection software for maintenance of concrete bridges. It has been based on the concept that inexperienced engineers can easily diagnose and indicate necessities for the detailed inspections through a visual check. The described software should also enable user to refer to many samples of deterioration patterns and to the structure types when clear diagnosis cannot be made. The causes and levels of deterioration are determined by the software, based on the data collected during the visual inspection. In this process, the inspection methods related to the causes already listed in the database are deduced automatically. Finally, the current condition and the result of diagnosis are stored part-by-part for each inspected structure so the history of inspection can also be traced

Parthiban et al [2005] presented a systematic study to predict the corrosion of steel in concrete (based on neural network) in order to develop a suitable method that can accept, analyze and evaluate experimental data that are at random and/or influenced by external, unpredictable variables using the back propagation method.

Papadakis [2005] and Papadakis and Efstathiou [2006] introduced and presented field studies for a computer software based on proven predictive models, for estimation of concrete service life, strength and cost. The software offers the possibility of investigating the efficiency of various protection measures, such as waterproof sealants, cement-lime mortar coatings, inhibitors, etc. Comparing the

software results with field measurements from various real structures, a satisfactory general agreement is observed.

Ferreira and Jalali [2006] and Ferreira [2004] presented a model and developed a software for probability based durability analysis of concrete structures in marine environment which was based on a special simulation - called Monte Carlo simulation.

2 GOALS OF THE RESEARCH

All previous studies are either limited to specific applications or require specialists to be available in the diagnosis of concrete defects. Moreover, none of them considers and differentiates between structural and nonstructural cracking. Therefore it was important to develop a computer software which can (a) differentiate between structural and nonstructural cracks, (b) diagnose with a high degree of accuracy the cause of the cracks, (c) be used by engineers of only limited experience in the diagnosis of concrete cracking and (d) be developed by user when further data is available.

3 METHODOLOGY

In order to arrive at the goals described earlier, the following steps have been followed:

1. Collection of data: This includes the collection of data available for all possible cracking in concrete structures. Specialists, experts, available literature (such as ACI manuals of concrete practice and RILEM publications) and the data provided by the internet, are all useful tools in this respects. These will form a data management system for the software.
2. The cracks data is then grouped according to the time of occurrence, spacing, geometry, depth location, width, length, extension and presence of colored material on the surface.
3. The data is incorporated in a computer software (named as **C**oncrete **C**rack **D**iagnosis **CCD** software) that can be easily applied by engineers.
4. Provide photos that can direct the engineer in the diagnosis.
5. Allow the user to add his own photos to the program, and hence be able to develop his own experience and compare similar cases.

4 THE "CCD SOFTWARE"

As a first step in the preparation of the software, cracks five different deterioration factors (corrosion of steel reinforcement, sulphate attack, alkali silicate reaction, freeze and thaw and plastic shrinkage) have been studied in detail.

In order to use the software, the user must first identify the crack if it is structural (due to excessive loads) or due to other factors (named here nonstructural), as shown in Fig.1.

Then the user can respond to some of the information given directly. Once the information is input in the computer, and depending on the information available, the possible cause(s) will appear on the screen. The user can then be able to view photos showing similar cracks. Fig. 2 shows the application and response to nonstructural cracking. The user can then continue previewing the photos offered by the program in order to assure the diagnosis offered by the software.

If structural cracking is chosen, the engineer has, first, to choose the member subjected to cracking (column, beam, foundation, wall, slab or beam-column). Once the member is chosen, the engineer can choose similar crack patterns; a double click on the chosen pattern will produce further information and photos, which guide the engineer in the final diagnosis. Fig. 3 shows an example of the application.

A Diagnostic System Created for Evaulation the Quality of Building Constructions

Attila Koppány[1]

T 71

ABSTRACT

The successful diagnostic activity has an important role in the changes of the repair costs and the efficient elimination of the damages. The aim of the general building diagnostics is to determine the various visible or instrumentally observable alterations, to qualify the constructions from the suitability and personal safety (accidence) points of view.

Our diagnostic system is primarily based on a visual examination on the spot, its method is suitable for the examination of almost all important structures and structure changes of the buildings. During the operation of the diagnostic system a large number of data – valuable for the professional practice – was collected and will be collected also in the future, the analysis of which data set is specially suitable for revaluing construction and the practical application of the experiences later during the building maintenance and reconstruction work. For using the system a so-called "morphological box" has been created, that contains the hierarchic system of constructions, which is connected with the construction components' thesaurus appointed by the correct structure codes of these constructions' place in the hierarchy. The thesaurus was not only necessary because of the easy surveillance of the system, but to exclude the usage of structure-name synonyms in the interest of unified handling.

The analysis of which data set is specially suitable for revaluing earlier built constructions and can help to create knowledge based new constructions for the future.

1. INTRODUCTION

It is important, that people in architecture science give a useful guide – especially concerning questions raised by new trends of the changing, transforming building activities and construction development – to people in the professional practice. Seeing that in the aspect of adequacy the appearance of new constructions and building materials always raises new problems to be solved, and the experts in practice busy with the daily tasks of the profession 'according to Möller [1945] cannot always pay enough attention to them'. The efficient diagnostic activity as it has been explained before plays a very important part in the formation of maintenance costs and elimination of damage. It has an equally important part in the preparation of a decision, as having a clear picture of the technological conditions of buildings or group of buildings can be of service at the preparation before making financial decisions of great significance.

2. DIAGNOSTIC SYSTEM

A faulty diagnosis can lead to incorrect decisions causing financial loss. The research group of the Széchenyi István University (Győr) worked out such a comprehensive diagnostic system (see Fig. 1.) which contains a common inspection method 'according to Molnárka [2000.] for the vast majority of constructional components (for traditional and actually used constructions in Hungary), and can be used for computer data registration and analysis.

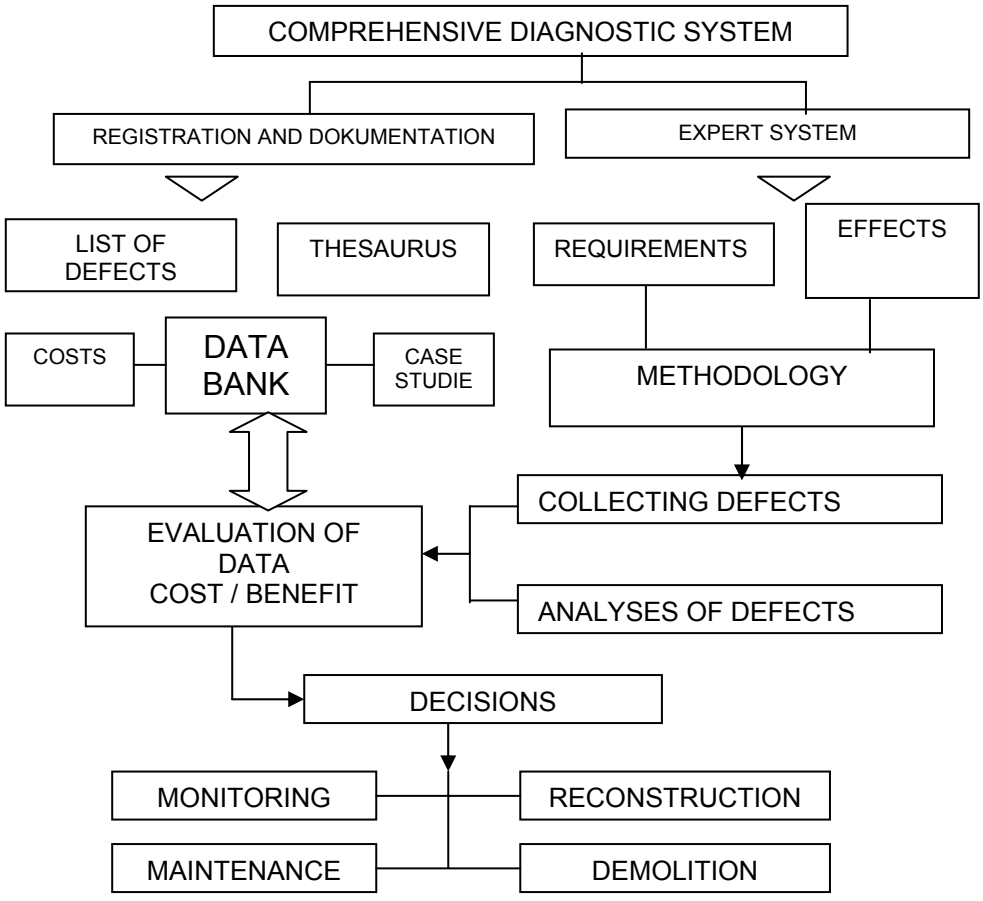

Figure 1.

The morphological box theory created by Prof. Zwicky [1966] is connected with the construction components' thesaurus denoted by the correct structure codes of these constructions' place in the

hierarchy. The theory of using morphological box for data registration in the process of building diagnostic that was published in Hungary eleven years ago [Koppány 1977]. The "matrix" construction of our morphological box fits to the methodology of the visual examination and to the hierarchy of the common building constructions in Hungary [Koppány 2002] (see Fig. 2.).

Figure 2.

The main task of our thesaurus (graph-version) is to help the visual survey. It can be very useful to understand the hierarchy and the connections in the field of building constructions (see Fig. 3.). The thesaurus is not only necessary the easy surveillance of the system, but to exclude the usage of

structure-name synonyms in the interest of unified handling. We have another tool too for the quick survey of the results of the visual examination, it is the hexagonal morphological box (see Fig.4.). The box shows the actual checked constructions or all constructions of the building.
The various conditions of the building constructions can be marked with corresponding colours in the box-fields (see Fig. 5.and Fig. 6.).

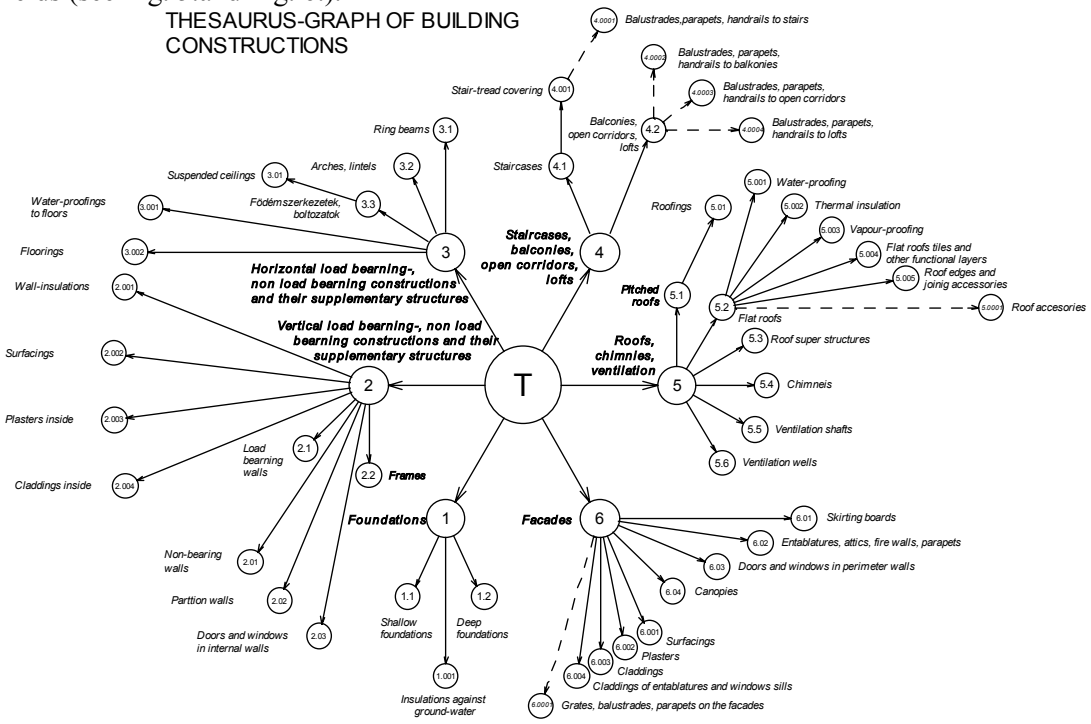

Figure 3.

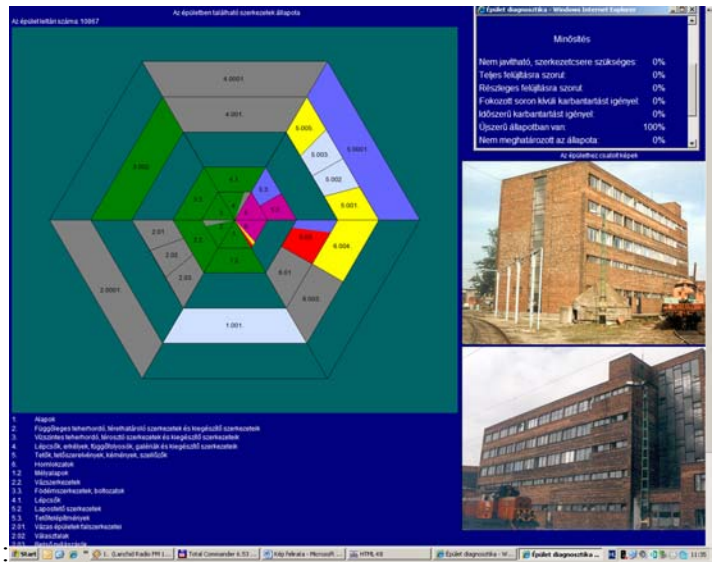
Figure 4.

The results of an examination are shown on Fig. 5., Fig. 6. and Fig.7. The diagnostic system has been successfully checked in the course of a course of an examination involving 60 buildings.



Colour	Rating

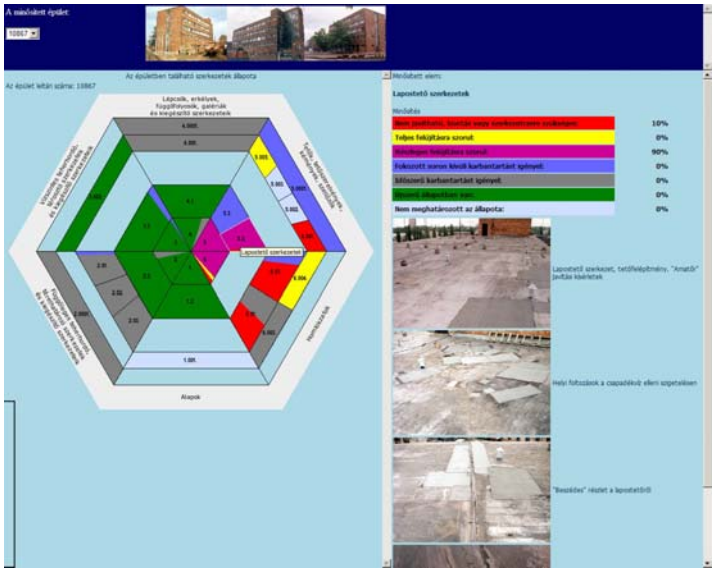

Figure 6.

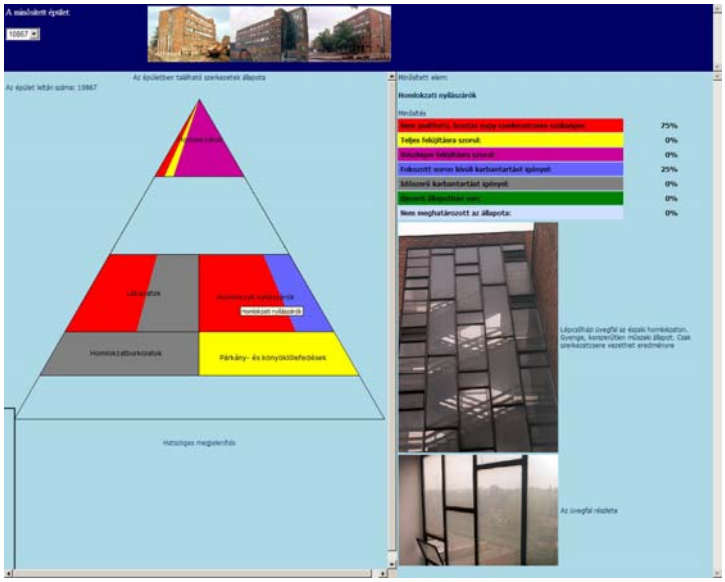

Figure 7. Qualification of the façade-details.

3. EXPERIENCES OF FLAT ROOFS EXAMINATION

The majority of the defects forming on *the flat roof water-proofing and heat insulation* can be observed on the conventional insulated roof. From the point of view of the protection of substance and providing of the proper application of the building it is very important to explore and repair professionally the failures as soon as possible. Concerning the costs it is very important to explore the failures in the beginning stage because the failures which can be repaired with relatively low costs at the beginning can be repaired only with much more expenditures and together with many other structures after the extension of the damage. It should be noted for example, that the water proofing should be checked by experts at least yearly because several extended and expensive damages can be prevented with this care. The typical failures of the roof can be systematised according to various points of view. The analysis can be performed by the layers of the layer construction of the roof insulation and water-proofing or according to the contribution to the creation of the roof insulation (e.g. material manufacturing, planning, execution, operation), but it can be carried out according the so called weak points, details of the structural nodes.

Before introducing the diagnostic procedures and testing methods applied for the flat roof construction it is reasonable to determine some principles [Koppány & Graf 1985] in connection with the examinations as follows:

- the examination mustn't inhibit the proper use of the building;
- the examination should be quickly performable with easily usable tools;
- during the whole process of the examination the least possible damage can come out in the flat roof water-proofing;
- if the destructing examination is unavoidable it can cover the least possible area and the place of sampling should be immediately repairable (in a waterproof way).

The diagnostic work can consist of several phases - which are important from the end point of view. At first before the examination on the spot it is reasonable to inform on the basic data, structures and building conditions of the building to be examined. In case of old roof it is not always possible since the plans and other documents could get lost and they cannot be often reconstructed. In a significant part of the cases the structural character, layer construction, the used materials and the technologies should be identified during the examination on the spot.

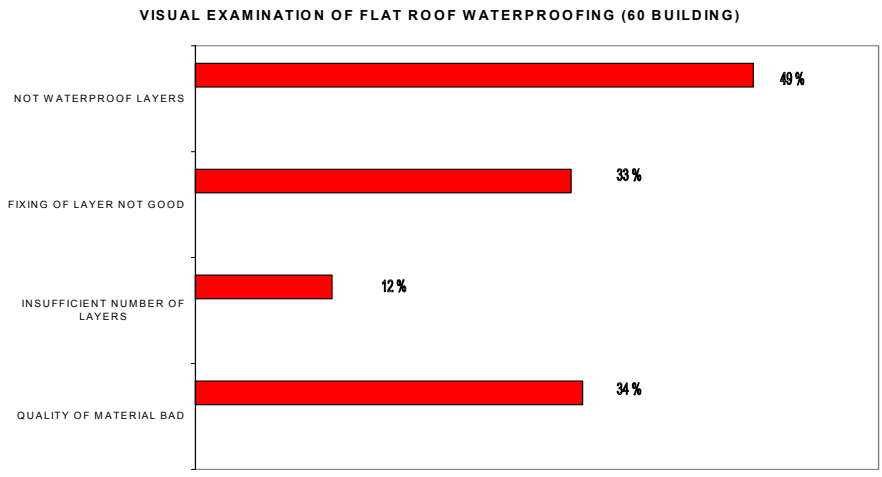

Figure 8.

During the visual examination the visual failures should be discovered then the analysis of the operation of the structure can lead to the determination of the more complex causes of the failures. During the visual examination the identification of the place of leak for large discontinuities (damages) on the water proofing of direct layer order has generally no difficulty. In case of quick examination the condition of the roof

water-proofing is determined basically with visual examination, completed with a deteriorate free instrumental measurement if necessary (see Fig. 8.).

For comprehensive examinations the procedure covers the all structural and complementary elements of the roof. The condition, load capacity, deformation of the bare floor should be examined, the building physical properties of the floor structure, etc. should be evaluated.

There are a lot of interesting data from the examination of 60 flat roof constructions (see Fig.9.) This figure shows the characteristics of frequency of the typical defects at the examined old flat roofs. The greatest number of defects were in the expansion joints area, nearly fifty percentage. The age of the examinnated roofs was on average 20 years. The roofs of the older industrial building had the worst condition, most of them were in bad repair.

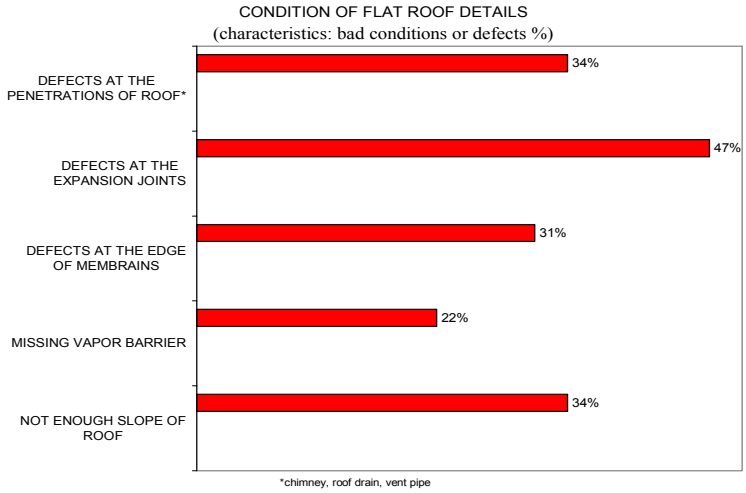

Figure 9.

So in order to maintain the condition, safe and durability of the flat roof water-proofing and insulation all significant factors should be examined even with a deterioration examination if necessary. It can happen that the diagnostics are started with a visual examination performed within the frame of a quick examination and to determine exactly the causes of the abnormalities, defects observed during the examination a complex examination is required.

4. **CONCLUSION**

The paper reported on the development and structure of a field based survey methodology by the research group at the Széchenyi István University. The methodology offers practical diagnostic decision support tools. The new system was developed for the one of the biggest building holder-operator organisation in Hungary. The diagnostic system is firstly based on a visual examination on the spot.
At the beginning of the developing work an important requirement was the visual demonstration of the examinations' results. It was expected from the system tools to be able to show the general condition of the buildings or the condition of the selected constructions. In the process of visual examination the experts have a big amount of data. For the effective handling and using the data the research group of the university created a registration subsystem with tools:
• morphological box for building constructions and
• thesaurus of building construction (connections with the morphological box).

The morphological box as a diagnostic tool had not been used earlier in Hungary. The first probation of this tool was successfully completed and our client, the building holder-operator has installed this tool in his data registration subsystem.

Using these tools the experts can survey the connections of the examined constructions and can use also a clear visual survey the different durability's of the existing constructions. Some details from the results of the visual examination of 60 different flat roofs can illustrate the efficiency the new subsystem.

It would be proper if the results of the constructional diagnostics, the experiences of the pathologic analyses make easier the work of experts using our registration subsystem. The practikal diagnostic decision support tool can help choose the appropriate correctiv maintenance procedures, and identify which remedy to the real causes of the failure.

'Comparative' Diagnostic: an Instrument for the Durability of Interventions

Antonella Guida [1]
Antonello Pagliuca [2]

T 71

ABSTRACT

An intervention for preserving a historical building, whatever its architectural or artistic value might be, is in general as much appropriate as deeper the knowledge of its following elements is manufacture, up-to-now evolution, materials, building techniques and carrying structure.

Therefore, considering a monument as expression of belonging to a defined environment, it is necessary to wonder how to act on it in order to preserve it from any deterioration.

The importance of the diagnostic stage cannot be ignored, for both interventions (and not only single procedures) control and global system behaviour, in particular within a long-term building maintenance program aimed to guarantee the durability of intervention itself.

Research focuses attention on the necessity of crossing results obtainable from different kinds of test (destructive and not destructive), in order to get data that may be qualitatively and quantitatively correct and extended to the whole building system.

The analysis and qualification of monuments building structures points out how much useful this approach is, in order to classify interesting pathological events and implement innovative solutions that could guarantee the durability of the recovery intervention on the building.

1 INTRODUCTION

The monumental building's reinforcement and restoration is strongly constructed both for the complexity of the built heritage and, sometimes, for the short availability of suitable means.
In fact, the monumental heritage's conservation issue has always been several researcher' object of attention. In 1931, the Athens Charter declared that "the question of the conservation of the artistic and archaeological property of mankind involves the community of the States, which stands surety for civilisation, […] hoping that the States will manifest their interest in the safeguard of masterpieces in which the civilisation has been expressed to the highest degree".
Assuming that the monument is an expression of belonging to a definite place, the problem is to define the right way to operate an intervention in order to protect the monuments from deterioration. In fact, prof. J. Kerisel, a famous researcher, recently has stated that if some artists had been necessary to construct old buildings, nowadays artists have still been necessary to their safeguard.
These are the assumptions of the present research:pointing out a methodology for the approach to the restoration interventions respecting every aspect which makes the architecturale heritage as a monumental work. In this way, diagnostic surveys have a great importance, because they became the condition to carry out an appropriate restoration intervention.The methodology used to develop this research is based on the direct survey on site through the use of destructive tests and not destructive tests and following processing of the results. And through the analysis and comparison of the results, it is possible to get quantitative and qualitative informations that can be considered as representative of the whole architectonic structure.

2 FROM SURVEY TO THE TESTS PROJECT

Nowadays, monumental heritage's safeguard and conservation shows various - sometimes alarming - aspects, which help us to identify the so-called "architectonic emergencies". This is linked to the great number and to the urgency of the cases to solve and, at the same time, to the short availability of time and of economic resources.
Observing a deteriorated monument, the restoration planner should reply essentially to three questions: "if" to carry out a restoration, "where" to carry out a restoration and "how" to carry out a restoration. It is possible to add the fourth question, where the economic aspect is strongly present: "when" to carry out a restoration. In order to suitably answer to these questions, it is necessary to proceed with following specifications, finding out the deterioration's cause, the assessment of the residual safety, the assessment of the restoration's necessity and suitability and, finally, the choice of the suitable intervention and the definition of its carrying out procedures. In the first step of data acquisition, the direct analysis of the building's characteristics and conditions and the checked deterioration' survey, must be accompanied by the research of the planning documents and the events which have affected the structure during its construction and its life. Transformation, changes, partial rebuilding and demolitions are quite frequent in the monumental buildings history. Since the reasons which have caused them are not always respectful of building static balance, the monument's efficiency is failing, that is sometimes difficult to find out for contemporary observers. A very high percentage of damages and settlements in monumental buildings is attributable to these not well thought-out changes, which have not respected of balances growed steady in time and have led into new stresses, not suitably distributed and/or controlled, [Togliatti 1973].
In the survey's step, an important element is checking and analysing the material's features. This information is essential in order to make a suitable model of the building, useful to a safety test of the current conditions. Now, several methods are available and they can be assembled in two different but complementary categories: destructive tests and non destructive tests, both carried out on site.
Non destructive tests on taking from walls samples represent the easiest approach in order to define deformability and resistance parameters, which characterize a building's masonry. It is important to point out that the taking samples must be undisturbed and really representative of the material's characteristics. The samples are also enough to guarantee reliability of results, considering the wide scattering of experimental data. Non destructive material's characterization tests are more indirect, but

more suitable for the restoration, even though they provide mostly qualitative data [Carabelli 1980]. Therefore it is necessary to combine the two kinds of tests in order to provide quantitative indications (deriving from destructive tests) which are qualitatively extensible to the whole structure (by means of non destructive tests). This comparison can draw a better and more complete knowledge of the building's condition in order to define suitable interventions and to guarantee their durability.

3 DIAGNOSIS AND NEED FOR A MODEL

After the analysis of the monumental building and the quantification of its deterioration, the most important and most charming part of the whole restoration process is the definition of its deterioration's causes.
The incapability of catching the real deterioration' causes, leads to wrong diagnosis: this leads to look after only the deterioration' symptoms, but it leads to negative interventions for the structure [Bonaldi *et al* 1980]. The constant progresses led to the structures' numerical modelling and the decrease of the analysis' costs allow a greater employment of these tools. Structural restoration interventions can be simulated realistically through a numerical or experimental model and their effectiveness can be assessed by the light of the achieved results. When it is not possible to assess the structure stress' state, the assessment of the safety factor can be only global and it points out the existing margin between current and limit collapse' conditions. Recently a theory, the so-called "theory of limit analysis" has been systematized. It allows to establish what is the margin which divides the building from the collapse, even though this theory is cautiously applicable to the masonries. In fact the material's conditions, required by the "theory of the limit analysis", are fulfilled only as a first approximation by the masonry [Binda 1982]. This topic represent an object of different studies and scientific researches. Recently some interesting results have been achieved. If the analysis on the numerical model provides uncertain results about safety, due to the lack of data or the assumption of too simplifying hypothesis, the use of reduced scale physical models and loading tests led on site, skilfully and carefully can provide the sought answer.

4 THE "SUITABLE" INTERVENTION CHOICE

This step goes from the choice of the intervention techniques to their implementation, to the planning of periodic checks until the restoration testing. The two steps which characterize the choice of the intervention can be summarized in the possible technical choices' analysis compared with the deterioration's level.
The economic factor is an important element in the intervention' choice, even in a monumental work; it represents an ambitious attitude, which is incompatible with the need for a positive use of the available resources. In order to increase the safety factor of a structure, it is possible to operate in two ways: removing the causes or opposing the effects.The first kind of intervention involves a reduction of the loads which burden on the structure. Typical examples are the chaining the vaulted structure, the shielding of the vibrations induced by traffic through a layers of soundproofing, the use of underpinning or grouting in case of structural settlements, etc. [AA.VV. 2003].
Furthermore, particular interventions on the structure's geometry - such as the creation of joints between adjacent blocks affected by differential settlements or the gradual correction of the juttings – are able to reduce drastically the imposed stresses.
The second kind of intervention, which tends to oppose the effects more than to remove the causes, involves integrations or additions to the material or to the structures, keeping geometries and loads unchanged. Where it is selected the restoration' intervention, it is suitable to carry out with a unit-methodology which involves interventions not differentiated in time. It is also fundamental that the technician of the structural restoration decides not only according to the materials' durability, but also to the changed parts' rigidity, in comparison with the adjacent ones. Putting too hard materials into the monument means to draw the most of loads on these areas. As a consequence, there is the possibility of fragile and localized breakings which can trigger a mechanism of chaining collapse in their turn.

For this reason, it is often advisable to replace deteriorated elements with materials which are more similar to the original ones or which have similar straining behaviours.
Among the interventions' specific techniques, which tend to oppose the effects of deterioration, two main groups can be considered: the first one concerns the interventions which tend to restore or improve the deteriorated materials' features; the second one, instead, concerns the interventions which place new supporting structures to the old ones even replacing completely their functions.
So, analysing in outline the problem of monument's structural restoration, it is clear how ethics and personal culture have to coexist in the technician in charge of the intervention. In fact, prof. J. Kerisel [Kerisel 1981], a famous researcher, has recently stated that if some artists had been necessary to construct old buildings, nowadays artists have still been necessary to their safeguard. This inevitably emphasizes the problem of the workers' training who worked upon the structural restoration. This promotional effort, supported by indispensable financing, legal and administrative means, could paradoxically build in the next future a "therapeutic intervention", which could be more successful for our monumental heritage [A.Guida *et al* 2005].

5 THE STUDY CASE: MATERA'S CATHEDRAL

This research focus upon the Matera's Cathedral, a massive architectural structure, built at the end of the XIII century. In Apulian Romanesque style, it keeps its formal and architectonic connotations almost unchanged outside, even though some interventions have substantially changed the style of the inside. It does not show any plain deterioration signs of its static structure, but it is plain a pathology outside.

Figure 1. The big dark spot on the external wall of Cathedral

It is a big dark spot 'Fig.1' which affects the whole building, along its perimeter. It seems to be caused by a deep phreatic rise which could have given birth to a humidity ascending pathology to the whole building, even though the spot's height is strongly doubtful, because it is difficult that ascending humidity reaches those heights. This kind of humidity, that raising from the subsoil, can be fed either by dispersed water or by an underground ground water table [Croce S. 1994]. The first one has been generated by local - and anyway limited - causes, such as the insufficient collecting of rain-waters, the leakage from wells or water pipes; all these causes have produced a local imbibition of the soil touching the foundations. They can often affect just one side of the building. They can be anyway shut off through suitable means and can be easily abolished. On the contrary, the underground ground water table is neither eliminable nor controlled. It attacks uniformly the building from the basis; it shows maximum rise height towards North North-East and minimum rise height towards the sunniest areas; it is widely spread to every buildings in the same area and it does not show any changes in the reascending height.
Analysing superficially the outer walls of Matera's Cathedral [Esposti W. *et al* 1983], the presence of ascending humidity could be observed as the result of the ground water table, since there are neither wells nor hollows which could allow the underground backwater. However, some hydrogeologic surveys carried out in this area, have shown that there has never been any underground ground water

table both nowadays and in the past. So, after verifying the ground water table lacking, it has been led a thermographic analysis 'Fig.2' of the whole building, in order to understand this big dark spot's nature.

Figure 2. The thermographic survey on Cathedral's façade

The thermographic survey [Eads L.G. *et al* 2000] is a non destructive test, which is based on the physical principle of the energy transmission by radiancy, through the electromagnetic radiation. The wave length of the radiation emitted by an object depends on its temperature, according to the Wien' s law Φ= A/ T. The wave lengths emitted from the objects usually belong to the band spectrum, which is situated into the infrared area (Φ included between 0.78 mm and 0.3 mm). Only at about 6000 K (sun's surface's temperature), the emission is at the centre of the visible spectrum. If you move on an object's surface from a higher temperature point to a lower temperature point, the quantity of radiant energy emitted in the two different areas will change (due to the Stefan's law) and the wave length of the emitted radiation will also change [Rosina E., 1997].
Thermovision scanner's explores the analysed surface using some wave lengths' band and point out the change of radiant energy's strength, according to standards UNI 10824. As this radiant energy is linked to the object's temperature only through emissivity, it is possible to evaluate the object's temperature knowing its emissivity coefficient and, opposite, it is possible to evaluate its emissivity knowing the object's temperature [Volpini S. *et al* 1990]. A suitable optical scanner system analyses the whole area of the camera shooting in details and then it generates an electric sign in a sequence according to the picture's thermal information and proportional to its strength, which is reproduced on the kinescope. To every change in surface' temperature will correspond a similar change in the radiant strength. The kinescope gives a particular colour to this changes.
The analysis was carried out in March 9th 2007. The outer temperature is 8°C and the air's relative humidity is 53%. An unusual result has been come out by the analysis of the achieved thermographic pictures: the lighter areas, corresponding to the dark spot on the façade, are hotter rather than colder, as it would have been expected if there had been rise humidity [Massa S., 1987]. This result would show that the masonry is actually dry and therefore the circumstances that masonry is hotter in the whole building's lower areas - even though at different heights - it would probably be justified as a different behaviour of the stone absorbing solar radiations and therefore the probable variation in the material's emission capacity. The big dark spot would seem to absorb more sunlight than the rest of the building, which has a light colour of the typical local stone, called "*tufa*". The physical mechanism that supervise this process is the irradiation that transfers the heat in the form of electromagnetic waves, in the specific case, directly from masonry irradiated by sunlight. For this reason, the spot is hotter than the rest of the building. However further tests on physico-chemical properties of the material and more detailed petrographic analysis are today being implemented to determine the exact nature of the phenomenon.
This kind of survey provides results, which are qualitatively acceptable, but it does not provide any information as for the quantity. This research aims to examine the possibility of comparing these qualitative results (deriving from the photograms analysis), with the quantitative results which can be derived from a destructive test such as the determination of the humid section's diagram.

In order to carry out this test, three cores have been taken out of the southern wall of the Cathedral, corresponding to S. Eustachio's altar 'Fig.3'.

Figure 3. The HIUTI DD-250E coring machine dry

It has reached 80 cm in depths inside the wall and got to the outer hewn stone. The 6 cm of diameter cores have been carried out using a HIUTI DD-250E coring machine dry. They have been taken out of walls along the same lines, 50 cm one from the other, starting from 2,70 m height from the floor. The samples have been wrapped up in the plastic film 'Fig.4', covered with paraffin and then catalogued in order to be analysed afterwards.

Figure 4. The samples have been wrapped up in the plastic film, covered with paraffin

The analysis has led to the definition of the water's content in the taken samples. In fact the material has been weighed when it was taken, then it has been dried in an oven and therefore it has been weighed again. The difference between the two weighings has defined the value of the water's content in the tested samples. It is necessary that every weighing operation has been carried out with the same scales in order to reduce instrumental mistakes. After weighing every container and sample have been put at 110°C in the oven for at least 16 hours and not more than 24 hours, according to the ASTM D 2216-80, D 2974-87 and CNR-UNI 10008 directions. When they have been dried, the samples have been weighed again: subtracting this value to the one collected before the drying process and comparing it to the dry weight, has been achieved the value of the water's content in every sample [Table]. So, analysing the data, it is clear that the masonry is dry and the water's content of the samples is the material's physiological content.

Table 1. The value of the water's content in every sample

CONCLUSIONS

This research shows how it is possible to compare the results achieved from different kinds of tests. To do this, it is necessary to correlate the results, in order to give systematized information on the conservation state of every monument, reducing the damage and the endangering of each structure.
The study aims to realize an applicative methodology more respectful of the built heritage, in order to avoid a simple acritical transposition of the calculation models in the recovery interventions.
The proposed methodology is based on a fundamental aspect of the refurbishment and/or restoration project which is the cognitive aspect, through tests on site and in laboratory. The following step is the realization - and then the validation - of the intervention and a periodical monitoring.
Technological tests were executed to determine the physical chemical and mechanical characteristics of the materials used in the realization of the buildings in the Sassi (tufa, mortar, plaster) and to evaluate the compatibility (chemical, physical, mechanical) with eventual new materials used in restoration's interventions and even to validate the choices made during some interventions.
This accurately projected surveys' plan presents oneself as a further knowledge instrument and as a mean to programme a recovery's intervention, respecting the ancient heritage and without compromising the requisites of durability and safety.
This research can also contribute to increment the typology of the tests to carry out on the masonry; in fact, in relation to all the problems of tests and investigations, it is not necessary to have only one kind of survey, but an organic plan to compare the results, to have a more possible complete cognitive frame. Often only comparing the analysis of more data, coming from different surveys, it is possible to interpret the real phenomena and give the necessary parameters to realize a correct intervention.

Jorge de Brito [3]

T 71

ABSTRACT

The network of elementary public schools within the city of Lisbon, managed by the Lisbon Municipal Council, consists of around 95 buildings with an average age of 50 years. The lack of preventive and planned maintenance activities throughout the years has led to various cases of major degradation, with an estimate value for repair of the building school stock near 30 Million Euros.

These buildings can be classified in four major groups according to the technology and date of construction: those until 1930, those between the 30's and the 70's, the ones between the 70's and the 80's and those from then on. In the first group the majority were not designed to fulfill the function of school equipment (originally they were dwellings) and belong to the oldest Lisbon districts. In the second group buildings were designed as schools and were built during the so-called Estado Novo (the non-democratic regime before 1974). The buildings of the third group were based on a standard school project (P3 type) resorting to prefabrication for the structure and the outer and inner walls. Finally, the schools built after the 80´s, even though the youngest, present a worrying degraded condition.

In the present paper, the results obtained through a survey of the condition of 6 schools built in Lisbon after the 80's are presented. The aim was to infer the degree of degradation achieved and the main anomalies resulting from it.

1 INTRODUCTION

The elementary school building stock of the public network of the city of Lisbon is, in its great majority, the property of the municipality of Lisbon which also ensures its maintenance and conservation. This network, which is constituted of 95 buildings and frequented by close to 15800 students, presents construction characteristics which can be divided into four distinct periods: before 1930, between 1930 and 1970, between the 70's and 80's, and after the 1980's. The global state of conservation of this building stock is presently considered rather worrying, resulting from not only the average age of construction being approximately 50 years, but also from the absence of preventive maintenance practices and the delays in the execution of the maintenance work already identified as necessary by the municipality of Lisbon. On the other hand, there are indications that the group of buildings constructed after the 1980's is degrading faster than was predicted [Raposo *et al.* 2007]. This paper presents and analyses the results obtained through the observation of six schools of recent construction. They are schools where, in an integrated form or not (different buildings), kindergartens and elementary schools (EB1) function. One of the schools visited is Vasco da Gama School where four grades of education function in an integrated form, and is considered a model school.

2 RESEARCH METHODOLOGY

During August 2007, research work was done of the existing data in the municipality for each of the selected buildings, ehere it was possible to obtain, essentially, project data and information resulting from the utilization of the different buildings on the part of their users.

The fieldwork was undertaken at the end of 2007. The principal objectives of this work were: the verification of conformity of the project with the actual building and the identification of existing discrepancies, identification of any alteration that had taken place in the utilization of the building and a preliminary analysis of the buildings performance. A visual inspection of the buildings was undertaken and photographic and written records were made of the principal discrepancies and anomalies detected. In each visit it was possible to speak informally with the teachers and support staff which served to complement and verify the information collected from the municipality and the observation carried out.

3 BUILDING CHARACTERISTICS

Prista Monteiro School (PM) came into function in the 1997/1998 school year and is comprised of two distinct blocks of buildings, where building A is used for the kindergarten and building B for the EB1 students. Block B, with approximately 2200 m^2 of built-up area, is made of two floors laid out in a U shape, surrounding the exposed playground and recreation area (fig.1). The direction, management, and support staff premises are located on the ground floor as well as a gymnasium and six classrooms. On the first floor, there are eight classrooms, a library, and an IT room.

The structure of PM building B is a system of slabs, colums and beams in reinforced concrete. The involving exterior consists of 0.30 m thick walls, a sloping roof coated with ceramic tile, openings with metal framing and single-pane glass with a venetian system of exterior protection. In the interior, the wall thicknesses vary between 0.15 and 0.20 m, in general having been plastered and painted, along with the ceilings. The floor covering materials are predominantly ceramic and vinyl.

The Vasco da Gama School (VG) came into function in the 1999/2000 school year. The building where the kindergarten and the three first grades of elementary school function, present a gross area of 8800 m^2 distributed over three floors and a basement, where the parking is located. The kindergarten and elementary school (EB1), the common areas, the pedagogic and administrative support staff, the

cafeteria and kitchen, and the gymnasium and locker rooms are located on the ground floor. The resource centre premises (library, auditorium with 200 seats), the management and the teaching support staff offices are on the first floor and the classrooms for elementary school grades 2 and 3 (EB2 and EB3) on the second floor. The building has non-traditional roof covering of ceramic material (Fig. 1).

Figure 1. View of the interior patio of the PM school (left); model and building of the VG school (center; right)

The Vale de Alcântara School (VA) came into function in the 2001/2002 school year. The building, where the kindergarten and primary school function, has a gross area of approximately 1700 m^2 distributed over two floors. On the ground floor there are three kindergarten rooms, the administrative areas, the gymnasium/multi-purpose room, and the cafeteria and kitchen. On the first floor there are eight classrooms for the elementary school, and the areas for pedagogic and personnel support staff.

The building has a reinforced concrete structure and the envelope is made of double walls coated on the exterior by one coat render and porcelain mosaic, a flat roof and openings with aluminum framing and double-paned glass. The partition walls are 0.20 m thick and are stuccoed and painted, and in the wet areas there is a wainscot of ceramic material up to 2.00 m in height. The predominant floor coverings (classrooms, management and teaching support areas) are in wood.

The Alto da Faia School (AF) came into function in the 2001/2002 school year and has twelve classrooms for elementary school (EB1) and four activity rooms for the kindergarten. The school spaces are organized into seven interconnected blocks (Fig. 2): A block - elementary school classrooms, B block - central atrium, C block - resource centre, D block - kindergarten activity rooms, E block - kitchen and cafeteria, F block - gymnasium, G block - covered recreation area of the primary school, and H block - interior patio.

Block A is made of a building of 2400 m^2 distributed over two floors where the classrooms are located. On the ground floor, the building is articulated by a central atrium (block B) where the administration services, teacher and auxiliary educators' rooms are. The structure of block A is in reinforced concrete with an envelope made of a waterproofed type of flat covering, plastered and painted exterior double walls, and openings with metal framing and single-pane glass.

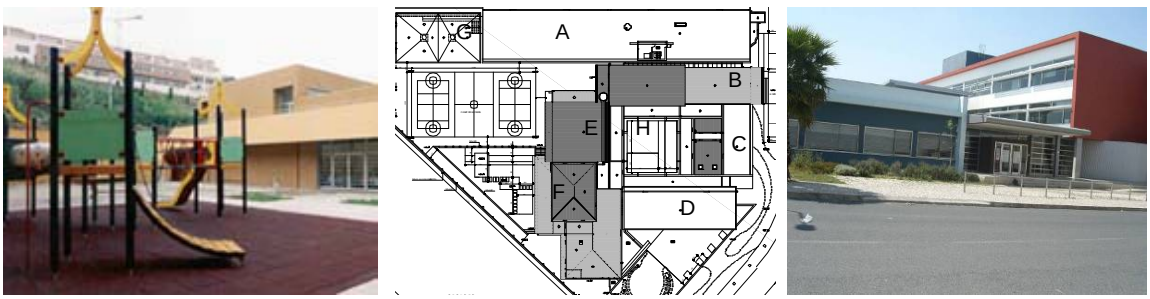

Figure 2. Posterior view of the VA school (left); campus plan of AF (center) view of the two floor block A building of the elementary school, B - central atrium and C - human resources (right)

School 34 came into function in the 2002/2003 school year. The building, where the kindergarten and elementary school function, has a gross area of 3000 m^2 distributed over two floors that are laid out in

plan in the shape of an L. For the kindergarten, there are four classrooms situated on the ground floor, and for the elementary school, there are twelve classrooms (four on the ground floor and eight on the first floor) linked by a corridor of 60 m in length (Fig. 3). The gymnasium, kitchen and cafeteria are located in the base of the L shape (the smallest area of the school), with ceilings twice the normal height.

Figure 3. View of school 34 (left); SB entrance and ground floor plan (center; right)

The structure of the classroom building is in reinforced concrete and the support services area is in metal. The envelope is made of double walls 0.30 m thick, a flat covering, and openings with aluminum framing and single-pane glass. The exterior walls present water-based paint on plaster finishing, exposed varnished concrete, and in the area of the metallic structure there are wooden formica panels. In the interior, the walls are 0.20m thick with a water-based paint finish, also used on the ceilings. The predominant pavement coatings are linoleum.

The São Bartolomeu School (SB) came into function in the 2003/2004 school year. The building where the kindergarten and elementary school function has a gross area of 3500 m^2 and is implanted on a landfill site which is very steep along the longitudinal and transversal development of the building. The building is made of two blocks: block A, a two floor building where the classrooms, administrative nucleus and teaching support staff function, and block B, of only one floor where the cafeteria and kitchen, gymnasium and locker rooms are located. The access between these two blocks is made through the use of a ramp and staircase beginning at the main atrium.

The structure is in reinforced concrete and the envelope is made of exterior double walls with perforated brick masonry, a flat cover, and exterior openings with aluminum framing and colourless double-paned glass. The exterior wall coatings are paint and ceramic material. The predominant coating of the partition walls is paint with a coating of ceramics wainscot and the flooring is a vinyl material with wooden baseboards.

4 RESULTS

4.1 Foundation and Structure

No significant structural anomalies were found, with the exception of the SB school where the opening of cracks of some dimension was noticed between block A and block B which seem to indicate the occurrence of diferential movements between the two structures.

In the case of school 34 and the AF school buildings, deteriorated expancion joints without grout were observed.

4.2 Building Envelope

4.2.1 Roofs

Three of the schools presented infiltration problems directly related with the roof: PM, AF, and VG. In the PM school, infiltrations were observed in the area of the gymnasium affecting the ceiling and the covering of the gymn floor, which already had been replaced in the area affected. The existence of broken ceramic tiles was subsequently aggravated by the fall of a drain pipe which, being damaged, led rain water to this area of the lining which was already fragile. The AF school presented infiltration problems in the roof areas of the elementary school building block with the building block of the main atrium, and in the gymnasium area with the curling staircase that gives access to the upper gallery of the gymn. (Fig.4). Lastly, the VG school presented infiltrations through the large skylight above the main atrium and in some areas of the roof.

In the SB school, the existence of a roof without the slope defined in the project, with uneven constituent elements, was identified. There were alterations to the project, with the introduction of a chimney originating from the boiler, cutting a hole in the roof without caution to the finishing necessary for the good function of the waterprofing system at this sensitive point (Fig. 4).

Figure 4. AF school - view of the gymnasium roof and the roof of the curling staircase which gives access to the upper observation gallery of the gymn where infiltrations were noted (left); VG school - infiltrations in the skylight (center); SB school - bad execution of the coating of the roof (right)

4.2.2 Exterior walls and windows

In the SB school, infiltration problems were identified in the bearing exterior walls, in the ramp linking the two floors, which has resulted in visible degradation of the interior coating of these walls (Fig. 5). The degradation of the coating of an interior lateral wall of a classroom located on the ground floor indicating a probable moistening of the wall by cappilary ascension of the ground water and waterproofing deficiencies (Fig. 5).

In school 34, the coating of the wooden formica panels presents signs of degradation due to acts of vandalism (scratches and *graffiti*) and presents the absence of a filling in the joints between the panels. In the AF school, accentuated degradation of an exterior wooden panel was observed located next to the interior patio (block H) (Fig. 5).

Figure 5. SB school: degradation of the interior coating of the bearing wall and the lower area of the classroom wall (left, center); AF school : very serious degradation of the exterior panel (right)

In relation to framing, no significant anomalies were observed in their function. Discrepancies were observed between the project and the construction: in school 34 and SB, polystyrene blinds were planned which do not exist. This situation stops the students from sitting next to the window due to the sun exposure, and also hinders visibility of the board. Curtains were placed, but now there are complaints about the thermal performance of the spaces with high temperatures in the summer.

4.3 Building Interior

4.3.1 Floors

The main anomalies detected in the coatings are directly related to the infiltration problems already referred to, caused by the roofs and the walls in contact with the soil causing localized degradation in the surface of the coatings, detachments and rotting. In the case of the gymnasium of the PM school, it was necessary to proceed with a partial replacement of the flooring.

In school 34, detachment problems were observed as well as lack of material at the level of the baseboards of the vinyl covering (Fig. 6). In the AF school, it was noticed that the flooring of the entrance area showed scratches and localized absence of material (Fig. 6), and in the VA school, some of the classrooms had loose floorboards with open joints.

The PM, AF and VA schools referred to problems related with the difficulty in maintaining the good appearance of the flooring because these demanded cleaning care and impractical maintenance (expensive materials, staff hours, poor durability of the appearance) namely of the floor coverings in wooden floorboards (Fig. 6) and clear-coloured vinyl floors.

Figure 6. School 34 - absence of a baseboard due to loss of adherence (left); AF school - detail of the wear and tear of the central atrium's floor covering (center); VA school - deficient maintenance of the floors of the rooms (right)

4.3.2 Walls and doors

In the SB, PM and VA schools, diverse fissures in the partition walls were observed, with the greatest incidence in the first building and probably related to the detected settling in its structure (Fig. 7). The most frequent anomalies are tied up with the deficient protection of the wall corners and the lack of adoption of wainscot in areas of great use causing aesthetical degradation.

All the schools referred to in-use problems of the interior doors with bad functioning of the locks (broken and jammed) and the deficient attachment of the handles. With less frequency, cases of degradation to the door coatings were observed which, in the more serious cases, has led to the visible appearance of the nucleus of the door (school 34 and VA). Some cases were observed of deficient attachment of the frame of the doors to the door itself (broken and loose hinges) as well as the frame to the masonry (school 34).

The model of the sliding doors used in the separation of the classrooms from the arts and crafts areas (school 34 and PM) showed functional problems related to maneuverability, vertical planing, deficient fixation, and loose runners. The most serious case was observed in school 34 (fig.7) where the doors were removed from one of the openings for safety reasons.

Figure 7. SB school - detail of the cracking of the walls of the ground floor (left); VA school - detail of a door deterioration (center); school 34 - removed sliding doors (right)

4.3.4 Sanitary services

One of the biggest worries referred to by the coordinators of the schools is connected with the maintenance of operability of the sanitary installations. Their ill-treatment by the users is associated with the breakdown of the equipment of the water and sewer networks, and has resulted, in the most serious cases, in floods. At the level of use, it is frequent for the faucets to be left open and/or the clogging of drains and toilets. The most frequent anomalies in the systems are: the breakdown of the toilet flow controllers, problems with the attachment of the faucets, problems in the enclosures of the washbasins and toilets, and problems at the level of draining capacity of residual waters.

In school 34, it was noticed that in the arts and crafts areas, next to the classrooms, there were signs of frequent water leaks from the washbasin siphons with constant ponding on the floor covering. The results of this anomaly are easily visible in Fig. 8 where three steps of the degradation process of the floor covering are presented.

Figure 8. School 34 - effect of the permanent water leaks on the floor covering

4 DISCUSSION OF THE RESULTS

The SB school, with five years of existence, is the one that causes the greatest worry due to the presence of three factors which, according to the CSA (1995), may lead to an acceleration of the degradation of the building: structural problems, a badly executed waterproofing system of the cover and buried elements with infiltrations. The observations show that it is necessary to make an analysis of the structure and of its eventual stabilization, perform reparation work of the cover (to replicate the project condition) and to the drainage system of the buried wall.

In the VG school, the non-traditional solution of the cover, in ceramic material, is not performing satisfactorily, with areas without a coating and others which are damaged. More studies are necessary, but the worrying signs of the impact of this anomaly on the interior of the building have already been felt with the rotting of the wood next to the door frames of the classrooms and with the repainting and substitution of part of the floor covering in the library. In the AF school, the existence of unevenness between building blocks, with the different types of covers, and the existence of infiltration problems in the interface leads to the establishment of a link between the two facts. It is unknown to what extent a detailed global study was done of the drainage of rain water in these sensitive areas, or if it is a question of bad project execution.

School 34 presents a worrying panorama due to the low quality of finishings used which, associated with a problematic population, is leading the building to high degrees of deterioration. Acts of vandalism have degraded the envelope of the building with walls showing marks and scratches, as well as in the wooden panels. In the interior, there is a worrying number of damaged doors (80% of the openings), detached floor coverings, unprotected white coloured walls without wainscot and with broken corners and serious problems in the function of the water system. It is thought that the doors specifications were not the correct ones in the face of their predicted use. In general this problem exists in all the finishing materials.

5 CONCLUSIONS

The principal observations of the visits to the six schools of very recent construction were presented in this paper. Although it deals with preliminary results, to be treated in greater depth in the PhD work in progress, this study seems to confirm the existence of problems originating from either the design phase or the execution phase, with consequences and important impacts in the maintenance phases and the use of the buildings.

In the envelope, problems can be detected in the roofs and in the bearing walls, areas where the repair could prove difficult to access and/or be onerous. A greater detailing of these construction elements in the projects, and a higher standard of quality control in the execution phase may become important in the reduction in the frequency of the anomalies. In the interior, problems with the doors, in the water systems and in the quality of the materials and finishings used can be detected. The managing entity should organize and improve its database in the sense of providing relevant information to the planners resulting from the utilization of the existing buildings, thus avoiding the repetition of errors and demanding better and more durable solutions in the future.

ACKNOWLEDGMENTS

The authors would like to thank João Semedo and his department of the CCL for aiding in the research on school building project design and available information exploitation. The authors also wish to express their thanks to all the school board management directorates for their time and views about their building.

Pathologies of the Industrialized Systems: 192 Flats Built in Avellino (Italy) at *Quattrograna West* District.

Francesco Paolo R. Marino [1]

T 71

ABSTRACT

This study is referred to 192 flats in *Quattrograna West* District at Avellino, completed in 1986, now object of building recovery and heavy restructured.

The 14 buildings have foundations realized with grade beams in reinforced concrete on drilled piles, and elevation structure in steel, constituted by HEB pillars, IPE beams and Z steel section folded up by pressure used as edge for the floors made by *prédalle*. The façades are constituted by non carrying infill prefabricated panels of the *solidale sandwich* type.

Of particular interest are: 1) the study of the pathologies of the system of façade, above all the penetration of water from the joints "head to head", interstitial condensations, cracking and putting out of concrete protecting the steel rods in correspondence of the pivots of anchorage of the non carrying prefabricated panels and the floors; and 2) the idea that is not necessary to make interventions of maintenance and building recovery, but that it is preferable to demolish and to reconstruct.

1 INTRODUCTION

The 192 flats of 14 buildings realized in *Quattrograna West* District, are part of an important intervention (1.023 flats) of financed building [Marino 2006] that was necessary after the '80s earthquake and was in the program of rebuilding and development of ruined zones of Campania and Basilicata, thanks to law 219/81.

The district is now object of a re-qualification program started in 1997 with *District Contract* that establishes the recover of residential districts with spread buildings degradation, urban surrounding and shortage services in context of lacking social cohesion and with living discomfort. This has been realized involving in projects inhabitants and local contractors.

Because of social reasons and inherent inadequacy of flats, even if without a careful analysis of existing pathologies and of recovering interventions, the municipal government has decided to demolish the originals 14 bodies of factory and the construction of a building "to open court" to the district, the realization of 3 experimental buildings too and the inner reconstruction of other flats with different dimensional cuts to adjust the dimension of the flats to the one of the family nucleus and to respond to users need.

In this study, it is paid the adequate attention to the evaluation of technical faults (such as general degrade of plastic plaster, water penetration in façades and from coverings, superficial and interstitial condensation, expulsion of the layer protecting the steel rods in correspondence of the walls of the sitecast stairwell and the precast infill panels of the façades, the elevation and the breaking of floors, condensation risk of steel elements), that is necessary to realize any recovering intervention or adaptation of buildings to guarantee the preservation of the same buildings and a good comfort for users.

2 THE PREFABRICATED FLATS IN *QUATTROGRANA WEST* DISTRICT

The "heavy" prefabrication in *Quattrograna West* District, is object of General Town Planning Scheme approved with deliberation of Town council executed in '91 and of Recovering Plane for *Mazzini* District and *QuattrogranaEst and West* Districts, according to the Law 457 of the '78 and according to the *Contract of District* as established by the Ministery of the LL.PPs. in 1997.

At the moment, the residential buildings have typological and the morphological characters very simple, that clearly denounce a standard and serial building process. The 192 flats are distributed in 14 bodies of factory, 8 of this form a "cross", while another group of 4 mark 2 opposed "L", 2 further buildings lined up form another body (Fig. 1). Every building has its typology in line, with two stairs, without elevator, that serve 2 flats by floor. The social centre, near the 4 buildings, is isolated from the first areas analyzed.

The bearing structure is realized with IPE beams and steel pillars HEA 140 that constitute the frameworks in longitudinal direction; the site cast stairwell have prefabricated flight and on the perimetrical pluggings are realized modulated *predalle* with base in reinforced concrete made in situ, to which the resistance is submitted to entirely the horizontal seismic resistance. The metallic frameworks instead are realized to resist to vertical actions for its own part. (Fig. 2)

In elevation, the buildings are developed on 3 floors plus the covering: the complete height is 13,61 meters. The groundfloor has a partial arrangement to "pilotis". In every buildings, on the groundfloor, there is a flat of 95 square meters, except to the building n° 11, smaller than the others, where there is a flat of 70 square meters; in this level, in every flats, there are the cellars. Inside there is a strong division between day and night zone. Furthermore the bathrooms are in surroundings without direct

aeration and solar light because of openings lack. Every living flat has 2 loggias.

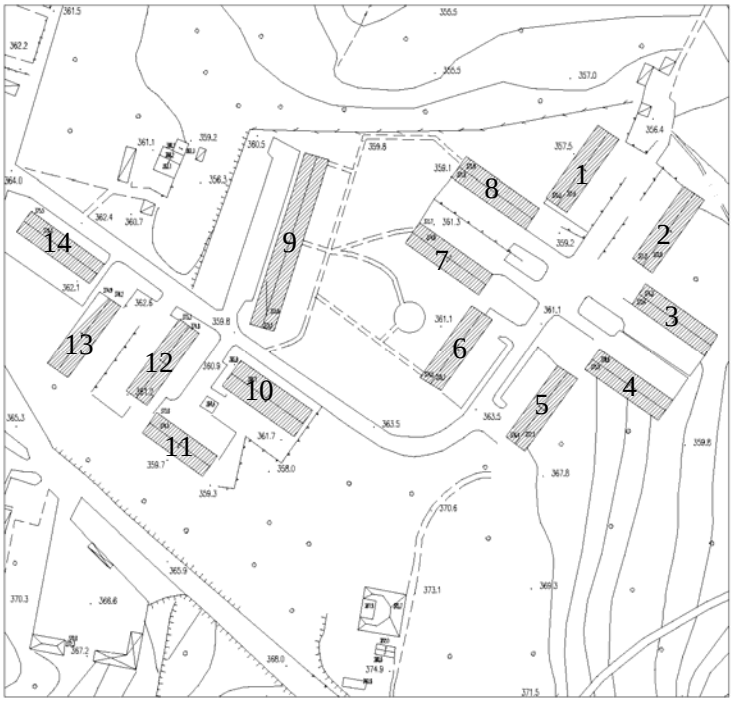

Figure 1. Aerophotografhy with location of the 14 buildings in the *Quattrograna West* District.

Figure 2. Bearing structures of buildings and non carrying infill prefabricated panels of façades

2.1 The Building Technique

The foundations are type indirect to upside-down beams corresponding to the steel pillars, and type grade slabe for stiffened cores, put on drilled caissons of diameter mm 500 and 800 and length m 17, fixtures in the carrying layer of the clays of base for around 5+7 m. The pillars are linked to foundation thought a base plate and hanger bolts in concrete. As said, the floors are “predalle” thick cm 25 lighted with panels of polystyrene (thick cm 5) and completed with laying of concrete in situ.

The external infill panels are realized with prefabricated concrete panels with electrowelded net, “*solidale sandwich*” type hight 300 cm and thick 20 cm, in these ones the external layer thick 7 cm and linked, through connectors that cross the central polystyrene stratus of 6 cm, to the inner one thick 7 cm. The link between panel and panel is obtained by smooth joints, type “head to head”, suture in concrete and sealed with polyurethane foam with closed cells. The structural scheme used is m 3,60 x 3,00.

The covering is realized with an auto bearing structure, with structural steels that form a truss fixed to the floor, completed with corrugated slabs made of eternit-cement-asbeat.

The external fixtures of the flats are realized in structural aluminium anodized with shutter opening, "coordinated block" type with PVC roller blinders. In the stairs, the frames are in structural aluminium anodized with *vasistas* opening. This materials are deeply degradated, so they are not suitable and functional anymore. The low ability to give a right isolation from atmospheric factors is proved by the fact that in most of estates, the users, on their own initiative, have installed a second series of external frames to improve the thermic isolation.

All the metallic parts are protected from corrosion with synthetic alkyl rustproof paint, 70 microns thickness, performed in the establishment previous SA2 abrasive blasting and following application, for the only parts at sight, of layers of oleo-synthetic paint.

Inside the pluggings are covered with stabs in plasterboard and insulating with a coat of glass fibre thick 4 cm. The inside division walls are realized with panels of plasterboard thick 13 mm built on metallic structure put on interaxis of cm 60. The complessive thickness of the separating is 10 cm with an air space thick 7,5 cm. For the separatings between flats, and for inner courts have been used 4 plasterboard panels thick 18 mm, alterned and insulated by glass fibre thick cm 4, built on frame bearing structure structured with plate zinc coated. The stairweel walls are made in reinforced concrete, isolated with polystirene thick cm 3 and whitewashed, the cellars ones in cement blocks of 14 cm thickness. In the loggias the pluggings are in hollow cement blocks, thick cm8, completed externally with plaster.

2.2 The Flats Typologies

There are 2 typologies of flats, each ones has on 2 sides of the buildings: flat type "F" (Fig. 3), with a net surface of 95 square meters; flat type "C" with a net surface of 70 square meters.

The author's analysis was restricted to the restructured buildings, so the typologies of buildings "A" and "B" are illustrated below. The "A" type are composed by one raised plan and 3 levels out ground for residential use. Every ground floor is composed by a flat "F" type with same height access; every residential level is composed by 2 flats "F" type. The buildings is composed by two flats per ground floor and 4 for level each ones linked to stair that serves 2 flats for level in total of six apartments. Every apartment has two loggias. The "B" type is composed by one raised plan and 3 levels out ground for residential use. Every ground floor is composed by a flat "F" type and by flat "C" type. The building has two flats per ground floor and four for type plane each linked by a stair that serves two floors on a total of flats. The "C" type has one loggia.

The flats have been dimensioned following the techniques indicated by the Execution Rule for Building Public Interventions for Municipalities of Campania Region.

3 MAIN CHECKED DEFECTS

The main defects checked and attributed to the building in object, are imputable to twos categories: typological-spatial deficit, or rather typological and dimensional inadequacy of flats; deficit of technical character.

As regards the typological-spatial aspects, deficiencies are translated in: lack of differentiation in the dimensional cuts of the lodgings, potentially too much great in comparison to the dimension of the family nucleuses; monotony of the façades and lack of recognition and articulation of the blocks; absence of elements of mediation between the inside space and the outside one; lack of quality of the external spaces and definition of the green spaces.

The technical faults are in the envelope of buildings (considering the cracks of the plaster coat of

façades, water infiltrations through joints head-to-head not sealed by panels and linked to frames, the degrade of frames, degrade of coverings, panels breached, inadequacy of the layer protecting the steel road) and in the bearing steel elements without zinc coating and not pre-painted, except to the pillars element where there is a too thin oleo-synthetic paint that has detached (high risk of condensation and presence of corrosion for differential aeration).

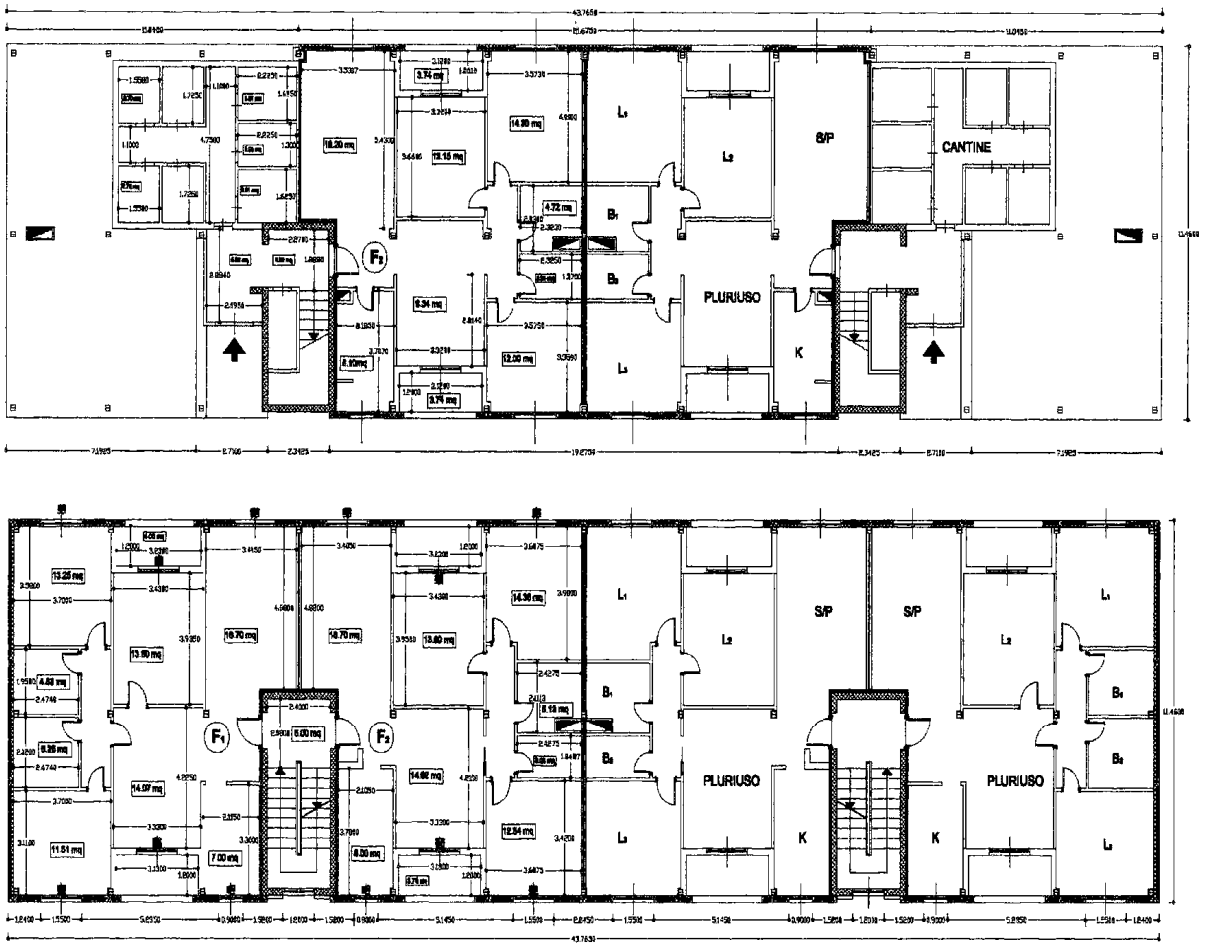

Figure 3. Example of the adopted typologies that are for the large part constituted by flats type "F" of m^2 95,00 of clear surface

3.1 The Pathologies Checked

The pathologies checked in the flats under examination, are attributable to a series of factors, among which there are errors of planning, errors of execution, lack of maintenance, lack of rules to control the quality of building product, particularly in the tendering for contract. In fact, the only considered parameter was the "cost", when is well known that this factor has no meaning when the aim is the quality, that is the "added value" on the final product.

For generally evaluating the state of the Quattrograna's buildings, investigations has been realized "in loco" to define the current conditions and performance evaluation sheets has been filled, before the building was divided in subsystems.

Main pathologies are: - corrosion of the steel elements; - expulsion of the layer protecting the steel road, above all recurrent in correspondence of the walls of the site cast stairwell, and on the façade panels; - water infiltrations along the window-sills; - interstitial and superficial condensations; - floors raising.

Very important is the status of the steel elements, that are protected (for the pillars) with anticorrosive paints applied during the realizations, but since the treatment subsequently has not refreshed and because of the lack of zinc coating, have been corroded by atmospheric agents and, in particular, above all by rainwater, that not only normally acts “by wind” (with West façades more exposed, otherwise in wind direction), but comes from by covering too, along the façade because is not efficiently protected by the overhang of a pitches.

The corrosion is diffused by differential aeration of steel structural elements, in particular in junction zones of the pillars to stairwell walls and in the arcades (Fig.4), as well as on the reinforcing rods and on the hooks of lifting and connection of the infill panels and on the hooking systems of the same floors panels (Fig.5).

Figure 4. Corrosion of the steel elements, beams and pillars

Figure 5. Corrosion of the hooks of lifting and connection of the infill panels and on the hooking systems of the same floors panels

The precast infill panels of façades are *solidale sandwich* type. They are in more parts breached and cracked: has been diagnosed the use of concrete of low quality, very porous and not very compact. The break up and the detaching of the layer protecting the steel rod (less than 20mm) causes the reinforcing rods corrosion (Fig. 6). The same causes are the origin of the corrosion of the reinforcing rods of the stairwell’s walls realized in sitecast reinforced concrete. Now they show the irons reinforcing rods, because the expulsion of the layer protecting the steel rod.

It must be added the disconnection of joints between panels and the low quality of the sealing realized with polyurethane foam. The swelling and the cracking of the plastic plaster (Fig. 6) of the external façades can be seen exactly in correspondence to joints and with horizontal orientation, in wide fronts zones. Corresponding to last floors panels, there are washing away of the arcade because of absence of roofing with drip to protect the cover element not very jutting, and humidity stains because of thermal bridges corresponding to horizontal roofing perimeter and because of condensation inside the stratification of the same package of covering.

Figure 6. Expulsion of the layer protecting the steel road on the façade panels.
Swelling and cracking of the plastic plaster

As regards the humidity pathologies, the research, realized on a sample of representative flats arranged to several floors, showed that the presence of problems connected to the formation of interstitial and superficial condensation and to relative apparition of humidity stains and moulds on the living walls, that comes again after every colour-wash painting, especially in the points where there is pour ventilation. There are humidity stains and moulds in the walls (inside walls and parts of ceiling), and this in spite of the general complaint of users for the low air quality of fixtures and for the inefficiency of heating systems. The mould presence in the rooms is not only an aesthetical problem, but a very hygienically one that gives no ambient wellness.

Humidity stains, superficial condensation, moulds are visible: - in bathrooms (without windows and with the ventilation system that in most cases does not work at all and is not used because of noise) at the intrados of the floor corresponding to the steel structural joint beam-pillar: corresponding to steel bear structure, the floor temperature, because of insulating lack, goes down referred to the inner air, because of the conductibility of the steel on the concrete; - in the corners of the bedrooms exposed to North-East, with moulds corresponding to thermal bridges between perimetral walls, floors and joints with the external wall; - in the kitchens on the inner surface of the panels of façade on the plasterboard layer in the low part of the window where the mould is caused by the condensation corresponding to thermal bridge; - in the loggias at the intrados next to steel bears.

Corresponding to box shutters and along the fixtures there are stains and moulds because of infiltration of meteoric water. Because of different acting of elements, humidity stains are checkable on the plasterboard slabs that cover the steel pillars inside the flats next to the joint between partition wall and floors.

The rising and the break-up of the floors in ceramics, even if they could derive from the lack of splitting up joints, united to the dimensional increase of the tiles caused by slow resumption of humidity from the environment and to the reduction of the available space caused by *fluage* of the floors, is in this case the consequence of low mortar quality, as checked in the users floors related to the floor damages on the durface because of massive solicitations and strokes (object fall, draging of heavy elements).

4 CONCLUSIONS

Is one more time clear how in the building prefabricated techniques, to a not careful project is usually followed by a bad execution, as demonstrated by the faults available so far. In fact very often the use of this building technique is required in case of unusual facts as calamitous events, and even in the project there is not the right attention to reliability, durability and maintenance.

Added to this, there is the lack of laws to control the quality of building product, in the tender for contract, in the project and in the realization, to obtain a "*finish product*" with a high control quality standard.

This research brings a contribution to Italy's researches to knowlwdge of buildings, creating a "data bank" [Lembo F. & Marino F.P.R. 2002] on pathologies and its causes, where study to "*feed the project with the memory of faults*".

An Example of Good Durability of Building Systems: Survey on 303 Flats Built in *Alvanite District* at Atripalda (Avellino,Italy), Made in *Coffrage Tunnel* and Precast Sandwich Panels for Facades

Filiberto Lembo [1]

T 71

ABSTRACT

The survey presents a study on a public residential intervention, realized after the destroying earthquake of 1980 (between 1983 and 1991) using industrialized building systems (reinforced concrete structure cast in situ in *coffrage tunnel* and precast sandwich panels for façades).

During construction, before the dwellings were accomplished, it were found humidity problems related with water penetration from facades and moisture condensation, and therefore were introduced many upgrade in design and in quality of constructional details, as an external insulation.

The result today is a conservational state many times better than similar and co-eval buildings - evidence that durability is the result of very critical factors, design and building stage.

In the report are showed results of this study, and is highlighted how some inhabitability problems existing in dwelling. They are related too, to design faults in passive ventilation of the rooms, related to the particular climatic conditions.

1 INTRODUCTION

In Italy, in the range of housing scheme, the use of industrialized buildings technique, that in '60 and '70 was typical of big public interventions of subsidized and conventioned building, at least the "10 years Plane" ones aimed to solve the problems of low cost flats in suburbs of big cities, such as Turin, Milan, Boulogne, Rome; in the following years has been and it's now bordered in particular occasions, in which is requested the production of big volumes built in short time, in confined areas and with typologies of "*mass housing*"; the natural diseases, in particular, improved this use, such the case of Pozzuoli's bradyseism, next to Naples, that caused the realization of a new city, Monterusciello, or the earthquake that hit Campania e Basilicata in 1980. In such emergency situations, the contract award procedures "*in concessione*" (with project and supervision of works assigned from the same working executor enterprise) have rendered ineffective the usual controls over quality projects an over execution, with the result of heavy pathologies, above all related to impermeability and to thermo-hygrometric type [Lembo F. & Marino F.P.R. 2002], [Lembo F. 2005], [Marino F.P.R. 2005], [Marino F.P.R. 2006], such as happened in England 10 years before [Lembo F. 1988].

It is surprising recognize that in some cases such as the object of this study, even a long time ago from the finishing, the flats built with industrialized buildings techniques "*by risk*", and especially with the Italian systems of awarding of contract "*in concessione*", after the earthquake of 1980, are in good conditions, except the following case. So, can be seen, for this case, an exception that proves the general rule.

2 DESCRIPTION OF ANALYZED DISTRICT

After the 23/11/80's earthquake, the historical centre buildings' of Atripalda, (with 7.000 inhabitants, in province of Avellino, situated at 50 Km east from Naples) were almost entirely damaged or collapsed, so they were demolished. The government commissioner for earthquake emergency decided, with order 16/06/81 n°323, to built n° 303 new flats, with 4 typologies, from m^2 45, 55, 65 and 85, with residential technique to improve their realization (with a strong "*acceleration prize*": 0,1% of the amount under contract for each day in advance in the fulfillment of the works, as the penalty for each day of delay).

The intervention was located on an area individuated out of urban perimeter, in Alvanite district, on a hill Nord West side along the motorway Avellino-Salerno (fig. 1) and the expected sum, with expropriation area and urbanization, was 20 milliards of Italian lires (i.e. about € 10,3 millions).

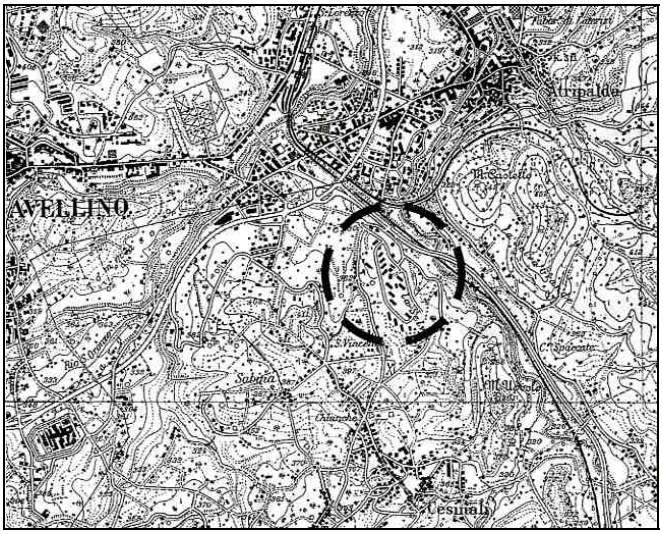

Figure 1. Chorography with location of the 303 flats in the Alvanite District at Atripalda.

The contractor offer tendering for "concession" (including the activities for the expropriation of the area, the design, the direction of the work, and the construction of housing and urbanization works) was the one submitted by the A.LO.SA. S.p.a. of Rome which provided the use of *coffrage* tunnel and precast sandwich panels for façade. The concession contract was signed on 13.12.1982. The draft drawn up by the dealer has provided 17 buildings in 3 or 4 floors above the ground. The dwellings have generally double facing, except the m^2 45 ones, and are characterized by constant span of m 3.60 interaxis, with a depth of m 11,10 (Fig. 2).

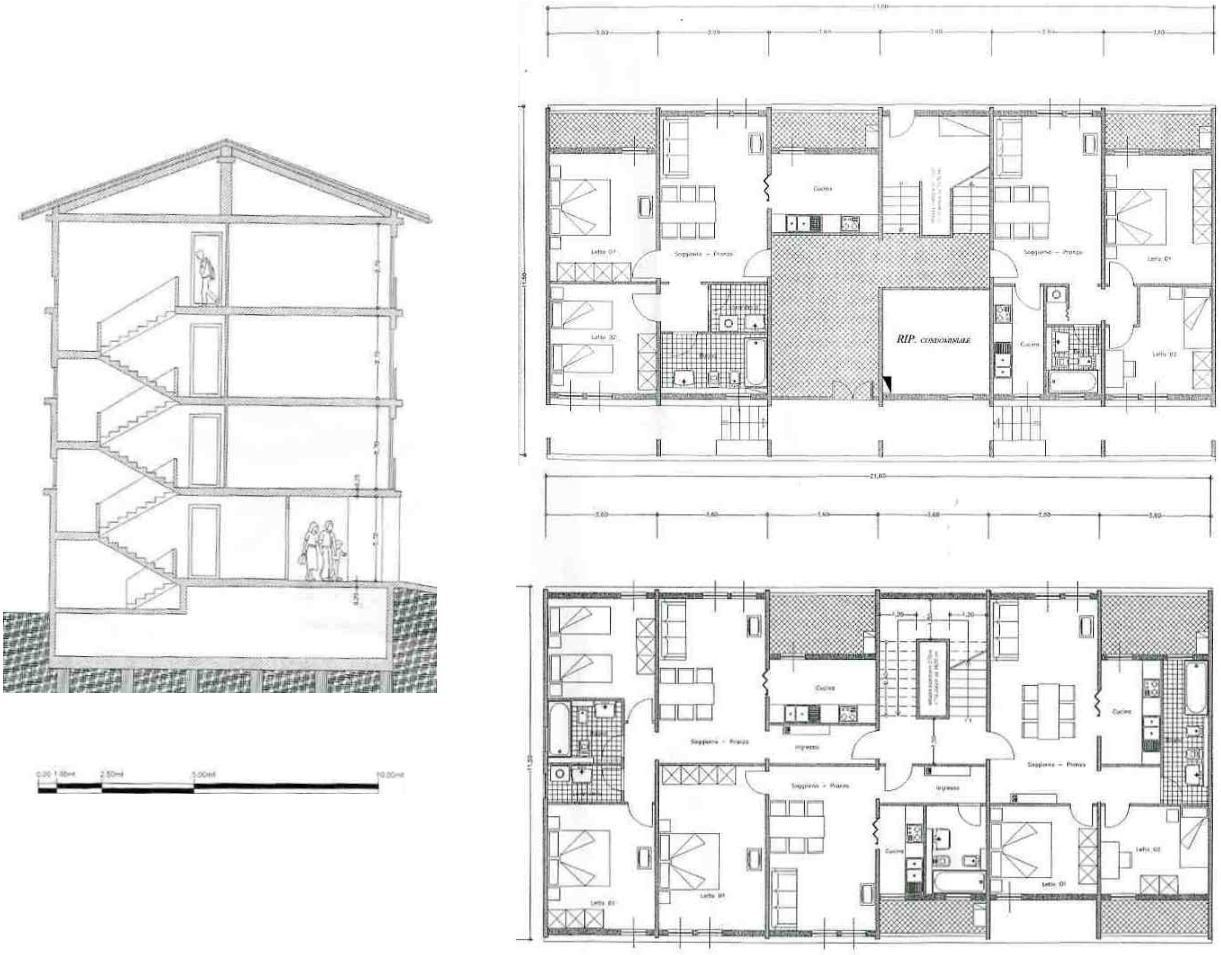

Figure 2. Typical plans and section of dwellings of various typologies.

The grant construction was issued on 10.11.1983, and the time available for the implementation of the work was 16 months (productivity: 227 flats/year). In reality, the residential buildings were completed only after more than double the time contractually agreed (September 1986) (real productivity: 106.3 flats/year). Main work parts has been finished after 2 years more (October 1988), while another part, with linking bridge to Atripalda's centre, has been finished after 3 years more (October 1991).

3 BUILDING CHARACTERISTS AND PROJECT FAULTS, CAUSE OF PATHOLOGIES AND DURABILITY REDUCTION

The buildings has been realized and projected according to *"tunnel builder's dream"*: equal spans, even the staircases ones, with transversal bearing walls (thick cm 14, interaxis m 3,60, to let the advantancing on longitudinal direction of castings, without (or minimal) deposits equipment exchanging. The head walls were isolated from the inside by pilaster slabs, with obvious problems of interstitial condensation (fig 3).

T71, An example of good durability of building systems: survey on 303 flats built in Alvanite district at Atripalda (Avellino, Italy), made in coffrage tunnel and precast sandwich panels for facades, Filiberto Lembo

The plugging of the façades was realized with sandwich panels made of light concrete (cm 4 inside and cm 6 outside) and middle expanded polystyrene from cm 6: useful only for the type section, but full of thermic links corresponding to ribbings, and linked to bearing walls and to floors to realize the formation of thermal bridges along the outline (figg. from 4 to 5) and the windows perimeter. There wasn't the isolations to the overlooking stairwell walls, not warmed.

Figure 4. On the left: vertical section trough external wall and intermediate floor - as built; on the right: horizontal section trough bearing wall made by tunnel and two sandwich lightweight concrete panel – as built.

Analytically, the project (so the unrealized work) didn't respected the following rules: Law 373/76 and Decree connected to the dispersions, Ministerial Circular LL.PP. n° 1351 of 22/05/67 and Ministry of Health Decree 05/07/75 connected to condensation control.

The design faults mentioned, have immediately determined, as soon as delivered the flats, at the end of 1986, water infiltrations in singular points, (in particular the joints between panels and tunnels related to the thermic dilatations and to the inefficiency of the join solution) and condensation phenomena, in particular where the flats were arranged according to particular orientations. For this, must be specified that here wasn't respected the project in consideration of particular climatic conditions, a peculiar of the valley where Atripalda and Avellino are; in literature this is well know because here the rain fall with a west wind that hit the façades in a horizontal way, causing a violent psychometric evaporation cooling [Massari G. & I. 1985, pp. 297-301].

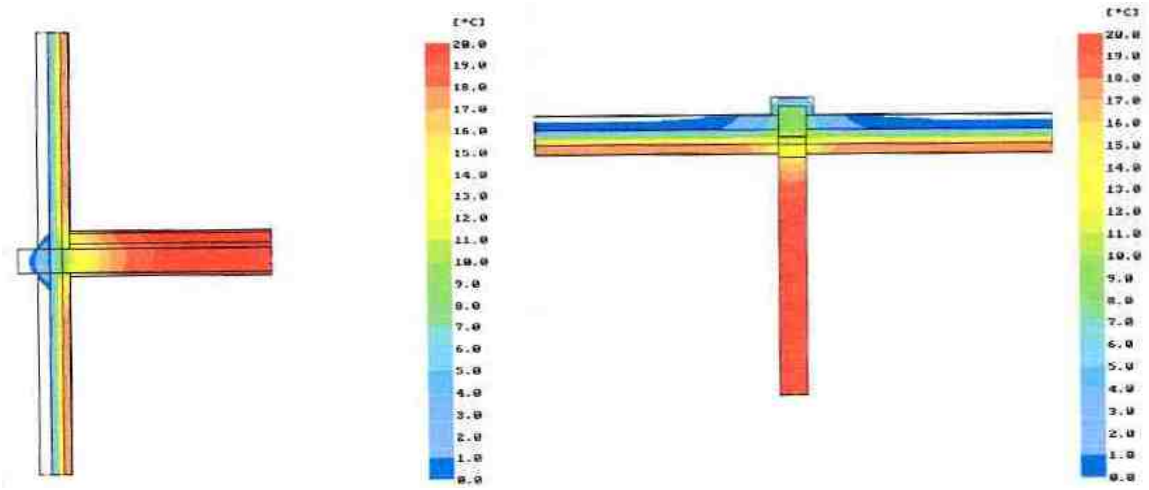

Figure 5. Temperature diagram, showing thermal bridges of Figure 4.

4 THE THERMIC RETROFITTING INTERVENTION REALIZED

The clever Municipal Government has programmed for "*correction*" of given buildings, a *thermic retrofitting* interventions of buildings facades, asking to Campania Region further financial supports that in 1993 (7 years after the finishing and the occupation) applying an isolation system from the outside with plaster thin on insulating (thick cm 3) and various sealing operations, tinsmith ryes and belt courses, on 13 of 17 flats, of € 516.000, and then, 3 years after, in 1996, on remained 4 flats (€ 697.300). In this way, the external walls has been improved for the impermeabilization (passing, according to French D.T.U, from type I – *mono-layer with hydrophilic insulating contact*, to type IIa - *with vertical capillarity cut, formed by an an-hydrophilic insulating*), and for the transmittance.

5 BUILDINGS STATUS AFTER 13/10 YEARS FROM RETROFITTING AND 20 FROM CONSTRUCTION

The research realized in 2004/2005 by Angela Laurino e Marco Moscati for their thesis in Engineering, showed that the thermic retrofitting realized was important for many problems. By an estimate check of calculation, the dispersion has been reduced to 19%, although the intervention wasn't referred to wall's of the stairs (if the intervention were realized here to, it would be verified a further reduction of 12%). The thermal bridges has been removed by every intervention on the walls, and with these the consequent condensation (these remains only corresponding to stairwell's walls, where there wasn't intervention).

Now there are:

- a massive humidity level in ground floor flats (many of these are not occupied), that comes from an insufficient drainage of superficial waters, that when it rains flood the sanitary interspaces under the ground floor floors, with relatives strong phenomena of capillarity rising and humidity saturation on sanitary vacuum walls and to the superior floor intrados, that absorbs humidity and transmits it to the upper flat (with consequence of fast degrade of reinforcings – fig. 6);
- execution defects of external insulating finishing, plus ground floors damages (because there isn't a specific and additional reinforcing against vandalism acts - fig. 7);
- allergy and pulmonary pathologies between inhabitants of the district.

Figure 6. Hollow space under first floor, with signs of flood and great humidity ratio. On the top, right-hand, steel bars spelling concrete cover.

Figure 7. Vandalic damages, made easier for the lack further of specific reinforcing.

6 LONG TERM RESULT OF INSUFFICIENT NATURAL VENTILATION OF FLATS

Without a specific epidemiological research, through the interviews realized with inhabitants, has been found a considerable diffusion of allergy and pulmonary pathologies, that comes from the insufficient natural ventilation of flats; in a flat with condensation on the stairwell's wall, that provokes the spread of moulds and pollens, can be defined the bad inner air quality, that can be the origin of pathologies.

After a careful study about the wind dynamics that hit the buildings (fig 8), that helped to understand the spots distribution for thermophoresis on facades, has been verified the renewing air rate in the flats

thought the apply of Italian rule UNI 10344 "*Warming of buildings calculus of requirement of energy system*", and resulted the renewal rate of 0,05 renewals/hour, while the rules gives a rate 10 times superior, 0,5 vol/h. For a flat of m^2 65 of surface, is m^3/h 84, it would be necessary obtain with a specific natural system of ventilation. There is a foreseeable consequence of use a building system not traditional, with characteristics different from the used ones: it is for itself watertight to steam, and has steel frames (and, for many flats, aluminium dead fixtures too), and has been sealed by addiction of insulation from outside. The flats in particular are the 45 m^2 ones, exposed by one side, that have the biggest problems for a natural ventilation.

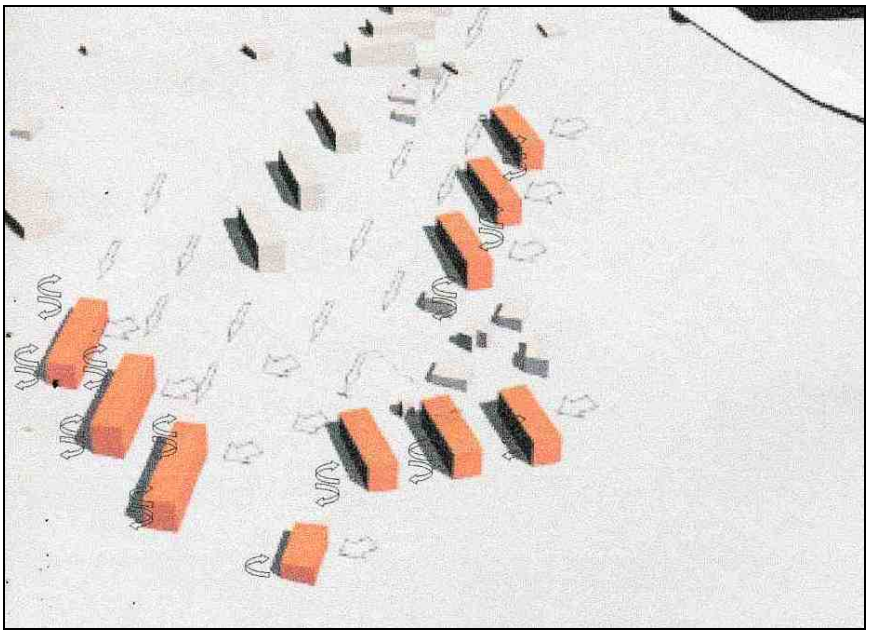

Figure 8. Tri-dimensional study of the winds and their effects on pathologies of buildings and on natural ventilation of dwellings.

It would been necessary realize (but is necessary now) specific air inlet and air outlet, for example equipped with polyamide filters (braids hygro-adjustable) that improve porosity, so the capacity to be passed by air, when the inner humidity level is high, and decrease on the contrary; disposed to let the perfect mixing of incoming air with the surrounding one (fig 9).

Figure 9. Study of specific devices for optimizing natural ventilation in dwellings.

T71, An example of good durability of building systems: survey on 303 flats built in Alvanite district at Atripalda (Avellino, Italy), made in coffrage tunnel and precast sandwich panels for facades, Filiberto Lembo

This system must born with the project and must follow it until the execution, when is decided the use of building systems impermeable to vapour.

7 CONCLUSIONS

The good durability performance of building industrialized intervention in Atripalda is not referred to the original project, but to the *thermic retrofitting* applied after the finishing; anyway there are many improvements that can be realized, to enlarge its life and improve the performances; and is necessary work on durability of the persons that live inside, introducing as fundamental element of project the quality of indoor air, and so a careful ventilation project, natural if possible.

ABSTRACT

Several hundreds of buildings made of reinforced concrete are now classified as historical in France. Their major pathology is carbonation induced corrosion. The cracking and spalling decays induced by this natural aging process cause loss of material incompatible with the deontology of historical monuments conservation. Therefore it is crucial to understand the corrosion process of embedded steel and to be able to evaluate precisely the corrosion activity on site, in order to predict and may-be to prevent such decays. Current on site non destructive tools for diagnosis operations are potential mapping or corrosion rate measurements. But, such electrochemical techniques are clearly season influenced. Moreover, corrosion rates induced by carbonation are often very low and therefore can be difficult to measure. As a consequence, in areas heavily affected by spalling phenomena, low corrosion activity is often evidenced, so that the interpretation of the results can be problematic. A last hypothesis could be that the oxide layer formed is so resistive that the conductivity necessary for the measurement is lost. In order to better understand the corrosion process of rebars embedded in carbonated concrete, and may be to improve the reliability of those diagnosis tools, it seemed interesting to try to correlate on site measurements with the identification of corrosion patterns. Therefore, on a 56 years old industrial building (Air Purifier of the Meudon Wind tunnel), several sets of potential mapping, resistivity and corrosion rate measurements were performed, respectively in winter time and in spring time, and after medium or heavy moistening. Then reinforced concrete cores were sampled both in supposed active and passive corrosion areas, in order to evaluate the carbonation depth and to identify the corrosion patterns.

1 INTRODUCTION

One of the major sources of decay of historical monuments made of reinforced concrete in France is carbonation. This phenomenon consists in a reaction between atmospheric carbon dioxide and the cement paste hydrates, inducing a decrease of pH from values up to 13 in a sound concrete, down to 9 in a carbonated concrete. At these lower pH values, concrete is no longer protective for the steel reinforcement and an active corrosion of the rebars can take place if enough water and oxygen are available. Nevertheless, this corrosion process, very influenced by atmospheric conditions, seems slow-acting, and therefore it is sometimes difficult to monitor on site through electrochemical measurements. Moreover, in heavily decayed areas, where thick oxide layers can be observed, sometimes very low corrosion activities are measured. As a consequence, interpretation of on site measurements can be tricky. So it seemed interesting on one hand to study the influence of atmospheric conditions but also of preliminary moistening on electrochemical on site tests ; and on the other hand to verify these measurements by identifying the corrosion patterns on points prior assessed either active or passive.

2 TESTING SITE AND PROTOCOLE

2.1. Description and Preliminary Characterization

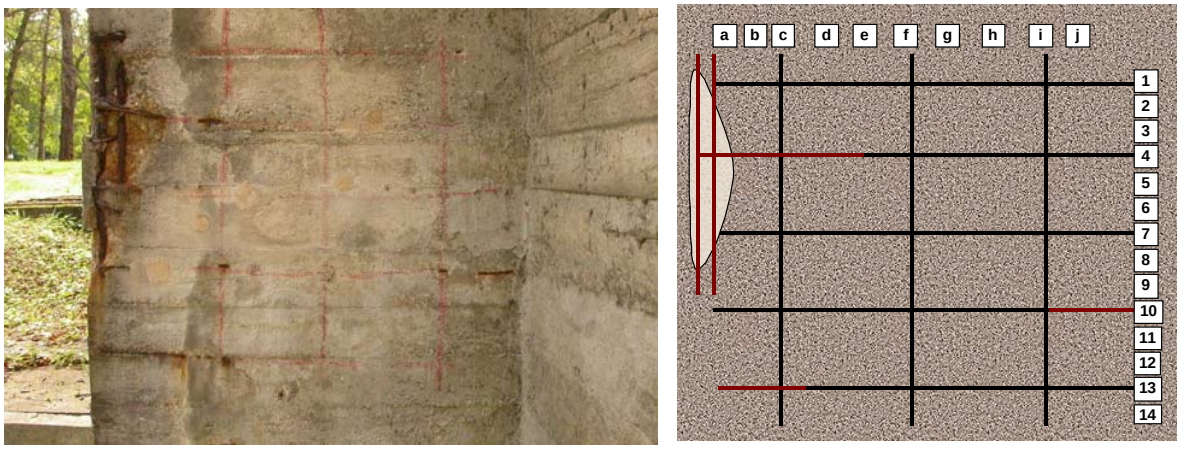
Tests were performed on the extension of a wind tunnel, built in 1950 in the western suburb of Paris (Figs 1 and 2). On the eastern façade, of this ancient air purifier, numerous honeycombing and spalling areas were visible on the pillars, with locally very thick oxides layers (Fig. 3). Due to the age of the building, a carbonation induced corrosion was suspected.

Figures 1, 2 and 3 : The air purifier (on the left) is an extension of the Meudon wind tunnel (in the center). It is locally very decayed, with large spalling areas (on the right) often linked to honeycombing.

In a prior study [1] characterization by optical and SEM observations of both fractures and cross sections revealed a great heterogeneity of the concrete ; locally very compact areas, with good cement-aggregates contacts, cohabiting with numerous very porous zones. A carbonation phenomenon was observed, portlandite being gradually replaced by calcite, but the extent of the reaction was clearly linked to the compactness of the concrete. Finally, cement was identified as an Ordinary Portland Cement containing small amounts of slag, which can be compared to a current CEM II/A.

2.2. Testing Area

A 1m² testing area, with a large spalling zone and visible corroded rebars was selected (Fig.4).
In this testing zone, 5 vertical rebars (2 being visible) and 5 horizontal rebars were located (Fig.5) using an electromagnetic technique (pachometer rebar plus©).



Figures 4 and 5 : In the selected testing area (left picture), 5 vertical and 5 horizontal rebars were located (right diagram).

2.3. Testing protocole

First in order to evaluate the influence of the climate on the corrosion activity, a series of electrochemical measurements (resistivity, potential mapping and corrosion rate) was carried out on site, both in winter and in spring time, after standard moistening of the examined surface. Then to study the impact of preconditioning, during the spring tests, 2 sets of measurements were performed respectively after heavy moistening or after heavy and repeated moistening.Then, as carbonation was the suspected source of corrosion of the rebars, the carbonation depth was evaluated through phenolphthalein tests, realized on cores.

Finally, cores containing a rebar were sampled on areas identified by the electrochemical measurements as active or passive. From those cores, in order to identify the corrosion species, cross sections were prepared and optical microscopy, Scanning Electron Microscopy (SEM) coupled to Energy Dispersive Spectroscopy (EDS), and Raman micro-spectrometry were carried out following the protocole described by Neff & al. [8].

3 ON SITE TESTING

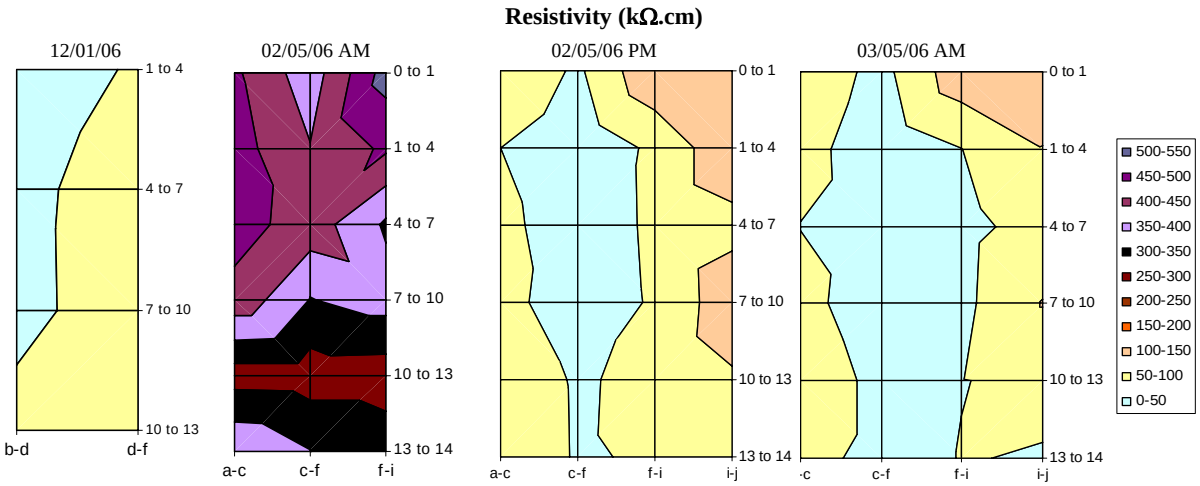
3.1. Resistivity Measurements

Resistivity measurements were performed with a Gecor6© device, using a copper-copper sulfate electrode. Four thresholds of corrosion risk are indicated by the manufacturer, from nil (ρ>100 kΩ.cm) to low (50<ρ<100 kΩ.cm), moderate (10<ρ<50 kΩ.cm), up to high (ρ<10 kΩ.cm). But in practice, such measurements which are so dependent on the concrete dampness and salts contents, are more used as a relevance indicator for electrochemical measurements. Thus, it is commonly admitted that when resistivity is higher than 100, the concrete is too dry, and when it is lower than 5, it is too water saturated, to perform electrochemical measurements.

In winter time (12/01/06, 5.2°C, 70% RH), resistivity values ranging between 9 and 30 were measured (Fig. 6), indicating a suitable moisture content for electrochemical measurements, with a moderate corrosion risk.
The first measurements performed in springtime (02/05/06 AM, 15.4°C, 53.3% RH, Fig. 7) after “standard” preliminary moistening, lead to resistivity values between 273 and 521 kΩ.cm, indicating that the concrete was clearly too dry.

After heavy moistening, a new series of measurements was carried out (02/05/06 PM, 18.5°C, 43.8% RH, Fig. 8), and resistivity values between 19 and 144 kΩ.cm were collected, indicating that the concrete was then wet enough for electrochemical measurements, even if the corrosion risk stayed moderate to low.

The day after, a last set of resistivity measurement was performed (03/05/07 PM, 19.7°C, 54.3% RH, Fig. 9), after heavy and repeated wetting of the testing area. Values very close to the previous ones, ranging between 10 and 133 kΩ.cm, were measured.



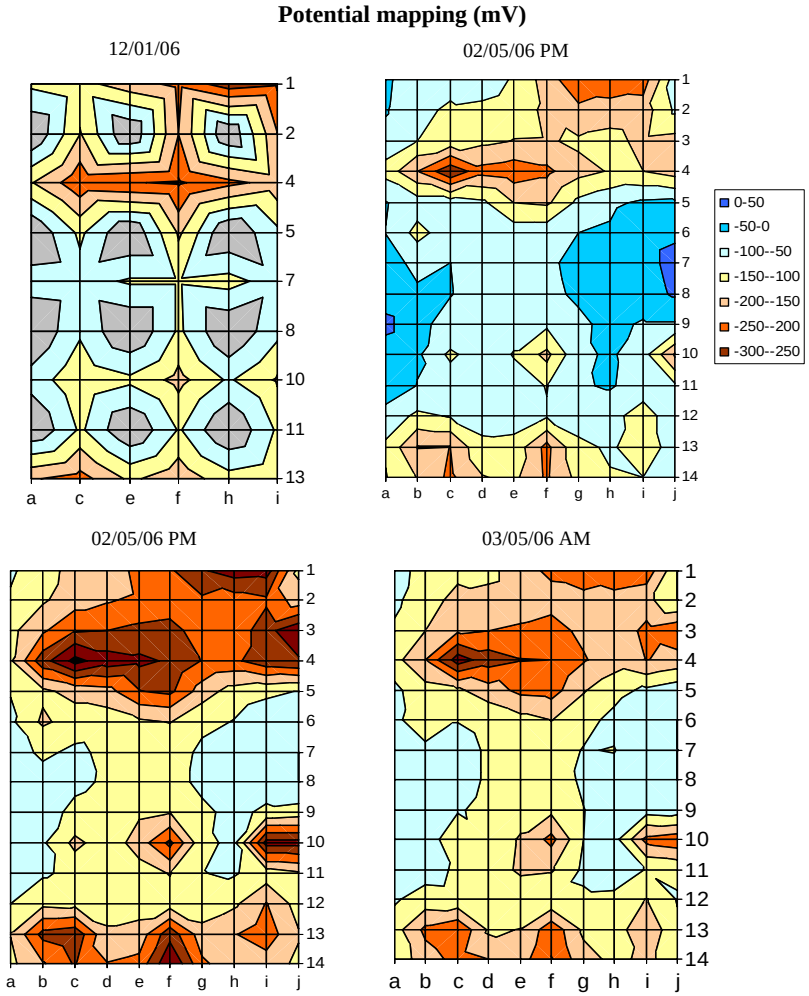
Figures 6, 7, 8 and 9 : Resistivity mapping realized in winter time (12/01/06) ; and in springtime after standard moistening (02/05/06 AM), after heavy moistening (02/05/06 PM), and after heavy and repeated moistening (03/05/06 AM).

3.2. Potential mapping

Potential mappings were carried out using a Canin© corrosimeter, equipped with a copper-copper sulfate reference electrode. If ASTM C876 standard defines thresholds of corrosion probability for potential measurements, it is commonly admitted that it is preferable to realize potential mapping and to identify potential gradients. Thus corrosion is considered as probable when potential differentials of at least 100 mV are encountered.

On the first mapping, realized in winter time (12/01/06, 5.2°C, 70% RH, Fig. 10), potential values quite high, ranging between –69mV and –275 mV were measured. According to the ASTM standard it would indicate a low corrosion probability, but clear potential gradients were observed on the top two horizontal rebars (lines 1 and 4), and on the bottom of the testing area, indicative of a probable corrosion.

Then on the second mapping, performed in springtime (02/05/06 AM, 15.4°C, 53.3%RH, Fig. 11), even higher potential values were obtained (between –292mV and +15mV), confirming the resistivity measurement, indicating that the concrete was very dry. But on the same time, evident potential gradients were observed at the same location as in the winter measurements (i.e., on the top two horizontal rebars = lines 1 and 4, and on the bottom of the two first vertical rebars = lines c and f).
Finally, the third and fourth potential maps respectively obtained after heavy wetting (02/05/06 PM, 18.5°C, 43.8% RH, Fig. 12) and heavy and repeated wetting (03/05/06 AM, 19.7°C, 54.3% RH, Fig. 13) were almost similar. The potential values drastically decreased (ranging between –20 and –367 mV) compared to the previous ones, but the same singular points were observed ; an additional one appearing more obviously on the fourth horizontal rebar (line 10).



Figures 10, 11, 12 and 13 : Potential mapping realized in winter time (12/01/06) ; and in springtime after standard moistening (02/05/06 AM), after heavy moistening (02/05/06 PM), and after heavy and repeated moistening (03/05/06 AM).

3.3. Corrosion Rate Measurements

Corrosion rate measurements were realized with a Gecor6© device, equipped with copper-copper sulfate electrodes. For each point, the values presented in this paper correspond to the average of at least three measurements, standard deviations being very low (0.01 up to 0.028).

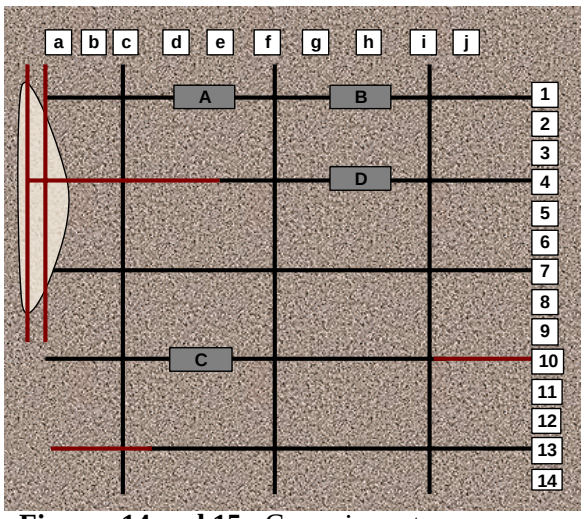
When possible, tests were carried out on areas where, according to the potential mapping, highly probable corrosion or on the contrary no corrosion were suspected (Figs 14 and 15).

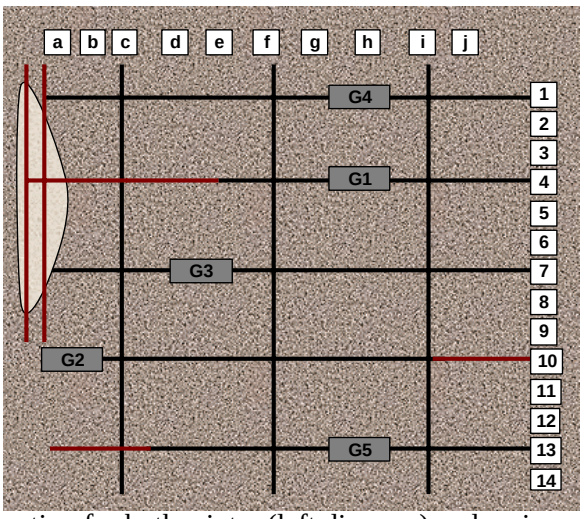
In winter time (12/01/06, 5.2°C, 70% RH, Table 1), four points were monitored, but for only three of them, exploitable data were obtained. Thus in points B and C, about 0.4 µA/cm² corrosion rates were measured. According to the RILEM TC 124-EMC recommendation (Table 2), in those points corrosion activity can be considered as low. When, on point A, a negligible corrosion activity was encountered (0.118µA/cm²).In springtime, after “standard” pre-wetting (02/05/06 AM, 15.4°C, 53.3% RH), as expected with the high resistivity and potential values previously obtained, none exploitable corrosion rate could be measured, the concrete being too dry.

After heavy moistening (02/05/06 PM, 18.5°C, 43.8% RH) and heavy and repeated moistening (03/05/06 AM, 19.7°C, 54.3% RH), two corpus of results were obtained :
- in points G2 and G5, corrosion rates almost nil were measured,

- when on points G1, G3 and G4, corrosion rates close to the low corrosion activity threshold were found.

It is interesting to notice that for both winter and spring measurements, the highest values were obtained on the same point (B or G4), where relevant potential gradients were also observed.





Figures 14 and 15 : Corrosion rate measurements location for both winter (left diagram) and spring (right diagram) measurements.

Table 1 : Corrosion rate measurements obtained in winter and spring.

Measurement Location	Icorr (µA/cm²)	Potential (mV)	Date

4 AUTOPSY

In order to validate the electrochemical measurements, six cores were sampled, notably in points prior identified as active or passive.

4.1. Phenolphthalein Test and Visual Observations

As expected, considering the visible concrete heterogeneity, confirmed by the SEM observations, wide-ranging carbonation depths (varying from none up to 4.2 cm) were measured by phenolphthalein tests (Table 3). As a consequence, as concrete covers varied from 0.7 cm, up to 1.5 cm, carbonation reached only part of the rebars.
Thus on sample O20, carbonation has reached the rebar which is visibly corroded. On the contrary, on sample O22, carbonation hardly reached the rebar which is not corroded.

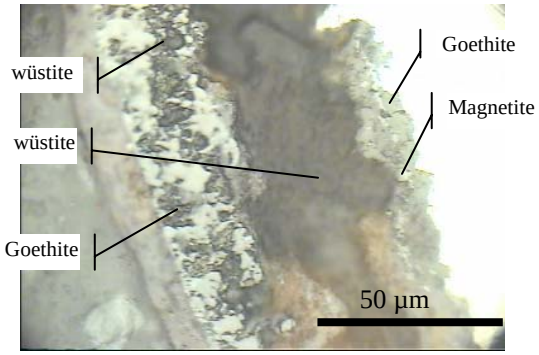
Table 3 : Phenolphthalein tests and visual observations.

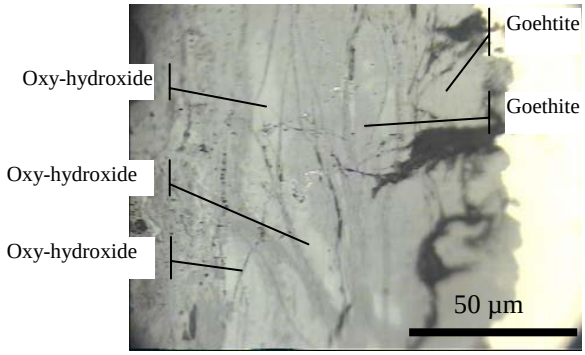
Core reference	Carbonation depth (cm)	Concrete cover (cm)	Rebars diameter (cm)	Visual observations
O19	2 to 4	1	0.8	Slightly corroded
O20	3 to 4,2	1.3	0.8	Corroded
O21	0.2 to 0.7	1.5	0.8	
O22	0.2 to 0.6	0.7	0.8	Non corroded
O23	0 to 0.7	x	no rebar	/
O24	0.5 to 1	x	no rebar	/

4.2. Oxide layers characterization

Two samples in which corrosion was assessed as either active (O20) or passive (O22) with the on site electrochemical measurements, were studied more in details.
Optical microscope observation of cross sections revealed an evident difference in oxide layers thickness between the two samples. Effectively, on sample O22 a quite homogeneously thin oxides layer was observed (average maximum thickness : 50 µm, but very locally up to 100 µm), whereas on sample O20 a very heterogeneous oxide layer was encountered (thickness varying from 10 µm, up to 600 µm).
Then SEM observations coupled with EDS and Raman microspectrometry were carried out, indicating first a complexity of the corrosion layouts but also an heterogeneity of the corrosion products formed on each rebar, on a given metal section. As shown in prior studies [7], corrosion patterns can be classified into three general types depending on the oxide layer thickness and on the corrosion products identified.
It is first to be noticed that on a given metal section several types were encountered. Thus, on sample O22, type 1 pattern, called the “orginal layer” was predominant. It was composed of wüstite (FeO), magnetite (Fe_3O_4) and hematite (α-Fe_2O_3). These phases are characteristic of hot working at temperature above 570°C, so that they were probably formed during the manufacturing process of the rebars. But in some localized zones, a type 2 pattern was observed, goethite (α-FeOOH) being detected between the “original layer” and the metal, which is characteristic of the beginning of an active corrosion (Fig.16). These layers were about 40 µm-thick, up to 100µm-thick in areas containing goethite.
On sample O20, two very different zones were also observed around the same rebar section. Thus type 1 was only locally detected. The major corrosion form identified was a type 3, which is very close to long-term corrosion layouts encountered on archeological samples [5]. It consisted in a thick oxide layer (up to 600 µm), mainly constituted of goethite, locally containing akaganeite (β-FeOOH), lepidocrocite (γ-FeOOH) on the external part of the corrosion layer ; and less crystallized phases appearing in lighter marblings inside the darker phases (ferrihydrite, $5Fe_2O_3.9H_2O$ and/or feroxyhite,

δ-FeOOH) (Fig.17). It is to be noted that at the end of a crack, a variant of this complex pattern was encountered, with traces of carbonates.





Figures 16 and 17 : Microphotographies of the corrosion layers observed on sample O22 (left picture), and on sample O20 (right picture).

5 DISCUSSION

As expected, due to the known influence of concrete moisture content on corrosion activity of the rebars, a noticeable season impact was observed on the on site electrochemical measurements, as on the same location, and after the same preconditioning, corrosion rate measurements indicated a low corrosion activity in wintertime and an absence of corrosion in springtime.
But preconditioning is also clearly of importance, as heavy preliminary moistening in springtime lead to results comparable to the wintertime ones. It is nevertheless to be noticed that heavy and repeated moistening did not improve the measurement, heavy preliminary moistening being sufficient.
Otherwise, among the electrochemical measurements performed in this study, potential mapping appeared to be the best corrosion indicator, as far as potential gradients and not absolute values were considered. Effectively, the corrosion phenomenon linked to carbonation doesn't seem to be very active, and therefore it is difficult to monitor it on site by polarization resistance measurements. Moreover, potential measurements could be performed even when the concrete was very dry, and potential gradients appeared on the same location whatever the season and the preconditioning.
Finally, an overall correct correlation was observed between the electrochemical measurements, the carbonation depths measured, and the corrosion layouts identified (Table 4). Nevertheless, quite complex patterns were observed, and as an example a noticeable impact of concrete defects such as cracks, was noticed on the nature of the corrosion products formed. This last phenomenon was already observed in prior studies [6] [7].

Table 4 : Results synthesis.

Core reference	Carbonation	Corrosion rate (µA/cm²)	Rebars observation
O20	Yes	G1b = 0.192	Corroded, thick oxides layers
O22	No	G2b = 0.007	Almost non corroded

6 CONCLUSION

In order to try to better monitor carbonation induced corrosion on site, a series of electrochemical measurements, coupled to detailed examination of the metallic reinforcement, was performed both in winter and in springtime, on the pillars of an air purifier built in the 1950ies with reinforced concrete.
On the basis of the tests performed on this specific concrete, on site electrochemical measurements appeared very seasonal variations sensible, potential mapping being the more reliable. Moreover, as carbonation was the main mechanism involved in the rebars corrosion process, very low corrosion rates were measured. As a consequence, a diagnosis based on polarization resistance performed after

standard preconditioning in springtime would have lead to contradictory conclusions compared to a diagnosis carried out in wintertime. Nevertheless, a clear influence of preconditioning was assessed, preliminary heavy moistening clearly improving the correlation between winter and spring measurements.
Finally, the examination of the corrosion layouts, generally corroborated the on site tests. But complex patterns were observed and a noticeable impact of the concrete local defects was noted. Therefore, complementary analyses are scheduled on the same building on areas where the interpretation of the electrochemical measurements was difficult, and a new series of tests will be performed on other types of concrete.

AKNOWLEGMENTS

The authors wish to thank the French Aerospace Lab (ONERA) team of the Meudon Center, for their kind help in this study, and the French Ministry of Culture for their financial support through the PNRC program.

Structural Health Monitoring of Historical Buildings Using Fibre Optic Sensors

Mariella De Fino [1]
Giambattista De Tommasi [2]

T 71

ABSTRACT

Structural health monitoring is widely used in engineering as a diagnostic tool for detecting the presence of defects, performance decreases or imminent failures, as well as for scheduling maintenance and repair operations. Among the different technologies for structural integrity control, fibre optic systems, FOSs, show some advantages over conventional devices, including immunity to electric fields and electromagnetic interferences, small dimension and light weight, durability in harsh environmental conditions and access to different measurands such as strain, vibration, temperature, humidity and chemicals. FOSs can be also multiplexed. More than a single sensor can be provided along an optical fibre, with interesting enhancement, in terms of flexibility and versatility.
Beside the wide interest to these technologies for monitoring composite and concrete structures, a lower attention has been given to masonry structures.
The paper is focused on the importance of integrated structural control for the historical heritage. It aims at proposing methodological guidelines and technical solutions in order to integrate FOSs into masonry structures, with particular attention to the conservation of the architectural, constructional and functional features of the buildings. Some laboratory tests with Fibre Bragg Grating sensor systems on a model wall have been also performed in order to assess the reliability of these technologies, by comparing their measurements with the results from traditional devices, namely strain gauges.

1 INTRODUCTION

Non destructive diagnostics offers innovative techniques for qualification of masonries. These techniques don't interfere with the structural integrity. They allow the investigation of elements that are not accessible with visual and direct inspection. They provide with comprehensive qualitative information on materials and constructional systems, state of conservation and transformations over the time. Nevertheless, they show some drawbacks. They may require the correlation with destructive diagnostics techniques, the control by skilled operators, the interruption of operating activities, the mobility of heavy equipment. As a result, they may be not effective, in terms of cost, time and results. Moreover, these techniques are generally used to support a correct diagnosis after an alteration in the constructional and static conditions may produce a damage.
Since that, during the last years, the scientific research has focused on new technologies that are cheaper, simpler, safer and quicker. Structural health monitoring is based on the physical integration into materials and structures of complex systems, composed of sensors and microprocessors that are connected by communication networks to platforms for gathering and elaborating data. These systems are able to provide with information on the local and global conditions of structures, in terms of stresses, strains, temperature, chemicals, humidity, with following detection of anomalies and defects.
Beyond a technological innovation, these systems basically offer a new methodological approach. From the classical knowledge process, where an operator takes a direct measurement in order to analyse and interpret the results, we are going towards an integrated system where detection and analysis are carried out by the structure that is able to transmit to the operator some information about its configuration. The sensor integration allows the structure at performing the constant and continuous control of the state of conservation (sensor system), the analysis of structural and environmental parameters all over the service life (elaboration data system) and the identification of a critical condition (interpretation and valuation system). Nevertheless, these technologies offer many advantages. Sensors are light, small and durable. Management costs are low. Data are updating continuously, with possible immediate intervention. System control can be carried out from remote places by Internet. Moreover, these techniques can detect a critical constructional and static condition before it producing a damage or even the failure.

2 FIBER OPTIC TECHNOLOGIES

Optic fibres, classified as dielectric light carriers, are one of the most promising and challenging technologies for the structural monitoring. They can be mounted on the surface and integrated into the material. From an input electric signal, a light is emitted by a laser source, it passes through the fibre, it is detected by an optic receiver and it is converted in an output electric signal. The variation of the electric signal, namely the light properties, along the fibre connected to the structure, can be valuated in order to gather information about the state of the structure, in terms of strain, stress, vibration, temperature, humidity, chemicals and to detect anomalies and defects.
Fibres transmit electromagnetic waves, with low losses. They are made out of two concentric layers: a central cylindrical core and an external cladding. Total diameter is typically 125 μm. The external layer is realized with a lower refractive index than the internal core, so that, according to the total refraction principle (Snell Law) the light is kept inside if the fibre does not undergo a sharp bend.
These technologies show several advantages. They are small and light, so that they do not alter the structural integrity of materials. They are resistant in harsh environmental conditions. They can undergo production and manufacturing processes with very high pressures and temperatures. They are immune to electric and electromagnetic interferences. They are compatible with the ordinary telecommunication fibres. They don't show significant signal attenuation.
There are different technologies based on fibre optic sensors, according to the investigated light property and the exploited physical principle. Nevertheless, they can be all grouped into three categories, in relation with the pattern of sensors along a single fibre. There are:

- Local sensors, where the measure concerns a single area that is generally several centimetres long over the fibre (for instance, interferometer sensors).

- Semi distributed sensors, where the measure concerns several portions, generally one millimetre long each, over the fibre (for instance, Fabry-Perot sensors and Bragg grating sensors).
- Distributes sensors, where each point of the fibre is sensor active (for instance, Raman and Brillouin sensors).

Beyond specific description, it is important to underline that these patterns correspond to different methodological approaches and technical applications.
Local sensors aim at gathering specific information referred to a limited area. Nevertheless, their application, also for historical buildings, generally concerns the control of cracks and /or deformations after defects or an anomalies have appeared on the structure and they have produced a visible damage. In this sense, that allow a traditional monitoring with innovative technologies.
On the opposite, semi distributed and distributed sensors go toward a constant and diffuse monitoring, by mapping and controlling a set of points during the whole life cycle of the structure. As a consequence, they perform when the structure is under working conditions and they can detect, or even predict, defects and anomalies before they produce a damage. Applications of semi distributed and distributed technologies are basically referred to steel components, reinforced concrete and fibre composite structures, while experimentation on masonries are really isolated.

3 APPLICATION OF FIBRE OPTIC SYSTEMS TO MASONRY STRUCTURES

Although the applications to masonries were isolated, the potential advantages of fibre optic systems for existing structures are really interesting. Static and dynamic performances of masonry structures, as well as mechanical and physical properties of traditional materials, are often very difficult to characterize. In fact, an existing building is the result of a comprehensive background, in terms of project, construction, transformation and utilization, that make it unique. As a result, mathematic models and information systems, created on the basis of the material, constructional, technical and technological characteristics, as well as of the simulation of damage and decay processes, can lead to simplified and schematic valuations that are non consistent with the actual structure. In fact, they may not consider the intrinsic balance that a building may achieve for its capability, acquired over the time, to respond and adapt to different external effects, both natural and human. On the opposite, integrated monitoring technologies are non invasive systems to know the structural conditions for a wide set of points and they let qualify the real behaviour of the structure. This approach is really interesting for the structure over its life cycle under ordinary working conditions. But it is even more attractive for the structure during a repair or maintenance work. In fact, a constant control enables the operator to plan properly the intervention, to know the response of the structure in progress and to valuate the structural parameters corresponding to the final configuration over mid and long terms.
According to the previous remarks, the application of fibre optic systems to masonry structures can be carried out in two ways:

- Integration of sensors into the structure
- Application of sensors on the surface of the structure

From the methodological point of view, the former approach can be validated, by studying the transfer of the experimental results achieved for reinforced concrete and composite structures, as well as for steel elements, to the technical solutions commonly employed for the maintenance and the repair of masonry structures [Fig.1-2]. In fact, a wide range of restoration and conservation strategies exploit the integration of reinforced cement injections, reinforced concrete slabs and carbon/glass fibre composites to improve and upgrade the mechanical behaviour of masonry elements.
As far as the latter approach is concerned, the application of optic fibre technologies to existing surfaces can be validated by experimentally studying how these sensors perform when they are bonded on different materials. The assessment of their suitability concerns different issues. Some are referred to the functioning of the sensor system:

- Reliability and relevance of measures
- Physical, mechanical and chemical compatibility between sensors and materials

Other issues have to be taken into account involving conservation principles and referring to the historical and cultural value of the structure, in terms of:

- Formal, architectural and technical compatibility between system and structure

4 LABORATORY TESTS

Some laboratory tests were carried out at the School of Construction Management and Engineering, University of Reading (UK), in order to assess the reliability and the compatibility of Bragg grating fibre systems applied on the surface of a model wall.
A Fibre Bragg Grating (FBG) is a longitudinal periodic variation of the refractive index of the optical fibre that can be induced by an intense ultraviolet source. This refractive index modulation allows the Bragg grating, which is about 10 mm long, at reflecting a specific wavelength of the incoming broadband spectrum. This wavelength, called Bragg wavelength, λ_b is expressed by the following equation:

$$\lambda_b = 2\, n_e\, \Lambda \qquad \textbf{(1)}$$

where n_e is the effective core refractive index and Λ is the period of the grating [Fig.3].

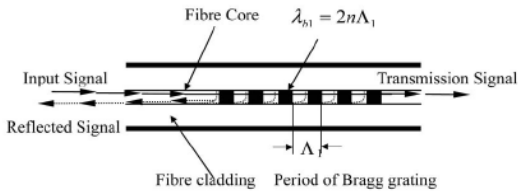

Figure 3. Configuration of a Bragg grating fibre

The Bragg wavelength can be shifted by parameters that can induce a change in the periodicity of the grating, as well as in the refractive index of the fibre. Such wavelength variations can be induced by changes, in terms of temperature and/or mechanical stress, in the structural area surrounding the grating. Specifically, the variation in the Bragg wavelength, $\Delta\lambda/\ \lambda_b$, can be expressed by the following linear relationship that combines the strain and temperature sensor response:

$$\Delta\lambda/\lambda_b = (1 - \rho_\varepsilon)\,\Delta\varepsilon + (\alpha + \xi)\,\Delta T \qquad \textbf{(2)}$$

where ΔT is the temperature variation, $\Delta\varepsilon$ is the strain variation, α is the coefficient of thermal expansion of the optical fibre, ξ is the thermo-optical coefficient and ρ_ε is the coefficient of photo-elasticity. α , ξ and ρ_ε can be determined experimentally.
According to (2), the wavelength variation results from a deformation, due to both temperature and mechanical stress variation. In order to know only $\Delta\varepsilon$, it is possible to measure ΔT with a second FBG sensor, coupled with the first FBG sensor. The FBG temperature sensor can be inserted in a metallic tube that allows at isolating the fibre from the mechanical stresses. As a result, the variation in the Bragg wavelength in the second FBG sensor, is due only to ΔT and the measure from the second FBG sensor can be used to compensate the measure from the first FBG sensor.
FBG can provide semi distributed measurements because a single fibre can be multiplexed. It can be up to hundreds metres long and it can contain up to 25 Bragg gratings. Each single grating is set on a specific Bragg wavelength, with a difference of 5 nm at least compared with all the other gratings on the same fibre.
An experimental validation of Bragg Grating Fibres were addressed.
Fibres were applied on a wall model in order to assess the reliability of these technologies, by comparing the measures with those ones coming from traditional devices, such as the strain gauges, during different compression tests. Wall was made out of light bricks, with a Young's modulus of 2200 MPa, maximum stress of 2.2 MPa and maximum strain of 1000 microstrains. Wall section was 880 x 260 mmq. Three fibres were applied. FBG1, placed on the back side of the model wall, had 1 temperature sensor and 1 deformation sensor. FBG2, placed on the left side of the front wall, had 5 deformation sensors, while FBG3, placed on the right side of the front wall, had 1 temperature sensor and 4 deformation sensors. Six strain gauges were mounted close to six fibre optic sensors [Fig. 4-5].

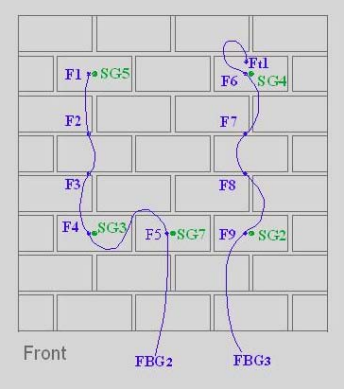

Figure 4. Sketch of the model wall. Front side

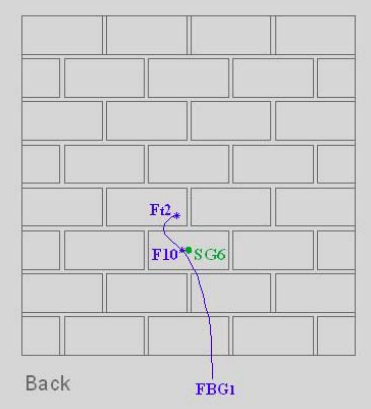

Figure 5. Sketch of the model wall. Back side

Deformation sensors [Fig.6] were bonded on the surface by using epossidic resin, while temperature sensors [Fig.7], protected by a plastic cladding in order to isolate the system from the mechanical stresses of the wall, were applied by using a simple adhesive tape, as the mechanical adhesion was not required. Since the passive elements on the fibres were short, they were not bonded on the wall. They were just applied by following smooth bends, in order to avoid signal attenuation due to sharp bends and break due to straight configuration.

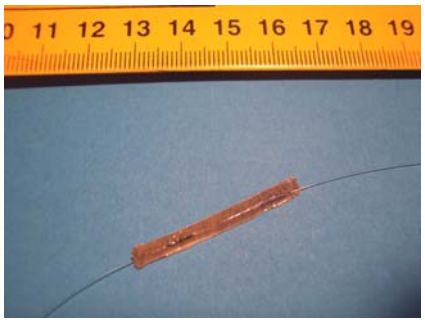

Figure 6. Deformation sensor

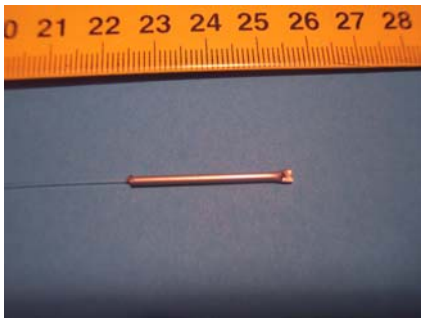

Figure 7. Temperature sensor

Tests were carried out by using Bragg Gratings written using an excimer laser (TuiLaser BraggStar 200) on 1550 nm optical fibres (Fibercore Ltd) that were provided by the University of Cranfield (UK).
In Table 1, the different wavelengths are listed.

Table. Wavelengths λb referred to each Bragg grating along the three optic fibres

Fibber	FBG1		FBG2					FBG3				
Sensor	T2	S10	S1	S2	S3	S4	S5	T1	S6	S7	S8	S9
λb (nm)	1538	1543	1538	1543	1548	1564	1559	1538	1543	1548	1564	1559

The Bragg grating interrogation system was IS7000 developed by Fiberpro (South Korea). The system was connected to a laptop via a USB cable where the sensor wavelengths were recorded using LabView (National Instruments).
Compression tests were carried out by putting on the wall a progressive load, with steps of 50 N, 100 N, 150 N, 200 N and 250 N. Loads were first centred, with maximum value of 600 (2/3 of the failure value). Then loads were 40 mm off-axis in order to achieve failure strains, with maximum value of 1000 microstrain, that was the calculated theoretical maximum value. Nevertheless, after the compression test with off-axis loads, the wall showed small cracks in some critical points.

RESULTS

In this application, the relation (2) can be expressed by:

$$\Delta\lambda/\lambda_b = (0.78 \times 10^{-6}\ \Delta\varepsilon) + (6.65 \times 10^{-6}\ \Delta T) \quad \textbf{(3)}$$

where $\Delta\varepsilon$ is 0.55 x 10^{-6} °C^{-1}, α is 6.1 x 10^{-6} °C^{-1} and ξ is 0.22.
In this application, the temperature sensors showed no temperature changes, as the surrounding thermal conditions were constant during the tests. As a result, the previous relation were simplified as:

$$\Delta\lambda/\lambda_b = 0.78 \times 10^{-6}\ \Delta\varepsilon \quad \textbf{(4)}$$

Results have demonstrated a good consistency between the measures, with an average error smaller than 15% [Fig.8 and Fig.9].

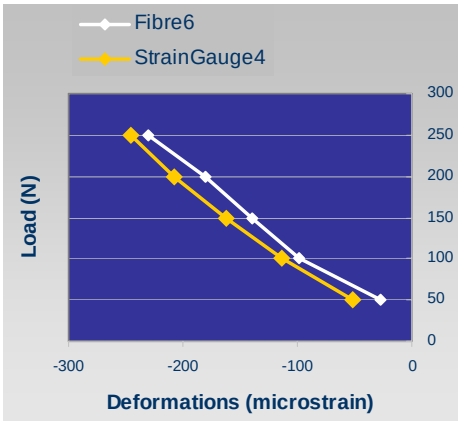

Figure 8. Comparison of results. Fibre sensor 6 and strain gauge 4

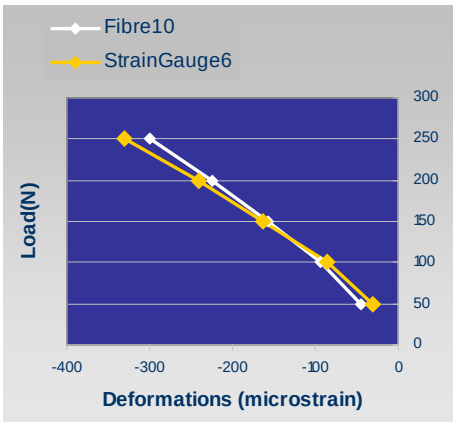

Figure 9. Comparison of results Fibre sensor 10 and strain gauge 6

CONCLUSIONS

Lab tests have suggested some operating remarks:

- Application of fibre optic systems on the surface of existing materials requires highly skilled operators in order to ensure a suitable adhesion and, as a consequence, a reliable mechanical transmission between sensor and structure.
- Fibres cannot undergo a bend with a ray smaller than 5 mm without any signal attenuation.
- Passive tracts of the fibres cannot be placed according to a straight line in order to avoid them to break for unpredictable tensions.
- Optic fibres can be covered by plaster without any alteration of measure.
- Fibres better perform if they are applied on the structure where it is unload in order to assess progressive, as well as further, deformations.

Nevertheless, from the methodological point of view experimentations have demonstrated that:

- Optic fibres show reliable and effective performances for monitoring strains on the surface of a structural element.
- Optic fibres represent a more practical and flexible technology compared with traditional devices. In order to gather information about a set of measurement points, a structure can be equipped by a single 0.125 mm width fibre, with different multiplexed sensors or by different strain gauges, each of them connected to the reading unit by a 0.5 cm width different cable.
- Optic fibres allow at detecting strain values until the failure of the structures. For the model wall, the off-axis compression test achieved 1000 microstrains, considered as the maximum theoretical value.

As a consequence, further developments will concern the experimentation of Bragg grating fibre systems on different materials that are typically present within the historical heritage, for instance stone and wood, both in not reinforced and reinforced conditions, in order to assess the effective signal transmission from the structure to the sensor and to analyse interface materials that can improve that transmission.

Artificial Stone at the Beginning of the XX Century: Materials, Technologies, Decay Processes and Refurbishment

Albina Scioti [1]
Fabio Fatiguso [2]

T 71

ABSTRACT

At the beginning of the XX century, the building area has been characterized by a significant interest towards innovative materials and techniques, whose feasibility and durability the planners have been completely relied on. A specific example is given by building elements realized with "artificial stone". This "artificial stone" was a "new" but nonetheless "basic" material, that allowed replacement of natural stone that was more expensive to procure and also more difficult to obtain. This study provides an in depth analyses of the use of artificial stone for façade. Previous research has aided illustrating both the positive effects, as well some potential critical points of this material. Furthermore, knowing that these elements can undergo specific material and technological decay require practitioners having the requisite knowledge or technological "culture" pertinent to the refurbishment of artificial stone, without which often leads to unsuitable maintenance and repair work. Particularly, the analysis of materials and technologies employed for the building envelope have been developed. Starting from the scientific knowledge of elements and typologies and from the taxonomical identification of potential decay processes and macroscopic alteration forms, that these handiworks could undergo, the study aims at investigating the possibility to produce an artificial stone to repair or replace the damaged material with particular attention to its composition and durability and the compatibility between ancient and new materials.

1 INTRODUCTION

Artificial stone is a building material that characterizes a large part of the architectural heritage built between the XIX and the XX centuries. The historical architectural value given to buildings rendered in artificial stone, seldom ascribed to the artificial stone as bearer of historical or technological value. As a consequence, one frequently has inadequate maintenance, refurbishment or restoration work that are typically oriented towards the replacement of elements rather than to their preservation.

The paper focuses on the definition of pathologies and decay processes for artificial stone used in the external façade of buildings in general, using the specific example of some Apulian buildings as a reference case. Hence the goal was to define suitable guidelines and operating criteria for maintenance and restoration of the artificial stone.

The study starts from the material-technical-technological evolution due to the introduction of a new material and to the development of a new technology within a process that took place, in great part, without the direct participation of academia, reconstructed also by the study of design patents lodged between 1870 and 1940 in Patent Office of the National Central Archive (of Italy) From the patent information, it is possible to draw extract information on mixtures and preparation techniques, and also defects and lack of performance that the new material demonstrated over time. Additionally, in certain instances the patent information provided empirically based diagnosis of the causes of defects or performance deficits and possible improvements in regard to both the selection of basic mix materials and the technology for maufacturing these products. The study made possible a direct comparison between mixtures and the manufacturing process through an analysis of appropriate case study of Apulia.

1.1 Artificial Stone Over Time

Research on the artificial stone manufacturing process has very ancient origins and represents a constant in the building history. Nevertheless, it is possible to outline a way characterized by testing and manufacturing aimed at obtaining materials that are both aesthetically like natural stone and guarantee of a greater durability for buildings.

Since Roman times, to obtain a stone that became hard when exposed to the air over time, a blend of one part crushed lime with two parts sand was used. Over the centuries, a good number of architects such as Bramante, Palladio and Bernini, have experimented with imitation stone with mixes that were basically based on lime.

During the Renaissance the use of plaster became common for covering building façades. Use of natural stone was limited to structures of civic or national importance, and as well to architectural decorations on these buildings. These elements were so limited that it was possible the low cost imitation by elements made out of common lime or water lime mortars. This employment is especially evident on the façades of residential buildings realized with ashlar stone: natural stone was used for the base of the façade whereas the upper part was realized using artificial stone and in an exact imitation of the course and pattern used for laying the natural stone in the base of the wall. During this period, rendering mixtures for artificial stone essentially included marble dust, lime and glue. [Cavallini & Chimenti, 1996]

There are several techniques developed in the XVIII and the XIX centuries to obtain a material that simulated cut stone. For example, mix of sand, hill and pigments applied on wood bases or plaster worked to simulate ashlars of stone, or cast iron worked for appearing as stone. Between the end of the XIX century and the first half of the XX century artificial stone has been achieved in large part due to the rapid growth of the use of Portland cement. The introduction of Portland cement, in the first decades of the XIX century and the consequent progress of the respective technologies made possible the production and the spreading of the new material with very low costs. The use of these techniques

to produce artificial stone permitted replacement of natural stone, a more expensive product and one that was difficult to procure given the distance to quarries and the cost and expenses of quarrying stone.

European and North American manufacturing centres started to produce artificial stones by earthenware or cement (Pulham stone, Haddon stone) and several mixes of modified gypsum plasters and were patented as artificial marbles [Proudfoot, 1996]. The use of the artificial stone became increasingly widespread and a symbol of progress obtained in the new industrial society. New production processes, industrial management methods, artisan traditions all found in the artificial stone building sector are illustrative of the close alliance between art and industry in this period of industrial development.

The imitation of natural stone, moreover, does not only concern aesthetical issues such as the choice of colours, grain or texture, as it was during the Renaissance, but also performance related issues such as flow, shrinkage and curing. As such, one has the development of a new technology that involves different parts of the building, particularly the external façade and those related to brick or stone masonry.
The new material seems to very well meet the requirements of the architectural culture at that time, which was connected to eclecticism and Art Decò; such type of architecture was characterized by extremely “plastic” elements that are easily produced using a cementitious mixture placed in moulds.

This evolution leads to the use of this material beyond that which was first proposed to replace natural stone, and from the 1930’s this product becomes an independent architectural subject, extensively used in the building industry and with shapes and element never before realized with natural stone.

1.2 Manufacturing and Patenting

First, we have some tests for the use of cement to simulate stone at the end of the XVIII century in France and England. The “Coade Stone” is one of the most widely used products first produced in England and used in European and American architecture until the end of the XIX century. However, from the second half of the XIX century, the largest number of patents is produced, in particular, those from America, England, France and Italy.

An early American patent, dating back to 1868, belongs to George A. Frear from Chicago for “Frear Stone”, a mixture of natural cement and sand with the addition of a shellac solution to enhance the strength in the curing first phase. This method is used and copied extensively with some differences in the choice of materials and methods; whatever is used however, today the specific typology of decay is evident.

"Coignet concrete" or "Coignet Stone" as developed by the pioneer of cement use in France, Francois Coignet, has a French patent that uses the cement as binder. This patent, dated 1869 and 1870, makes use of Portland cement, water, lime and sand as raw materials to manufacture prefabricated cement elements. These are immediately modified in the US manufacturing process with a mixture of sand and Rosendale cement. Hence, in the 1870 American patent awarded to Coignet, this modified formulation is sold to an American, John C. Goodrich Jr., who founded the New York and Long Island Coignet Stone Company. This company manufactured the artificial stone for the Cleft Ridge Span in Prospect Park, Brooklyn, New York, and consdered to be one of the earliest known use of this type of architectures in the USA.

The patent of Frederick Ransome is one of the most widespread English patents, in which is used a mixture of sodium silicate and calcium chloride to obtain calcium silicate blocks, whereby the removal of sodium chloride produced from the process is completed by means of washing with water during the cure. But for a great number of formulations we have soon the use of Portland as binding, that is a more reliable and less expensive product.

First the experimentations and the success of the new material are focused on a cheap artificial stone as a substitute for more expensive and less available natural stone. Then the manufacturing doesn't aim anymore at an imitation of the natural stone from an aesthetic point of view, but also and above all in regard of performances.

As evidence we have a large number of patents of the different kinds of mixture brought onto the market between the XIX and the XX century. There, we can see an advanced research aimed at improving the physical-mechanical feature and at developing a new technology, in a process mainly based upon products whose definition is the result of experiences made in artisan way but with proto-industrial developing for production.

The goal of the study of patents registered between 1870 and 1940 in Italy is the historical, technical and technological knowledge of this material. The research was carried out by means of a critical review of patents that allowed cataloguing these in accordance with essential mixtures and with regard to the binder used.

For each one of this typology declared defects and probably causes has been identified, and then, for each defect, improvement strategies suggested with regard to the mixture form, as wells as to technique and manufacturing procedures.

In the first manufacturing phases of these materials, during the XIX century, the main required performances are design, durability, cheapness and easy fitting. As a consequence, the manufacturing aims to guarantee and to improve these requirements for the market.

The main used bindings are lime, Portland cement and Sorel cement. The latter is largely used by the best producers of that period like the Union Stone Company in Boston that adds sand or crushed stone to the hydrate cement in order to obtain a variety of artificial stone.

Since the end of the XIX century many patents declare some defects of products on sale and suggest adding some additives that improve their performances. In specimens with lime and sand, we can have frequently change of geometry and cracks in the final products. The reason of this is the type of lime, the additives used to make easier the cohesion between ingredients and the content of water in the mixture.

When the caustic lime is used, the most common aim is to obtain crystallized masses by adding sulphuric or sulphurous acid in the mixture. But this doesn't produce the expected results, because reactions with sulphuric acid are too quick and they don't allow a good combination between lime and gypsum.

On the opposite, the mixture containing sulphurous acid slows down the natural process of cohesion and it doesn't permit to arrive at a strong and firm level of cohesion. So this type of mixture is modified using water lime (Patent No. 52901- 28/08/1899 Kiefer) to replace the caustic lime, and the production process is helped adding sulphuric acid that in this situation acts at the right velocity.
With regard to the content of water, it cannot be checked with accuracy, because often the sand used is not completely anhydrous but it shows variable and not measurable quantity of water. Then the indication is to make row materials totally anhydrous, by means of centrifugation for example (Patent No. 53024 - 25/09/1899 Schwartz), and to add the right quantity of water just after carefully mixing.
Further described defects concern the poor compactness of mixture after setting that can cause fragility and strength below expectation.

To face up to this inconvenience we have many indications. Some patents suggest to obtain a better cohesion in the mixture increasing grain size assortment by fine milling of sand (Patent No. 74288 - 15/11/1904 Kwiatkowski), or in other case to let the lime slake at the same time of lime and sand

milling and mixing.The slaking can happen in one or two subsequent steps. In the first case (Patent No. 72121 - 13/05/1904 Stoffler) the lime slaking is contemporary to the milling and the mixing of lime, sand and water. In the second case (Patent No. 74288 - 15/11/1904 Kwiatkowski) part of sand is milling with quicklime to obtain his partial slaking using the content of water of the sand. Then, the remaining sand is added with the water needed to end the slaking and to obtain the expected density.The success and the diffusion of the new material lead the manufacturing to correct the defects and to satisfy the increasing performance request. So, for example, a large number of additives are added at the main row material in order to obtain the same workability of stone, a good fire resistance, weatherproof, lightness and insulating capacity. It is suggest (Patent No. 71963 - 29/04/1904 Cordes) to add barium hydroxide or carbonate in the mixture of water, lime for cement and gypsum in order to manufacture an artificial stone that is workable with saw and chisel, light, with a good strength, fireproof, weatherproof, and insulating. Some shavings are put in the mixture in order to manufacture a quick and durable stone hardening, to help particles cohesion, and so to increase the strength of final mass wood. The use of coal ash guarantees a uniform distribution of wood shavings in the mass because the ash adheres to the shavings and prevents their floating into the mixture.In compounds with Sorel cement as binding agent it is often possible to have volume variations and cracks that make the artificial stone not much durable, sensitive to freeze-thaw cycles and to the presence of water. To obtain a better durability for the product with magnesia binding, the water absorption capacity, typical of Sorel cement is reduced, as well as the consequent variations of geometry and volume that cause cracks in the handmade, by adding phosphate of lime in the mixture (Patent No. 43116 - 22/03/1896 Preussner). The phosphate lime combined with the magnesia avoids the production of calcium chloride that is responsible for water absorption.To obtain a good strength to freeze-thaw cycles it is suggested (Patent No. 51473 - 20/04/1899 Ameloung) to add amorphous silica with inert like soil sand and sawing. In this way the additions react with cement to obtain magnesium silicate; the obtained stone is porous and it is necessary to use soluble glass or alkaline solution as a finishing surface.In compounds with Portland cement as binding it is often possible to assess vulnerability to atmospheric agents, to variation of temperature and to acid etchings. To improve the behaviour of the material it is suggested to insert many additives in the mixture like, for example, (Patent No. 69147 - 09/09/1903 Jurschina) a mixture of soda silicate and milled clay, that makes not alterable the traditional mix of Portland and sand or marble dust, after cooking at 1000-1400°C. In the same case, the Portland cement is totally replaced with the aim to increase the strength of the products. Substitutes are, for example, residual products of combustion of coal and of metal founding like the cast iron or the steel. These are milled and mixed with lime at a ratio of 83:17 or 66:34 (Patent No. 57293 - 15/10/1900 Martinelli).

Finally, there are many patents in which, a part of the binding typology, suggestions are given to improve specific features such as the impermeability, freeze-thaw cycles resistance, as well as fire resistance, atmospheric agents resistance and colour stability. Among the suggestions (Patent No. 71166 - 18/02/1904 Muller) there is the adding of vitriol, iron, copper or metal oxide in the mixture.

2 PATHOLOGIES AND DECAY PROCESSES

As it is clearly underlined within the patents, defects and pathologies are characteristic of artificial stone since the period of its greatest production. They are basically referred to some categories, shown in Table1.

They can be connected with the quality and the typology of the raw materials, as well as to the manufacturing techniques. Some pathologies have also been surveyed by an investigation on some samples of artificial stone buildings in Bari. In fact, in Bari, and more generally in Puglia, artificial stone was widespread, also due to the development of some firms, like Ditta Peluso and Ditta Ghilardi [Peluso, 1931], with national and international relevance.

Case studies were chosen according to some significant parameter, for instance functional destination (economic and popular building, middle class building, monumental building, public building)

because it is connected to the different quality of materials; exposition to natural and anthropical agents (e.g. proximity to the sea or a town centre having high traffic levels); location of samples on the façade (base, column) and their interaction with close elements. Figure 1 shows the form used to catalogue to building survey information and from which an analysis was based for each case study that was conducted. As was evident from the critical analysis of the available patent information, the durability of artificial stone depends on several factors: the quality of materials, care in execution of the work, and from the degree of exposure to environmental agents casing deterioration. In some cases, the resistance of this product may be comparable or superior to natural stone. Nevertheless, the survey on some artificial stone samples shows a decaying process that relates to several casual effects.

First, the dirt depositing with the action of atmospheric and polluting agents, above all on the elements in relief as capitals, pilasters and trabeations, decorations and friezes, often subjected to break-up of mortars and erosion of surfaces. Then, the grain size composition, making the surface more or less rugged, significantly influences the capability of pathogenic agents to adhere to its surface, such as the incapability of materials, and particularly of binding, to resist to the breaking action of water.

Table 1. Pathologies verified during the period of greatest production

Binding Agent	Defect	Pathology	Causes
Lime	Loss of geometry	early strength to temperature variations early strength to moisture variations early strength to atmospheric agents	typology/quality of raw materials quantity of water content
	Cracking	early strength to temperature variations early strength to moisture variations early cohesion of particles	typology/quality of raw materials quantity of water content manufacturing process
	Fragility	early cohesion of particles	grain size variety inadequate typology/quality of raw materials manufacturing process
Sorel Cement	Variation of volume	high capacity of water absorption sensitivity to freeze-thaw cycles	typology of raw materials
	Cracking	high capacity of water absorption sensitivity to freeze-thaw cycles	typology of raw materials
Portland Cement	Variation of volume	early strength to temperature variations early strength to atmospheric agents	typology/quality of raw materials quantity of water content
	Cracking	early strength to atmospheric agents early strength to temperature variations sensitivity to freeze-thaw cycles	typology/quality of raw materials quantity of water content manufacturing process
	Superficial crumbling	early strength to temperature variations early strength to acid etchings early strength to atmospheric agents	typology/quality of raw materials quantity of water content

Variations of temperature and humidity cause a loss in dimensional stability and loss in mass of the stone; cracking is evident due to the expansion and the shrinkage that these stresses cause to building materials. With regard to the realisation of elements in artificial stone we have often too thick elements without any reinforcement or clamping elements. This condition produces the separation of parts that are more or less significant in relation with the grain size and the binding.

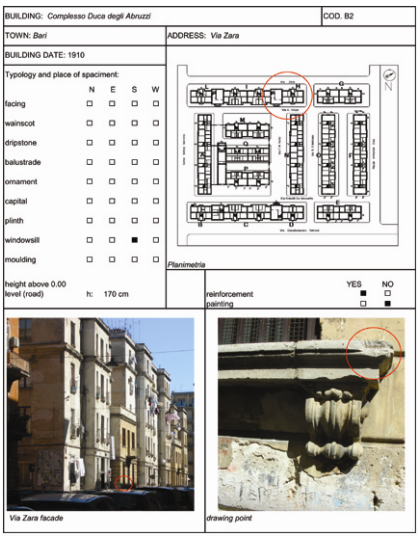

Figure 1. Specimen taken from a windowsill

Poor connections between adjacent elements made in factory and subsequently placed in work determine wide cracks, as well as scarce protection of clamping and clinging elements that causes their corrosion. Again the efficacy of protection depends to the quality of material forming the mixture that envelopes vulnerable parts by corrosion. Bad maintenance interventions, commonly performed during years: superficial treatments through covering paintings, often preceded by impregnation of the supports with irreversible fixatives, besides altering chromatic values of the material, compete to bait phenomenon of decay, even of notable entity. The start points of the described decay can be located in edges and relief parts, in surfaces of portions reinforced with metallic elements subjected to oxidation, in connections among different elements, in the zones of lifting and separation of following paintings, where deposit of particles and/or meteoric waters is possible.

Specimens were submitted to diffractometry and spectrographic tests to characterize the physical chemical petrographic. Results are not yet complete, however, no substantial differences in the composition of the mixtures are evident at this stage. Further tests are necessary to further understand the phenomena of decay of these materials

From an analysis of case studies and patents, and also with reference to a taxonomic systematization [De Tommasi & Fatiguso, 2005], a matrix of pathologies for artificial stone facades was defined that summarizes and classifies the main decay processes related to the mixture as provided in Table 2.

Table 2 - Pathologies for artificial stone facades summarizing the primary decay processes

DECAY		POINT OF CRISIS				CAUSES						PATHOLOGIES
A6	Crumbling	PI4	PI5	PI16		C3	C4	C5	C6	C8	C14	P1 P3 P4 P5 P6 P7

P4	early cohesion of particles
P5	high capacity of water absorption
P6	sensitivity to freeze-thaw cycles
P7	early strength to acid etchings

3 CONCLUSIONS

The Second World War, as well as the definitive affirmation of a "modern" architectural and technical-technological culture in which the assumptions that favoured birth and diffusion of artificial stone don't find place anymore, decrees the end of the brief success season of such technologies. They quickly disappear with the men that produced them and with the knowledge mainly derived from their experience. As a consequence, actual lack of a "culture" of artificial stone is the cause of a frequent difficulty of action that leads to wrong maintenance and/or restoration interventions, or even worse, to the removal of such elements. According to what has been said, the research has to be oriented toward the definition of specific operational procedures for maintenance, refurbishment and integration of manufactured articles in the artificial stone.

A preventive phase of knowledge of building is fundamental therefore, referred to chemical-physical characterization of materials and their components, to measurement and survey of environmental parameters, to study of previous refurbishments and use conditions, to recognition and description of macroscopic alterations, to be followed by a phase of diagnostic of decay and individualization of relative causes. Such phase of knowledge, will be the object of further researches, must be structured in order to allow definition of types of intervention and operative guidelines.

Particularly it is necessary to define specific techniques and technological solutions for interventions, referred to both the integration and/or remaking of lacking parts and the maintenance of coverings of façade. For the former, research aims at the individualization of re-proposition modalities of technologies and original materials. For the latter the objective is the definition of typologies of intervention in relation to the required performances, of specific executive methodologies and of fittest materials for conservation of elements.

Energy-Based Damage Measure for Reinforced Concrete Frames

Nilay Celik [1]
Yuri S. Petryna [2]

T 71

ABSTRACT

In the most seismically active zones, such as exist in Turkey, it is often necessary to estimate the damage level of existing buildings that have already experienced one or more earthquakes and may face another in the near future. A reliable and rapid classification of the building environment according to its damage level is a challenging task when assessing and managing risk of structural failure in such areas. Additional difficulties usually arise, for example due to the poor quality of structural components or the lack of documentation. For that purpose, there exist several empirical approaches based on visual inspections and other descriptive assessment procedures. Unfortunately, these do not provide sufficiently reliable results to resolve the requirement for damage appraisal and related risk assessment.

The present work focuses on the dominant structural type in the Istanbul area, namely reinforced concrete frame structures. Starting from the moment-curvature relationship of rectangular cross-sections, the secant bending stiffness of the members is derived with damage related to the concrete cracking and yielding of the reinforcement. This local damage information helps define a global damage index based on the virtual work associated with the damaged stiffness. The proposed damage measure is thoroughly tested by both simulation and experiment on a two-storey structural frame fabricated in a laboratory setting. The results obtained show that it is suitable for the in-situ assessment of reinforced concrete frames. It provides a reliable measure of the overall reduction of the bearing capacity even without finite element analysis. Therefore, it can be used, in combination with straightforward non-destructive techniques, to provide a rapid classification of damaged structures following the occurrence of an earthquake.

1 INTRODUCTION

The durability of structural components and systems generally implies their continued reliability with respect to failure, serviceability and functionality. In earthquake areas, additional requirements must be fulfilled with respect to the seismic safety of structures. In the most seismically active zones, such as Turkey, it is often necessary to estimate the damage level of existing buildings, which have already experienced one or more earthquakes and will certainly face the next one in the near future. A reliable and rapid classification of the building environment according to its damage level or seismic capacity is a challenge for the risk assessment and management in such areas. Additional difficulties usually arise due to a poor quality of structural components and the lack of documentation.

Several damage measures for seismic damage assessment have previously been described and are reasonably well known. A comprehensive overview of these can be found, for example, in [Yao et al. 1986; Kratzig & Meskouris 1998]. Although some of these reflect purely empiric approaches, such as the inter-storey drift, others refer to the use of the cross-section level, such as the ductility index, stiffness index or the energy index, the latter approach defined based on moment-curvature relationships. Thus, they are generally not suitable for the entire structure. Some damage measures are empirical in nature and mechanically inconsistent, such as the combined index derived from relative displacement and relative energy as devised by Park & Ang [1985]. The damage index proposed by Krätzig & Meskouris [1998] accounts for the hysteretic energy dissipation during cyclic loading in beam and frame members. It requires, however, an explicit modelling or recording of response history. Several general damage indices have been proposed in [Krätzig & Petryna 2001; Petryna & Krätzig 2005] basing on the simulated or recovered structural stiffness under damage. In addition, such approaches presume the knowledge of the original, undamaged, i.e. the reference stiffness, which is generally unknown for many already existing structures.

Although the state-of-the-art nowadays offers several suitable approaches, they are nonetheless, not readily applicable to the above mentioned problem that requires a specific damage assessment for use in seismic areas. There exist several alternative empiric approaches based on visual inspections and a rather descriptive assessment procedure accounting for the number of storeys, the existence and the kind of balconies, or similar linguistic information.

Obviously, it is hardly possible to develop a simple, unified and reliable measure for all structural types. Therefore, the present work focuses on the dominant structures in the Istanbul area, namely on reinforced concrete frames that are also typical of most buildings located in the Mediterranean area. Starting from the moment-curvature relationship, the secant stiffness of the member at different critical sections in the damaged state is first derived. In order to use this local information for a global damage measure, each local stiffness is superimposed to a virtual displacement field, this field being typical of local earthquake activity. From a comparison of the virtual work, associated with both the original and damaged stiffness and along the same virtual displacement field, a scalar energy-based damage index is ultimately defined. Based on the nonlinear finite element analysis, useful results in combination with “realistic” displacement fields are obtained, but also with almost arbitrary virtual displacements, which simply look affine to the latter. The damage assessment, proposed in the present work, does not require any calculations with the exception of the moment-curvature relationships for various cross-sections, the corresponding secant stiffness and related virtual displacements. It can therefore be applied with the use of standard computers and office tools, and without any special software for structural analysis.

2 DAMAGE MEASURE

The damage in material may generally be defined as softening of its stiffness that can be easily illustrated using the one-dimensional damage-affected elastic material law:

$$\sigma = E \times \varepsilon = (1 - D) E_0 \times \varepsilon \,. \tag{1}$$

The extent of damage in the material can be properly quantified through a reduction of its current modulus of elasticity (E_x) with respect to an initial value in the non-damaged state (E_0) and the critical value (E_f) at failure:

$$D = \frac{E_0 - E_x}{E_0 - E_f} \,. \tag{2}$$

The obvious advantage of this definition is: a scalar damage variable, D, ranges exactly from 0 (no damage) to 1 (failure).

A similar definition can be applied to structural members by use of proper stiffness values. For example, the reduction of the bending stiffness EI of the beam elements can serve as damage measure defined on the cross-sectional level:

$$D = \frac{(EI)_0 - (EI)_x}{(EI)_0 - (EI)_f} \,. \tag{3}$$

In steel structures, the Young's modulus, E, can decrease due to the plasticity or damage of steel. In reinforced concrete structures, EI can decrease due to yielding of reinforcement as well as cracking of concrete. Both cases are usually taken into account during structural design, and thus are entirely acceptable as structural states with damage.

For the risk assessment in seismic areas, it is however necessary to quantify damage on the structural level. Due to the high degree of uniqueness of civil engineering structures, the development of general damage measures, suitable for diverse structures and damage mechanisms, is still a challenge [Yao et al. 1986]. In the case of structures, a proper way is to associate the current degree of damage to the current structural stiffness or capacity, similar to the material or the cross-sectional measures proposed by Krätzig & Petryna [2001], specifically:

$$D = \frac{\lambda_0 - \lambda_x}{\lambda_0 - \lambda_f} \,. \tag{4}$$

Unfortunately, structural stiffness is a multi-dimensional function, not a scalar. In structural simulations using the finite element method, one deals, for instance, with the global stiffness matrix K, containing thousands of individual stiffness values. The choice of the proper scalar values λ in equation (4), that correlate well with the overall reduction of the structural stiffness, is a challenge.

Hanganu et al. [2002] proposed to deduce damage measure from the relation of the actual free energy, Ψ , of the damaged material and the elastic free energy, Ψ_o , of a fictitious undamaged material as follows:

$$\Psi = (1 - d) \times \Psi_0 \,. \tag{5}$$

By integrating the free energy over the entire structure one can relate its total deformation energy to that of a fictitious structure without damage as follows:

$$W_p = \int_{V_o} \Psi dV = \int_{V_o} (1 - d) \rho_o \Psi_o dV = (1 - D) W_p^o \,, \tag{6}$$

Where from the global damage measure, D, can be successfully derived:

$$D = 1 - \frac{W_p}{W_p^o} = 1 - \frac{\int_{V_o} (1 - d) \rho_o \Psi_o dV}{\int_{V_o} \rho_o \Psi_o dV} \,. \tag{7}$$

Herein, W_p^o, is the fictitious ever-elastic potential energy due to the actual strains and W_p is the actual potential energy. By use of the finite element simulation, this energy-based global damage index can be calculated for the actual displacement field as follows:

$$D = 1 - \frac{W_p}{W_p^0} = 1 - \frac{\sum_e \mathbf{a}^T \int_{V_e} \mathbf{B}^T \boldsymbol{\sigma}\, dV_e}{\sum_e \mathbf{a}^T \int_{V_e} \mathbf{B}^T \boldsymbol{\sigma}_0 dV_e}, \tag{8}$$

where **a** stands for the nodal displacement vector, **B** for the strain shape matrix and V_e for the volume of each finite element e. Further, **σ** denotes the actual stress vector and $\boldsymbol{\sigma}_0$ the stress vector calculated for the undamaged material and the same global displacement **a**. Herein, the total potential energy W_p as well as W_p^0 is accumulated over all finite elements.

In order to apply such an energy-based scalar damage measure to experimental damage assessment, we propose to transform (8) by use of the element stiffness matrices of the damaged ($\boldsymbol{K}_d$) or non-damaged ($\boldsymbol{K}_0$) structure respectively and to use a suitable virtual displacement field $\mathbf{a}_V$ instead of **a**, which originates from the finite element calculation. Finally, the proposed virtual energy-based damage index reads:

$$D_V = 1 - \frac{\sum_e \mathbf{a}_V^{(e)T} \times \mathbf{K}_d^{(e)} \times \mathbf{a}_V^{(e)}}{\sum_e \mathbf{a}_V^{(e)T} \times \mathbf{K}_0^{(e)} \times \mathbf{a}_V^{(e)}}. \tag{9}$$

3 TEST FRAME

The above damage measure has been tested on the nonlinear response and damage evolution of a two-storey reinforced concrete frame (Fig.1). The 2.30-m high and 1.2-m long plane frame consists of columns with a 10 by 15-cm cross-section and storey beams with a 15 by 15-cm cross-section. The bottom beam containing a hole serves to clamp the frame to the test floor. The variation of the reinforcement in the columns and the beams leads to totally 8 cross-sectional types with different stiffness. The basic six cross-sections are presented in Fig. 1; the remaining two cross-sections differ only by the position of the non-symmetric reinforcement. The applied material properties are given in Table1.

Table 1. Material properties of the reinforced concrete frame under consideration.

Concrete		Reinforcing steel	
Young's modulus	E_c = 35400 N/mm²	Young's modulus	E = 200000 N/mm²
Poisson's ratio	ν = 0.15	Poisson's ratio	ν = 0.3
compressive strength	f_c = 53 N/mm²	yielding strength	σ_y = 550 N/mm²
tensile strength	f_{ct} = 3.8 N/mm²	ultimate strength	σ_u = 580 N/mm²
ultimate compressive strain	ε_{c1u} = -0.0035		

The frame is subjected to a single horizontal force at the top corner and experiences a quasi-static load history with several loading-unloading loops until failure. The stresses and strains as well as the damage states during the entire load history are continuously monitored for comparison with computer

simulations. The failure of the frame is accompanied by a rapid growth of displacements at the almost constant force of about F = 12 KN.

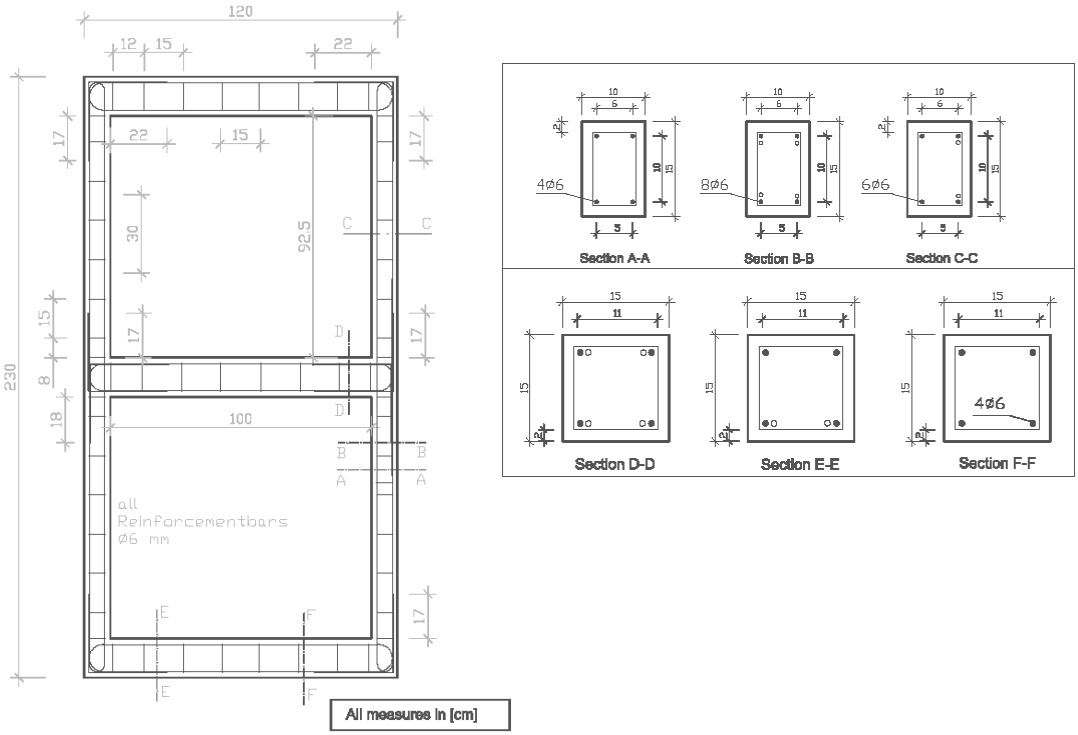

Figure 1. Geometry, cross-sections and reinforcement of the test frame.

4 DAMAGE ASSESSMENT BY SIMULATION AND EXPERIMENT

The frame response under static loading and damage are first simulated with a finite element program (FRAME) developed in-house and within the Matlab environment [2006] using classical beam elements. The nonlinear constitutive equations are implemented in the form of moment-curvature relationships for rectangular cross-sections taking into account cracks in the concrete and yielding of the reinforcing steel. The calculated load-displacement diagram for the horizontal displacement of the top corner (load application point) shows an excellent agreement with the experimental results (Fig.2). The damage state is characterized by progressive cracking of the concrete at multiple locations. The location and depth of the cracks observed in the experiment correlate well with the extent of damage computed by FRAME, as can be seen in Fig. 3 that illustrates the state of the frame at failure.

The FRAME program was then extended to calculate the damage indices according to equation (9). In the present study, damage is associated only with the change in bending stiffness, EI, of each cross-section due to cracks in the concrete and yielding of the reinforcement. The global non-damaged stiffness of the frame, $\boldsymbol{K}_0$, is calculated by use of the original EI_0, whereas the damaged one, $\boldsymbol{K}_d$, originates from the secant stiffness, EI_d, of the current damage state. Both values EI_0 and EI_d can be determined from the moment-curvature diagram for each cross-section of the frame.

Thus, the damage index D can be calculated according to equation (9) at each step of the loading path by taking the damage state, $\boldsymbol{K}_d$, and the displacement state, $\boldsymbol{a}$, from the current finite element solution. Figure 4 shows such an evolution of the damage index D during the monotonic loading of the frame until failure.

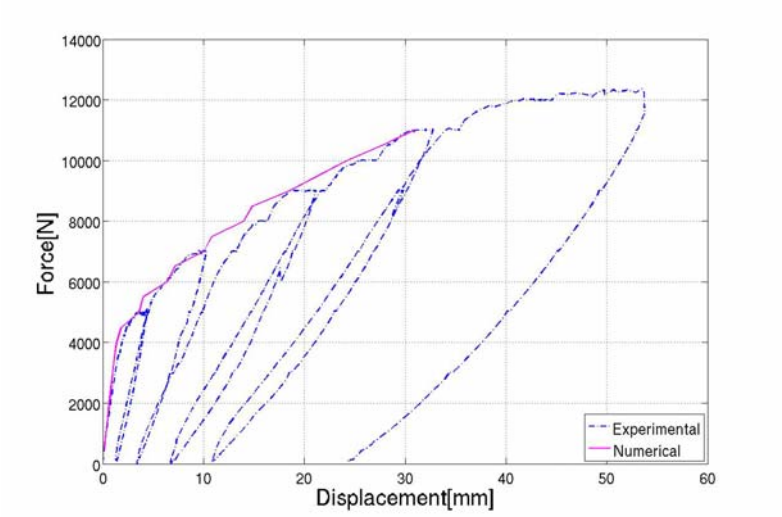

Figure 2. Experimental and numerical load-displacement diagram.

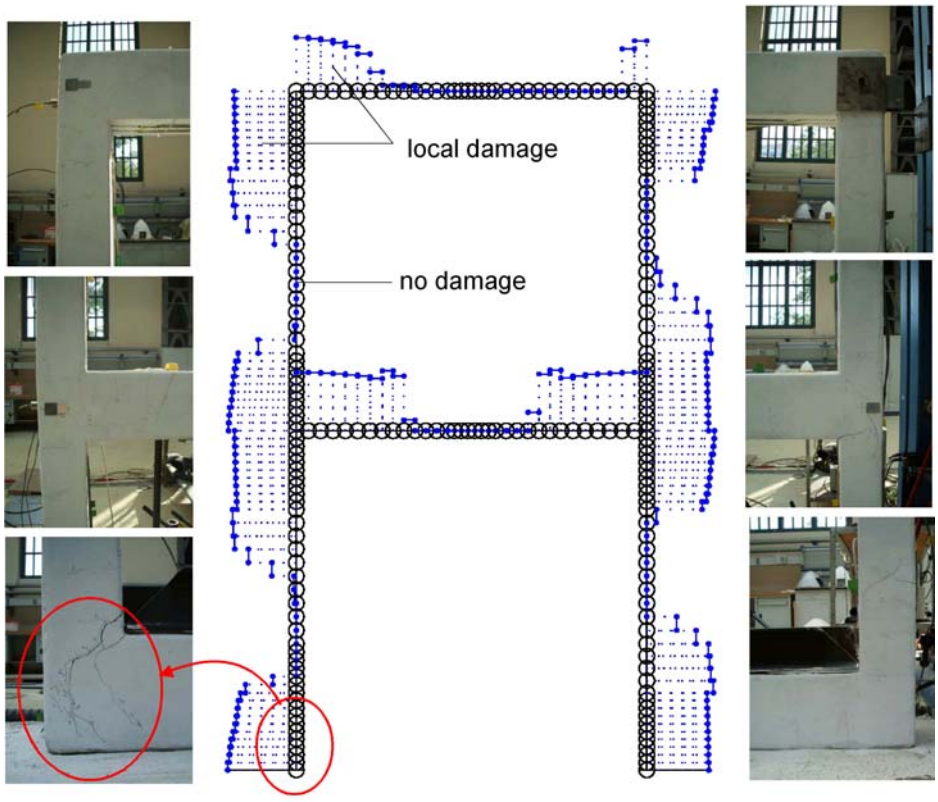

Figure 3. Experimental and numerical damage state at failure.

The first damage increments appear at F = 4 KN due to the first concrete cracks. Then, the damage grows rapidly up to D = 0.8 due to extensive cracking at multiple locations. One can see the corresponding plateau in Fig. 4. After that, the damage growth decelerates significantly resulting in the change of the slope in Fig. 4 above of F = 6 KN. It can be associated with the opening of existing cracks and the yielding of the reinforcement. The damage index D = 0.92 at failure is quite close to the theoretical value of D = 1.0. The difference can be explained by the fact, that the frame loading has been stopped before the real failure occurs in order to study the corresponding damage state. Moreover, the experimental failure load of F = 12 KN could not be reached in the finite element

simulation due to the loss of the convergence. The achieved level of damage must be objectively smaller than that at failure (D = 1).

The damage evolution curve in Fig. 4 was obtained by use of the complete stiffness matrix and all degrees-of-freedom. However, very similar results have also been computed by use of a relatively coarse mesh; in this instance, it is assumed that all really damaged areas are in fact captured.

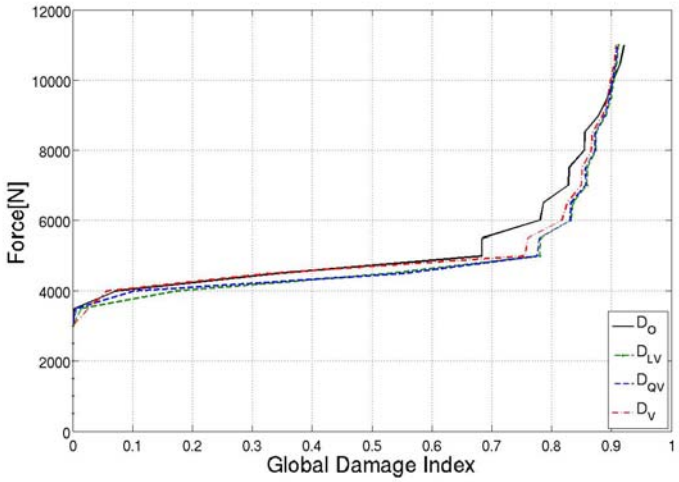

Figure 4. Load-damage diagram of the frame.

4 IN-SITU DAMAGE ESTIMATION FOR SEISMIC RISK

The approach presented above by use of simulation and experiment is less suitable for the classification of structures in earthquake areas. The primary reasons for this include: the lack of time, of material and structural data, as well as of appropriate measurement instruments and computer tools available on-site. In order to apply the proposed damage measure for this purpose, we presume solely the damaged areas Ω_i in concrete frames to be approximately known with respect to their length L_i and depth δ_i , as depicted in Fig. 5. By interpreting these areas as damaged beam elements of length L_i and with a crack depth δ_i we can calculate their original, non-damaged bending stiffness EI_0 as well as the damaged stiffness EI_d using the moment-curvature relationship. If no information on the reinforcement is available, we assume a symmetric one with a certain cross-section area. The boundaries of the damaged areas can be taken as reference nodes. We further apply a virtual displacement field $\mathbf{a}_V$ on these nodes to compute the virtual energy-based damage index D_V according to equation (9). Although the virtual displacement $\mathbf{a}_V$ can, in principle be arbitrarily chosen, it is an advantage if this conforms to the loading type. For instance, we can assume a linear $\mathbf{a}_{LV}$, a quadratic $\mathbf{a}_{QV}$ or a stepwise linear $\mathbf{a}_{SV}$ virtual displacement field for the test frame, as depicted in Fig. 5. The only necessary condition is that all damage areas are accounted for by means of the reference nodes. Thus, finite element analysis is no longer required to estimate the extent of damage of the framed structure.

As can be seen from Fig. 4, the proposed approach provides very good results. Three curves for the evolution of the damage index have been calculated at each step with the actual damaged stiffness and a virtual displacement field: D_{LV} for linear, D_{QV} for quadratic and D_{SV} for stepwise linear displacements. The fourth curve is obtained by use of the direct finite element solution. All curves correlate very well, thus, confirming the applicability of the virtual displacement approach. Finally, we consider a coarse mesh of only selected reference points, which correspond to the boundaries of the damaged areas (Fig.5). The local crack depths and the length of the cracked areas have been estimated from the visual

inspection of the frame after finishing the experimental program described above. These input data should be similar to those of the in-situ inspections of real concrete frames.

Although the values obtained for the damage index ($D_{LV} = 0.75$; $D_{QV} = 0.75$; $D_{SV} = 0.84$) differ from the critical ones at failure that were presented in Fig. 4 for the finite element mesh, they still provide acceptable estimates of the damage state of the frame shortly before collapse.

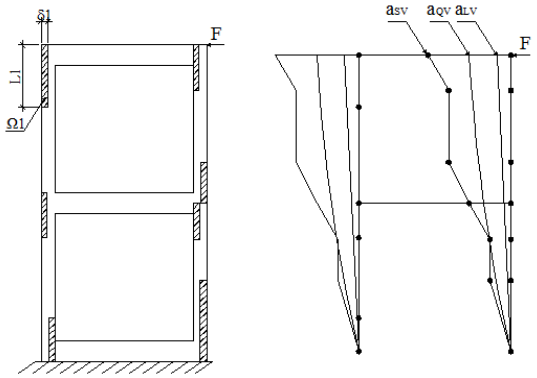

Figure 5. Damage areas Ω_i and applied virtual displacements.

5 CONCLUSION

A virtual energy-based damage measure suitable for in-situ estimation of the overall damage of reinforced concrete frames has been proposed and tested. It provides a reliable and appropriate measure of the residual structural capacity without any finite element analysis. Therefore, it can be applied for the rapid classification of frame structures subjected to earthquake loads.

ABSTRACT

Stratified housing is now becoming a trend of living style among the urban professional community in Malaysia. The main difference as compared to a landed property is the need for residents to set-up a Management Corporation (MC), as a body to regulate and manage all the amenities provided by the developer, as stipulated in the Strata Title Act 1985. To a certain extent, the idea seems to work successfully for about a few years after the housing schemes are granted with the final title. Subsequently, being so long with the facilities provided, coupled with ineffective management, a gap is identified between the residents as stakeholders and the council members of the Management Corporation, which also comprised of members of the same housing scheme. This research looked into the matter, with particular focus on the facility management construct. The satisfaction level formed the primary measurement criteria in identifying and measuring the gap between the residence and the Management Corporation. The findings of this research revealed that there were significant difference in terms of satisfaction between the Management Corporation and the residents, where the Management Corporation reported a higher level of satisfaction compared to the residents in every criterion. The sample selected for this study was non low-cost stratified housing only, thus making the results limited within this particular focus group. Further research is suggested to find ways to minimize the gap identified as well as to develop an effectiveness model as a tool to measure the performance of the management body.

1 INTRODUCTION

Living in stratified property has become the trend in Malaysia today especially among the town dwellers. One of the reason people prefer to stay in a stratified property is the facilities provided within the housing area. The residents have to pay a fee for the facilities provided. The MC is the responsible party to manage all the facilities.

The management of stratified housing in Malaysia can be categorised into three periods namely, before the establishment of Management Corporation (MC), during the initial period and after the developer had handed over the management responsibilities to the residents [DBKL 1999; HBA 2003; Sapian 2003]. The stratified housing is governed by the Strata Title Act 1985 (herein after is called STA, unless otherwise specified). The concept of STA in Malaysia is inherited from the New South Wales Conveyancing (Strata Title) Act 1961 [Alinah 2004].

This paper focused on stratified housing managed by the residents through the MC. The former two periods are not included in this study because the management is temporary in nature and the residents have no say at all in managing their own property. Theoretically, in managing stratified property, both parties, i.e. MC and the residents have to achieve a consensus in all management-related matters. This is to ensure an effective management for stratified housing schemes. Unfortunately, this study found that there was some pattern of management gap between MC and residents, who are the beneficiary of the facility management services. In discussing this matter, the paper starts briefly on several key issues that led to a management gap. It is then followed by the methodology in identifying the management gap and the prominent findings from this study.

2 ISSUES REGARDING FACILITY MANAGEMENT IN STRATIFIED HOUSING

Stratified housing is a unique property and it differs from landed property, such as bungalows and terrace houses. Its uniqueness presents itself during the management era after the properties have been occupied, where facilities management became an issue [Linariza and Ashok 2003]. To handle the issues pertaining to the management and maintenance activities, STA was implemented in 1985, to accommodate the insufficiency of the National Land Code that was ineffective in handling the issues that arose in stratified housing schemes [Tiun 2006]. According to STA, the MC is accountable for all the management and maintenance aspects of the properties and common facilities in the building [Teo 1993; Jamila 1994]. Unfortunately most of the housing schemes found were not effectively managed. Residents complained through the mass media and the issues were always about incompetent facility management i.e. dysfunctional lifts, rubbish not collected according to schedule, vandalism, misuse of sinking funds; as well as disputes among resident. In short, all the issues raised were centred around the 3 aspects in providing effective facility managements, namely financial, maintenance and people, i.e., the residents themselves.

On the management side, the most challenging issues faced by them in managing a stratified housing scheme was collecting monthly maintenance charge and to run facility management activities [Liias 1998; Jamila 1994; Malaysia Government 1999; Sapian 2003; Tiun 2006; Eddy 2004a]. Maintenance charge is a fee imposed on all the residents to maintain the facilities [Malaysia Government 2003d]. For stratified property, the amount charged is based on the share unit for every parcel [Malaysia Government 2003d]. Unfortunately, there are some residents who believe that the amount charged is higher than what they expected and refused to pay.

Illogical excuses were created, for example, they claimed that they did not fully use the facilities provided [Jamila 1994] and the charge was not reasonable as compared to the service quality [Malaysia Government 1999; Tiun 2006]. According to Teo [1993], although the MC can prosecute through a court of law in collecting the arrears as stipulated in Sect. 52(2), Sect 53A, Sect 53(2) and Sect 55A of the STA, it is rarely enforced due to its impracticality [Tiun 2006] and it might affect the overall housing complex occupants' pride and image [Sapian 2003]. When most occupants neglect to pay the charge, consequently, the fund was insufficient. As a result, most of the facility management activities cannot be carried out on time and thus affect the facility management effectiveness for the building as a whole [Malaysia Government 1999; Tiun 2006].

These issues led to the management gap in managing facilities of stratified housing. The management gap occurred when the expected services by the residents cannot be delivered by the MC. The residents were paying on a monthly basis and expected the facility management to be effective. Under STA, there is a legal provision for the MC to engage the services of a Management Agent as the party responsible for running the facility management activities. In practice, most MC functions in that way because they do not have the expertise to run and maintain the housing complex. If the MC fails to function well as stipulated in STA, the residents of the particular housing complex have the right to summon the said MC. Therefore in order to avoid this case, the MC normally engages a Management Agent in order to transfer their liability towards the housing complex.

Even so, the management gap continued to exist as referred to the on-going issues reported in mass media [Tiun 2006]. Residents continued to complain about the low service quality of facility management provided by the Management Agent, as well as the responsibility of MC in ensuring effective facility management. In discussing this matter, this paper looked into the Malaysian case study to identify the management gap in stratified housing. The framework of the study that was used as a measurement basis is presented below.

3 THE FRAMEWORK OF EFFECTIVE FACILITY MANAGEMENT IN IDENTIFYING MANAGEMENT GAP

The framework as depicted in Fig. 1 shows the linkage of 12 variables in measuring the management gap via effective facility management for stratified housing. It is categorized under 3 constructs namely financial, maintenance and resident; which is then supported by its own dimensions. In between construct and dimension, there is respondents' category namely Members of MC, Management Agent and Resident.

The financial construct has 3 dimensions namely financial resources, financial allocation and financial expenses. In running the day-to-day activity, the MC needed resources, otherwise little can be done. In medium and high cost stratified housing, the problem of monthly collection was not threatening since the collection of maintenance charges was just fair enough to run the activity. On top of this, the financial aspect needed to be planned via allocation and monitoring of its expenses. As an example, allocation for cosmetic recovery should be the last agenda in housing maintenance activity [Amarilla *et al.*, 2002]. An effective facility management is not merely based on the collection of fund itself, the management of the limited resources by the MC need to first be looked into [Hui, 2005].

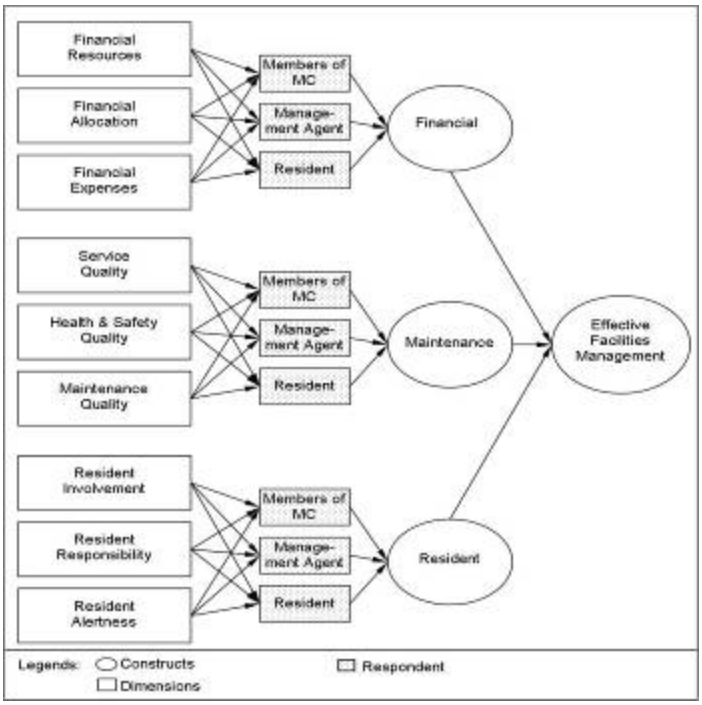

Figure 1. The Research Framework

The second construct, maintenance, also had 3 dimensions namely service quality, health and safety quality, and maintenance quality. The aspect of building maintenance was one of the crucial tasks in facility management [Thompson 1994]. It also played the main role in providing sustainable housing. Theoretically maintenance can be seen from a 'hard' and 'soft' perspective. The 'hard' perspective referred to the maintenance output or product, which the resident can see and feel the impact of maintenance work. As an example, landscaping provided good scenery and a tidy environment, in which the resident can view and enjoy. The 'soft' perspective looked into the service quality demonstrated on the process of carrying out the particular work and more to human respond i.e. counter service. For the safety and health, it was also put under the maintenance consideration to safeguard the resident's health interest, so that they felt secure and comfortable living within their compounds.

The third looked at the resident construct, which also had 3 dimensions, namely resident involvement, resident responsibility and resident alertness. In providing effective facility management, the end-user had to respond accordingly to the management. The participation of residents was crucial since all the facility management activities were designed for and dedicated to them. In addition, the residents were paying the maintenance charges. The involvement of residents was really needed during the Annual General Meeting to set-up the MC, to determine the amount of monthly fee and to agree upon a few things as stipulated in the STA. Other than involvement, the residents had to understand their responsibilities as those living in a community i.e. having neighborhood spirit and avoiding selfishness; which were largely dependent on the residents' background and status (owner or tenant). The residents' alertness were towards the on-going changes i.e. housing rules and community activities within their stratified scheme, environmental condition as well as maintenance service standard (especially routine maintenance work).

4 RESEARCH METHODOLOGY

The research strategy adopted was quantitative in nature and data collection technique was through a personally assisted questionnaire. The questionnaire was formulated based on the described facility management variables above which consisted of financial, maintenance and resident constructs. The respondents had to respond accordingly to a Likert scale of 1 to 5, which expressed the respondents' satisfaction level. The range of the scale were 1=not satisfied, 2= less satisfied, 3= neutral (neither satisfied nor dissatisfied), 4= quite satisfied and 5= very satisfied. The software for data analysis was Statistical Package for Social Sciences (SPSS) version 12.

Based on the statistics provided by the Land Office, there were only 495 non low-cost housing complexes which fulfilled the samples' main criterion, namely the non low-cost stratified housing that had conducted their First Annual General Meeting. Out of 495, this research had drawn approximately 30% or 150 housing schemes as its sample, in order to get a 96% confidence level (sampling calculation via www.custominsight.com). The selection of sample was done using the SPSS software. Each non low-cost housing complex was represented by 5 respondents namely 3 members of MC, 1 Management Agent and 1 resident (who had experienced being the MC's member). Therefore, the total number of respondents interviewed was 750 people.

In identifying the management gap, this study looked into the differences in satisfaction level via the analysis of MANOVA and ANOVA. Before proceeding with the MANOVA, the statistical pre-test had to be conducted via Levene and Box's M test to determine the equality of variance assumption and the variance-covariance matrix. In order to proceed, both pre-test should get the result of non-significance i.e. p *value* > 0.05. It was only then that the MANOVA and/or ANOVA can be conducted. To further study the differences between respondent categories, this study proceeded with the Bonferonni test. The gap existed when there was a significant difference in levels of satisfaction between respondents.

5 ANALYSIS OF DATA AND DISCUSSION OF FINDINGS

Before proceeding with the final field work survey, a pilot study was carried out involving 150 respondents (30 housing schemes) which was selected randomly from the total respondents to justify the reliability of the measurement scale of each variable. The result of the reliability test was that all the variables achieved internal consistency and was considered to have a high reliability with the value of Cronbach's Alpha above 0.8 for each variable. To determine whether a parametric or non-parametric test was to be used, the normality test using Kolmogorov-Smirnov (because the respondents were more than 100) was carried out. In short, the p-value was less than 0.05, but the skewness value was between -1 and 1. Therefore the data could be categorized as normal and the parametric test was used for the statistical analysis.

The unit analysis was the satisfaction level among the 3 categories of respondents, namely members of MC, Management Agent and resident. According to the research framework (as per Fig. 1), this study only concentrated on the analysis of satisfaction level on the central concept (effective facilities management) and among the 3 constructs only. This showed the pattern of management gap in providing effective facility management. The result of the study is presented below.

Table 1. Levene Test For Constructs

Constructs	F statistic	P value
Financial	0.224	0.799
Maintenance	0.039	0.961
Residents	1.095	0.335

Table 2. Box's M Test For Constructs

Value	F statistic	P value
4.574	0.378	0.972

Table 1 and 2 shows that there were no significant difference in both Levene and Box's M test. Therefore the MANOVA and ANOVA were valid to be adopted in measuring relationship between the constructs and respondents category.

Table 3. Result of MANOVA & ANOVA For Constructs

Multivariat Test					**F statistic**	**P value**
Wilks' Lambda					7.717 (0.941)	0.000*
Constructs	**Respondent**	**N**	**Mean Score**	**Standard deviation**	**F statistic**	**P value**
Financial	MC	450	3.2737	1.0355	3.377	0.035*
	Mgt. Agent	150	3.1408	1.0060		
	Resident	150	3.0353	0.9916		
Maintenance	MC	450	3.2747	0.7139	9.163	0.000*
	Mgt. Agent	150	3.4227	0.6993		
	Resident	150	3.0754	0.6939		
Residents	MC	450	3.1082	0.7809	3.750	0.024*
	Mgt. Agent	150	3.0727	0.7325		
	Resident	150	2.9107	0.7579		

*Significant at 0.05

Based on the result in Table 3, the MANOVA found that collectively, there was a significant difference among the constructs and the respondents' category. The ANOVA also showed that there was significant difference in satisfaction level of respondents for every single construct. Looking at the mean score, the resident reported the lowest satisfaction level for all constructs as compared to MC and Management Agent.

Table 4. Result of Bonferonni Test For Constructs

Constructs	**Respondent**	**Respondent**	**Difference of mean score**	**P value**
Financial	MC	Mgt. Agent	0.1329	0.503
	MC	Resident	0.2384	0.040*
	Mgt. Agent	Resident	0.1055	1.000
Maintenance	MC	Mgt. Agent	-0.1480	0.080
	MC	Resident	0.1992	0.009*
	Mgt. Agent	Resident	0.3472	0.000*
Residents	MC	Mgt. Agent	0.0355	1.000
	MC	Resident	0.1975	0.019*
	Mgt. Agent	Resident	0.1620	0.203

* Difference of mean score was significant at 0.05

Table 4 shows further differences in each respondent's category. It also depicts a pattern of significant difference, especially between MC and resident for each construct. Other than that, there was a significant difference between Management Agent and resident for maintenance construct, whereby resident was less satisfied in the maintenance construct as compared with Management Agent. After looking in detail into the 3 constructs, it seemed that the resident was always less satisfied than the other respondents. In other words, it showed the existence of a management gap in managing facility management of stratified housing. To achieve confirmation in a bigger perspective, this study discussed the central concept of effectiveness of facility management as follows:

Table 5. Levene Test For Concept

Concept	F statistic	P value
Effectiveness	0.916	0.400

Table 6. Result of ANOVA For Concept

Concept	Respondent	N	Mean score	Standard deviation	F statistic	P value
Effectiveness	MC	450	3.4015	1.0774	3.851	0.022*
	Mgt. Agent	150	3.2222	1.0105		
	Resident	150	3.1489	1.0981		

*Significant at 0.05

The pre-test as in Table 5 (where P value was not significant) showed that it was valid to conduct an ANOVA to measure the relationship of respondent's category towards the effectiveness of facility management. Based on Table 6, there was a significant difference in satisfaction level among respondents for effectiveness concept. Also, the satisfaction level of residents was lower than the others.

Table 7. Result of Bonferonni Test For Concept

Concept	Respondent	Respondent	Difference of mean score	P value
Effectiveness	MC	Mgt. Agent	0.1792	0.227
	MC	Resident	0.2525	0.037*
	Mgt. Agent	Resident	0.0733	1.000

* Difference of mean score was significant at 0.05

Table 7 shows the only significant difference in satisfaction level towards effectiveness of facility management was between the MC and residents, where the residents were found to be less satisfied. This finding further confirmed the existence of management gap in facility management of stratified housing.

From the analysis above, the main reason behind all the issues that arose in facility management of stratified housing in Malaysia is now clear. The management gap which existed, in turn formed a barrier in providing effective facility management. The residents were always found to be less satisfied than the MC. The management gap is termed 'in-house' since in almost all cases; there was no significant difference in all constructs and effectiveness concept between Management Agent and the MC, as well as the resident. Based on the findings, the management gap was still in its infancy and considered not serious since the difference in mean score was not more than 1.

Therefore there is room for improvement for both parties i.e. MC and resident to rectify their relationship via minimizing the gap to provide better scenario of effective facility management.

6 CONCLUSION

This paper discussed the identification of management gap in stratified housing in Malaysia. Management gap exist when there is significant difference in satisfaction level among respondents towards the concept of effectiveness and the constructs behind it i.e. financial, maintenance and resident. The issues of facility management in stratified housing is reported quite extensively through the mass media, thus giving some clue about the gap in stratified housing management. This study has confirmed the existence of management gap, which is the answer to why the issues arose. It also had been a barrier for both parties namely the Management Corporation and resident to cooperate in creating effective facility management. In relation to the literary discussion, the identified management gap also contributed to the 'chicken and egg' scenario. What is heartening is that the management gap is still not in the serious stage, thus giving an opportunity for parties involved to minimize the gap. It is feared that the condition might worsen in the near future. It is thus necessary to identify the exact needs and expectations of both parties towards each other. Since there was no significant difference in the perspective of Management Agent (except for maintenance construct), it is suggested that they play the role of mediators in bridging the management gap.

ACKNOWLEDGEMENT

The authors would like to acknowledge the parties that helped in preparing the paper, in one way or another, especially the Public Service Department (JPA) Malaysia, Universiti Kebangsaan Malaysia and University of Malaya. Last but not least, to all family members who had given their endless support and encouragement.

T 72

ABSTRACT

Algeria launched in 2004 a vast construction program which envisages the realisation of more than 450 infrastructure assets, of which 80% are bridges. In addition to this program, there are more than 8000 existing bridges that require maintenance and monitoring in both the short and medium terms to prevent structural deterioration due to environmental effects and traffic loads. For this reason, the Ministry of Public Works launched few years ago a rehabilitation program to monitor, repair and strengthen more than 80 bridge structures. This paper presents a research and development program established to generate information related to various deterioration phenomena using new techniques. Such information will be used to improve the planning of repair and rehabilitation programs for existing infrastructure and also, for the design of future projects. Information is provided on a preliminary study of a Road Bridge located on the west coast of Algeria, a concrete structure first built 80 years ago. An evaluation has been conducted based on ultrasonic pulse velocity testing; as well as ambient vibration tests before and after rehabilitation.

1 INTRODUCTION

Algeria, by its geographical situation, is exposed to natural disasters like earthquakes and floods, which affect various structures. Statistical studies showed that there are a lot of reinforced concrete structures which need repair or strengthening [MTP 2005]. These structures present cracks and spalling due to concrete degradation, reinforcement corrosion or insufficient steel reinforcement to cater for high modern load traffic. These disorders are also induced by errors in the design phase, materials properties or lack of good quality control during the construction phase. Lack of preventive periodic maintenance also accelerates deterioration mechanism. Before strengthening or repairing these structures, a detailed investigation campaign should be conducted to decide on immediate preventive action to limit the propagation of degradations. This will be followed by a detailed investigation using suitable monitoring techniques and conducting non destructive and laboratory testing. Reinforcement and repair works are usually conducted to reinstate the original rigidity and strength to the deteriorated elements and if possible improving their performances and their durability.

The Ministry of public works in Algeria has undertaken a monitoring program of bridges exceeding fifty years of age. The existing structures are composed of more than 40% of structures over 50 years of age and hence need rehabilitation [MTP 2006]. The techniques of non destructive tests can be local, that means those that give reduced information and only in the controlled zone, as the ultrasonic tests, and those that are general and give global answers of the structure tested as the dynamic tests to ambient vibrations, forced vibrations or to optic fibres. These methods along with the infrared thermography and radar have been used successfully to detect the location and the size of deterioration, delamination, voids and other structural damages.

The aim of this paper is to present a case study of an 80 years old reinforced concrete bridge monitored before and after strengthening using non destructive tests and ambient vibration method.

2 ALGERIAN BRIDGES INHERITANCE

The inventory established by the Algerian Ministry of Public work in 2006, showed the existence of about 8000 bridges of which 4808 are road bridges and 4000 railway bridges, with 80% highways and national roads bridges, and 20% small rural road bridges (Fig. 1). It is noted that 1032 bridges are in either bad or medium conditions.

Moreover, the analysis of the level of the rate of deterioration of the various bridges components shows that over 2308 bridges need to be rehabilitated. These bridges are mainly those over 50 years of age. They are masonry, reinforced concrete, prestressed concrete, steel or composite structures. The rehabilitation program aimed to optimize the use of materials, products and repair techniques. It aims also to analyse the information generated from the diagnosis, repair and rehabilitation of these structures to learn some lessons for the design of new projects. In 2003, the Ministry launched an international tender for the diagnosis and rehabilitation of 25 bridges. In 2006, two other tenders were launched for the diagnosis and evaluation of 50 other damaged bridges all over the Algerian territory [MTP, DEER 2006].

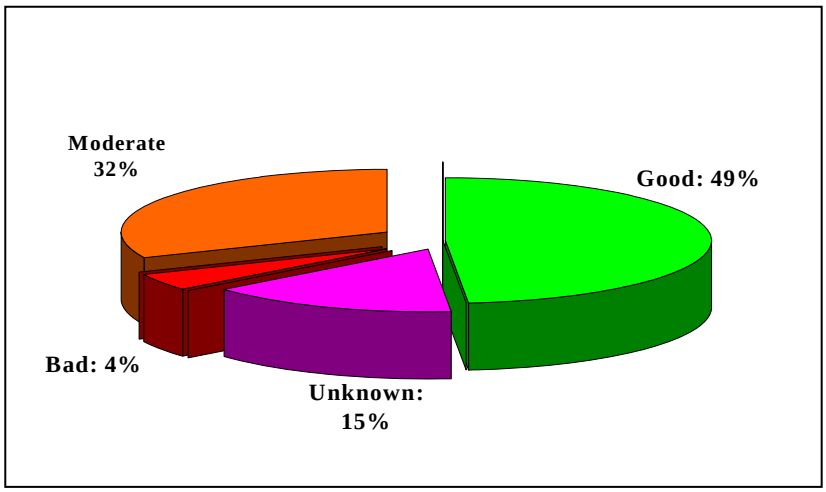

Figure 1. State of road bridges in Algeria

3. DETERIORATION DIAGNOSIS

Concrete bridges are required to maintain their serviceability over long periods of time, hopefully 100 years or more [Mallett, 1994]. The life of any bridge depends on the preservation of the physical integrity of both the superstructure and the substructure. Before deciding on a repair, it is necessary to check the cause of the damage and the degradation mechanisms. The main objective of the proposed program is to develop a rational integrated procedure for condition assessment of concrete bridges components involving existing test methods. Radar and Impact echo methods [EDG 2007] to detect steel corrosion of steel bars in reinforced concrete and prestressed cables in prestresed concrete structures or to evaluate the mechanical characteristics of concrete (propagation velocity, possible cracking, honeycombing, voids, etc) are widely used. Other testing methods based on global structural behaviour such as ambient or forced vibrations tests and optical fibres tests have been recently introduced.

The introduction on the Algerian market of new rehabilitation and repair techniques and materials requires some care and a good quality control as for their practical use and suitability for the local hot and aggressive environment. Indeed, quality of workmanship and quality control of materials is always a major concern of the Ministry of public works in construction of infrastructures and rehabilitation works.

For more than fifteen years [SAPTA 2004], the public work sector has undertaken repair and strengthening work on some strategic infrastructures, such as Sidi Rached Constantine cable stay Bridge, El Harrach white bridge in Algiers, Laghouat Road Bridge and Tipaza Oumazer River Bridge. The choice of repair materials and techniques is guided mainly by the nature and magnitude of the damage, the availability of the materials and local expertise. In Algeria, carbon fibres composite materials are the most used rehabilitation technique in bridges due to their ease and speed of application where repair work could be done without closing the bridge to traffic. Other advantages include their corrosion resistance, high tensile strength and low weight [Ferrar 1999; Djellal 1998 and Abdessemed 2003].

4. A CASE STUDY: OUMAZER BRIDGE

Oumazer Road Bridge was constructed in 1920 and is located few meters from the Mediterranean Sea coast in a high seismic activity region. It is a reinforced concrete bridge with three spans composed of four reinforced concrete beams with variable inertia, and two piles each one composed of four

Figure 2. Oumazer river Road Bridge

Some degradations were visible on its structural elements. Concrete delamination, steel corrosion and cracks were observed on its columns and girders (Fig. 4). This is due probably to the high aggressive marine environment. The diagnosis reveals also diagonal cracks with 45° on main beams which is primarily due to the increase in shear stresses due to traffic increase (SAPTA, 2004). The repair consisted mainly of reinforced concrete jacketing of piles, epoxydic resin injection of the cracks, ready mixed repair mortar application for spalled concrete and the strengthening of beams by carbon fibre composite sheets.

Figure 3. State of degradation of the bridge piles

5. REPAIR EVALUATION

5.1 Cracks Repair and Ultrasonic Tests

Epoxy resins were used to fill and repair the cracks of the damaged beams. In order to assess concrete quality of the bridge and to check the filling operation of the cracks, ultrasonic tests were performed before and after cracks repair (Fig. 4).

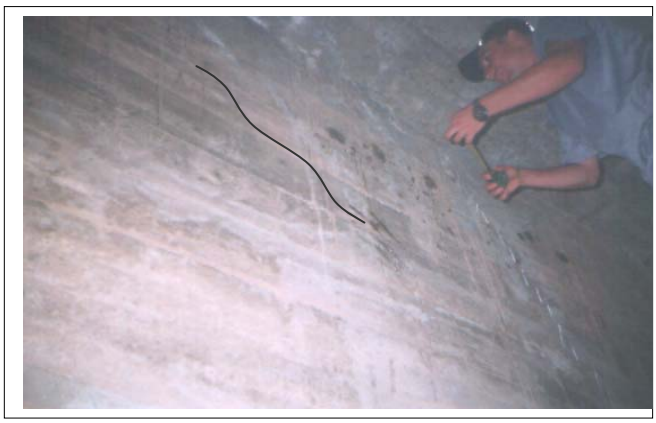

Figure 4. *Ultrasonic assessment of cracks* repair

The principle consists in measuring pulse velocity in concrete over a crack. Velocity increases with modulus of elasticity and therefore with concrete strength and density. In case of unfilled cracks or voids, velocity is decreased and hence the efficiency of the repair could be evaluated. Table 1 summarizes pulse velocities values measured on cracked beams: two tests were performed, on the top and the bottom of the crack.

Table 1. Ultrasonic velocity on a cracked beam

Distance (m)	0.25	0.45	0.70	0.92
Speed before resin injection (m/s)	2523	2335	940	1034
Speed after resin injection (m/s)	2604	2444	2818	30213

As shown in table 1, an increase in velocity is observed after the injection of the resin. Crack injection by resin improves concrete homogeneity up to 70 % and contributes to the enhancement of its durability. However, it should be noted that measured velocities remain low because of the low concrete quality. Consequently, it was necessary to reinforce the bridge structural elements (beams and columns) by carbon fibre composite materials.

5.2 Applied Repair Materials

To restore to the deteriorated elements their initial performances, it is important to choose adequate repair materials for the structural elements to support new high traffic loads. In fact, strengthening of the bridge consisted of piles jacketing, application of an unidirectional wrap fabric for beams sides and a laminate carbon fibres on beams lower faces. Table 2 summarizes the used materials properties.

Table 2. Repair Materials properties

Repair Materials	Modulus E (GPa)	Density	f_t (MPa)	f_c (MPa)	Elongation (%)	Thickness (mm)
Resin	12.8	1.8	30	55	-	-
Wrap fabric	230	-	3500	-	1.5	0.13
Laminate	165	1.5	2800	-	1.7	1.2

5 .3 Non Destructive Tests on the Bridge

Ambient vibrations tests were conducted on the bridge before and after repair and strengthening. The test is considered to carry out recordings of basic noise using a CityShark II-6 recording station, and four Lennartz seismometers. The CityShark station can simultaneously record six sensors signals. For this study, only four sensors were used (Fig. 5). These sensors are equipped with three components: a vertical component, and two perpendicular horizontal components between them. Recording duration is 15 minutes. Measurements of the natural frequencies were taken on the bridge before and after application of carbon fibres composite sheets. The main aim of this test is to determine the most dominating modes of vibration and see the influence of the composites on the bridge behaviour. The seismometers positions (Fig. 6) were selected based on numerical modelling using SAP2000 finite element software. Seismometers C1 and C2 are placed on the two pavements and at the transverse axis of the bridge, and C3 and C4 are placed six meters away from C1 and C2. After achieving the measurements, the seismometers are moved along the bridge until covering the total length. Two other measurements were taken on the two piles. The obtained measurements are illustrated in tables 3 to 5.

Tables 3 to 5 synthesize the results obtained for each phase of measurements of the frequencies of vibration of the bridge. The reference case is the test done before the application of composite materials on the main beams of the bridge. Measurements were made according to three directions' of the bridge, namely the vertical direction (table 3), the transversal direction (table 4), and on the bottom of the piles (table 5). The obtained values show a little effect of composite materials on the ambient frequencies of vibration corresponding to 0.02 Hz accounting for only 0.05% for the vertical natural mode, 0% for the horizontal mode, and 1.6% for the piles.

Figure 5. City Shark station and Lennartz seismometer

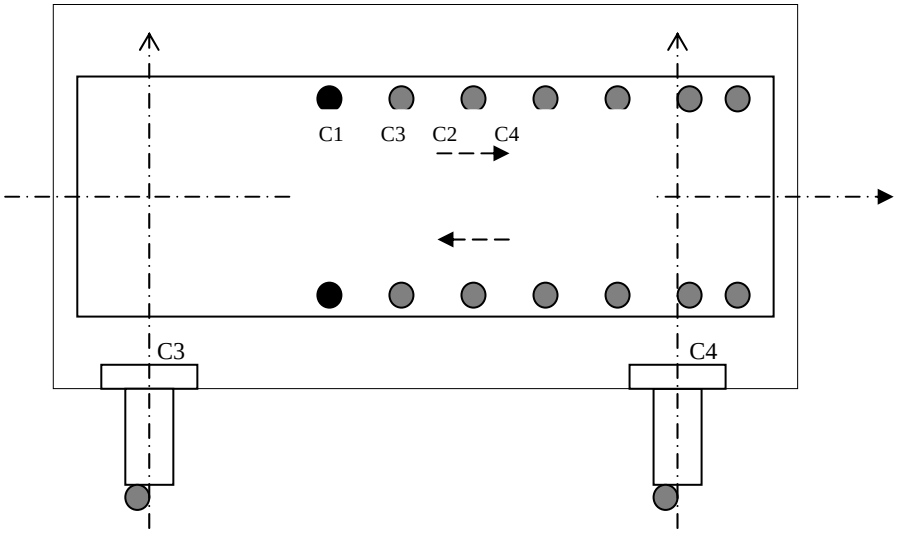

Figure 6. Seismometers position on the bridge

Table 3. Frequency values before and after repair of beams (Vertical peaks)

	Frequency (Hz)	Frequency (Hz)	Frequency (Hz)	Frequency(Hz)
Measurements	C 1	C2	C 3	C 4
Before repair	5 .01	4.60	4.90	4.58
After repair	5.00	4.58	4.92	4.56

Table 4. Frequency values before and after repair of beams (Transversal peaks)

Measurements	Frequency (Hz)	Frequency (Hz)	Frequency (Hz)	Frequency(Hz)
	C 1	C2	C 3	C 4
Before repair	3.97 – 5.01	3.97 – 5.01	3.97 – 5.01	3.96 – 5.01
After repair	3.97 – 5.01	3.97 – 5.01	4.00 – 5.00	4.01 – 5.01

Table 5. Frequency values on piles

Position	f_0 (Hz) transversal	f_0 (Hz) longitudinal	f_0 (Hz) vertical
Left pile	4.50	3.91	10.5
Right pile	4.46	3.85	10.5

One can note the following dominating frequencies modes:

- Natural frequency of the transversal mode of vibration of the slab is 4.51 Hz ;
- Natural frequency of the vertical mode of vibration of the slab is 4.90Hz ;
- Natural frequency of the longitudinal mode of vibration of the piles is 3.88 Hz ;
- Natural frequency of the transversal mode of vibration of the piles 4.48 Hz
- Natural frequency of the vertical mode of vibration of the pile 10.5 Hz.

These tests have shown that ambient vibration test, comparatively with forced vibration or dynamic test by vehicle or traffic can not be very significant for the determination of dynamic evaluation for bridges of small or average length. The mass variation due to the composite addition is low comparing to its effect on the rigidity K of the structure which differs before and after the application of the composite. The composite materials addition affect the vibrations amplitude of the structure, while the natural frequency is not affected (absorption of the vibrations by the composites) [CSTB, 2001 and Freyssinet International, 2004].Thus, it is recommended to carry out other dynamic tests on other existing bridges to help in the establishment a consistent database to evaluate the current state of the Algerian infrastructure.

6. CONCLUSION

A maintenance program has been established by the Algerian Ministry of public works for monitoring, repair and strengthening of existing bridge. In fact, repair and rehabilitation of existing structures for durability makes it possible to enhance the remaining service life and the actual field performances. Development of a rational integrated procedure for condition assessment of concrete bridge components, involving existing and newly developed diagnostic tests contribute to detection and location of structural damages. In our study, ultrasonic tests enabled us to ensure successful cracks injection in a reinforced concrete beam bridge, while ambient vibrations test allowed us to evaluate the performance of strengthening by fibre reinforced composite sheets.

Mikael Kedbäck [4]

T 72

ABSTRACT

Construction projects include large amounts of information that has to be communicated to a number of actors, such as authorities, companies, clients and end users. Information exchange is complex, involving various players on different levels and phases of the construction process. For private clients, who generally have little experience and knowledge of this process, the on-going "Bygga Villa"-project has developed a web-portal, which offers them relevant information about the process and a number of services to facilitate realisation of their projects. One of the services provides a tool for supporting long-term strategy planning. The tool is based on the Life cycle Management System (LMS) that is a predictive and generic life cycle-based management system, aimed to support decision-making and planning of optimal design and maintenance of any construction works. The LMS-Bygga Villa tool estimates service life and maintenance intervals of different building parts and systems based on environmental-dependent degradation models. Simulated scenarios can give optimised solutions by applying life cycle cost analysis. This paper presents two case studies within LMS-Bygga Villa. The first case focuses on service life performance analysis of exterior parts of buildings. The second focuses on service life performance analysis of energy systems; here specifically a borehole assisted heat pump system used for heating a Swedish single-family residence.

1 INTRODUCTION

A construction project includes large amounts of information that has to be communicated to a number of parties, such as authorities, municipalities, companies, clients and end users. The information exchange is complex, involving various players on different levels and phases of the construction process. Private clients, who generally have little or no experience and knowledge of construction projects, often see this process as complicated and time-consuming. Authorities, municipalities, county councils and companies offer a number of electronic services (e-services) that are intended to support the private client in the construction process. However, there is no common "entrance" to these services. The Swedish Administrative Development Agency (VERVA) has been commissioned by the Swedish Government to promote the development of electronic public administration and promote the development of services that will improve the access to public information [Finance Ministry 2007]. As a part of this mission, VERVA has published a handbook with guidance on development of websites and e-services in the public sector [VERVA 2006]. On basis of this guidance, the Swedish Governmental Agency for Innovation Systems (VINNOVA), has granted 6.5 million SEK to the "Bygga Villa"-project in order to develop a website where a number of e-services, supporting private clients in the construction process, are gathered [Ottosson 2005]. This paper will present an e-service that provides a tool that support long-term strategy planing and decision-making of design and maintenance of buildings and heating systems. The aim of the service is to give the private client an aid to and understanding of the long-term performance and future need of maintenance of buildings.

2 LIFE CYCLE MANAGEMENT SYSTEM

Promoted by an increased European focus on research and development on sustainable construction, several EU-projects [Haagenrud et al 1999, Haagenrud 2001, Sarja 2004] have developed methods, systems and tools for predictive maintenance management in order to meet the demand on sustainability during the whole service life of the construction works. A result of the projects is a predictive and generic Life cycle Management System (LMS), which aims at supporting all types of decision making and planning of optimal design, maintenance, repair and refurbishment (MR&R) activities of any construction works and systems therein. Due to its predictability function, it is possible to adopt short-term as well as long-term planning in which decisions may be based on economical, environmental, safety, cultural and social values etc. The LMS is a system by which the complete system or parts thereof, works in co-operation or as a complement to existing business support systems. The system is module-based, where each module represents a sub-process within the maintenance management process. Figure 1 shows the structure of LMS (6 modules) and its connection to other business support systems. The first module, i.e. the *Inventory Registration Module*, contains systematic registration, classification and description of technical and administrative data of the objects/systems. The *Condition Survey Module* includes systematic recording of condition data. This includes guidelines and protocols for condition assessment and survey in order to obtain consistent and reliable inspection/observation results on the items and their environment. The "heart" of the system is the *Service Life Performance Analysis* (SLPA) module. This module contains applicable degradation models and simulates the loss of performance over time of a material, component item or a system. The *Maintenance Analysis Module* includes systematic analysis of different MR&R alternatives by utilising the predictive functions of the SLPA module in order to evaluate the efficiency of the MR&R alternatives. The *Maintenance Optimisation Module* contains models for optimisation of those MR&R actions suggested in the Maintenance Analysis Module. It takes into account a number of aspects such as Life Cycle Cost (LCC) and Life Cycle Ecology (LCE). The final module within the LMS is the *Maintenance-Planning Module.* This module serves to establish optimised long-term plans of MR&R actions.

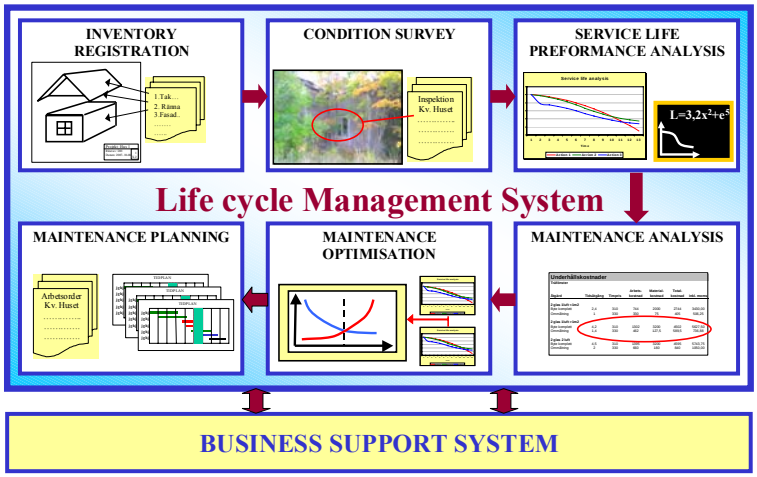

Figure 1. Structure of the module based LMS

3 THE LMS-BYGGA VILLA TOOL

User friendliness, simplicity and consistency have been keywords in the development of the LMS-Bygga Villa tool. The tool is not intended to be an advanced simulation tool for experts of design and maintenance management, rather a simple tool that will give the private client a hint of future need of maintenance and long term performance of the building and its heating system. The LMS-Bygga Villa tool is built on database technique and is divided into two interfaces; an administrative interface and a user interface. The administrative interface is restricted to those who are responsible for maintaining and upgrading the tool. This part of the tool consists of a catalogue of building types, building components and different heating systems, building materials and corresponding damage functions. The administrative part is linked to the user interface in which the user will be able to define a building, its location and calculate the service life for each building component/system. The location of the building is selected from a list of cities or from a Geographic Information System (GIS) map (the latter will be developed in the near future). Each location (city) has a defined environment, based on data from meteorological and environmental institutions as well as from the cities themselves. This data is coupled to the city and stored in the administrative part of the database. The building is composed piece by piece, in a hierarchical order, where each building component and system is selected from the building type catalogue. This will guarantee a consistent definition of the building. Figure 2 shows the calculation process in the LMS-Bygga Villa tool.

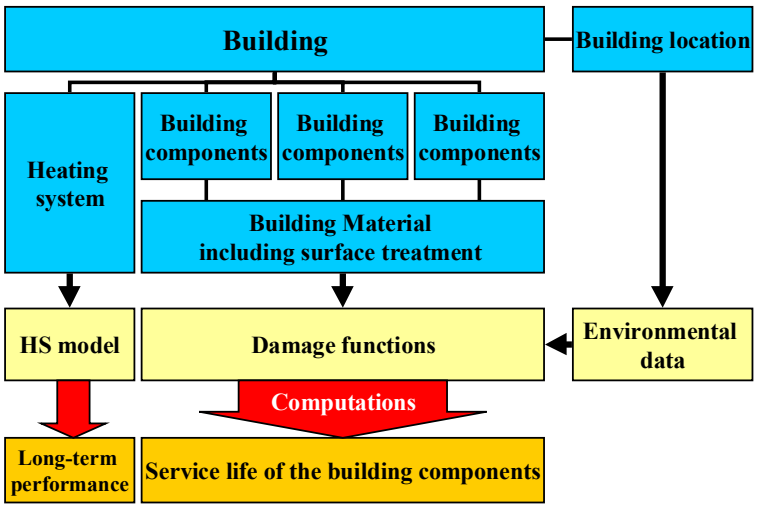

Figure 2. The calculation process in the LMS-Bygga Villa tool.

The computation is done directly in the database manager and the result is presented for all defined building components/systems. On the basis of the service life calculation/ long-term performance analysis results, it will be possible estimate the life cycle cost of each building component. A life cycle cost module adapted for the LMS-Bygga Villa tool is under development. In the following sections, two case studies will show some examples of service life calculations and long-term performance analysis and how the results may be used in the LMS-Bygga Villa life cycle cost module. The first case illustrates the LMS-application on windows and roof for a building situated in Gävle, Sweden. The second case shows performance degradation of a heat pump system with a borehole heat exchanger.

4 CASE STUDY 1

4.1 Exterior Part - Windows and Roofs

The service life of a building is expected to be at least 50 year on condition of normal maintenance [EOTA 1999]. Roofs and the windows are two examples of important parts of the building. The roof protects the rest of the building from being exposed to above all, rain and snow. A leak in the roof will soon lead to heavy damages on the rest of the building. It is therefor important to maintain the roof properly. The window is a complex component of the external wall construction with additional number of functional requirements to meet, such as inlet of daylight, visibility and aesthetics. Windows are also quite expensive since the replacement cost varies from a couple of hundreds to over thousand of Euros, depending on size, type and quality. Replacement of windows in Sweden is normally done after 30-70 years in service, often in combination with major building maintenance/repair actions [SBT 1984]. The following case will compare calculations of service life of windows made of wood and tin roofs of coil coated galvanised steel.

4.2 Service Life Calculations

A number of damage- and lifetime functions derived from the ICP Material program [UNECE 2004] and from the MOBAK study are included in the LMS-Bygga Villa tool. The MOBAK project, accomplished during the second half of the 1980's by initiative of the Nordic Council of Ministers, was a comprehensive study aimed to develop a methodology for data inventory of building materials and damages [Tolstoy *et al.* 1990]. The study encompassed damage inventory and condition assessments for a number of building components. By using extrapolation techniques, Andersson [1994] developed a number of lifetime functions based on the results from the MOBAK study. These functions are basically damage functions derived indirectly from inventories of maintenance intervals and therefore suitable in calculations of maintenance intervals. Following damage-/lifetime functions are used in this case study.

Service life (L) of painted wood [Andersson 1994]:

$$L = \frac{1000}{1{,}03 \cdot [SO_2] + 87{,}5 + 260 \cdot [H^+] \cdot rain} \quad (1)$$

Service life (L) of coil coated painted galvanised steel [Andersson 1994]:

$$L = \frac{1000}{0{,}37 \cdot [SO_2] + 62{,}9 + 95 \cdot [H^+] \cdot rain} \quad (2)$$

Service life (L) of coil coated galvanised steel [UNECE 2004]:

$$L = \left(\frac{10 - ASTM}{(0.0084 \cdot [SO_2] + 0.015 \cdot Rh + f(T)) + 0.00082 \cdot Rain} \right)^{\frac{1}{0.43}} \quad (3)$$

f(T) = 0.040(T-10) when T<10°C, otherwise -0.064(T-10). Equation 3 referes to the ASTM scale, 1 to 10, where 10 is good condition. The limit for maintenance actions is set to 5.

Environmental data on SO_2 (μg/m^3), H^+ (mg/l), Rain (mm/y), RH (%) and T (°C) is obtained from The Swedish Environmental Research Institute (IVL), Centre for Built Environment (BMG) and Gävle Municipality. Inserting the environmental data into the damage- and lifetime functions gives the results presented in Table 1. The result considers a 50-year planning period.

Table 1. Calculated service life for different coating materials in Gävle, Sweden.

	Painted wood (eq. 1)	Painted coil coated galvanised steel (eq. 2)	Coil coated galvanised steel (eq. 3)
Service life	8	13	18

It is assumed that the maintenance action on the roof is to repaint the roof. Thus, the following maintenance intervals will refer to painted coil coated galvanised steel, which will be necessary every 13 years. The total number of maintenance action on windows, i.e. repainting, is 7. The total number of action on the roofing is 4. This information, in combination with action cost data will be then input to total cost calculations. Man hour- and material costs data are estimated values. The result is presented in Table 2 and considers a 50-year planning period.

Table 2. Calculated action costs for wooden windows and tin roofs (1 Euro ≅ 9.20 SEK).

Building part	Type of action	Action cost	Number of actions per period	Periodic action cost
2 light window, 2 glass	Replacement	5740 SEK	1	5740 SEK
	Repainting	1050 SEK	7	7350 SEK
Tin roof, coil coated galvanised steel	Repainting	120 SEK/m^2	4	480 SEK/m^2

5 CASE STUDY 2

5.1 Borehole Assisted Heat Pump System

The use of borehole assisted heat pump system in Sweden has grown remarkable fast during the last decades, where half of the European heat pump market is in Sweden. The heat pump technology has been seen as an "environmental friendly" energy alternative which reduces the electricity consumption and thus the environmental impact. However, the Seasonal Performance Factor (SPF) of electrical heat pumps is about 2.5 – 3.0, which gives a similar CO_2 contribution to the atmosphere as heating system based on fossil fuel. To preserve the "environmental stamp" and the environmental arguments for installing heat pump systems, it is important to increase the SPF. Borehole assisted heat pump systems consists of a heat pump coupled to a Borehole Heat Exchanger (BHE), where the depth of the BHE varies from 60 to 170 m depending on the heating requirements [Akander *et al*. 2007]. During operation of the heat pump system heat will be extracted from the BHE, which reduces the ground temperature. When the ground temperature decreases, the heat pump system has to operate for a

longer period to meet the heating requirements. This reduces the SPF. A model for simulation of this effect is presented by Akander *et al*. [2007].

$$SPF = \frac{Q}{W_t + E_{aux}} \tag{7}$$

where Q is heat output during a considered period of time, [J] or [kWh], W_t is energy supplied to the heat pump (electricity) during the period, [J] or [kWh], E_{aux} is heat or electricity (auxiliary energy) supplied to the heat pump system during the period, [J] or [kWh] [Akander *et al*. 2007]. The energy (electricity) supplied to the heat pump i.e. the required energy to extract energy from the BHE is given in eq. 8 [Akander *et al.* 2007].

$$Q_{extracted} = \left[1 - \frac{1}{\eta}\right] \cdot (Q_{SH} + Q_{DHW}) + \frac{T_{cold} - \Delta T_{evap}}{\eta} \left[\frac{Q_{SH}}{T_{SH} + \Delta T_{cond}} + \frac{Q_{DHW}}{T_{DHW} + \Delta T_{cond}}\right] \tag{8}$$

where Q_{SH} and Q_{DHW} are space- and DHW heating requirements, respectively, [kWh] or [J], T_{cold} temperature of the cold carrier exiting the heat pump, [K], T_{SH} and T_{DHW} are supply temperatures for space heating and DHW, respectively, [K], ΔT_{evap} and ΔT_{cond} are temperature differences between the refrigerant and carrier in the heat exchangers of the evaporator and condenser, respectively, [K]. When the BHE temperature decreases, the temperature of the cold carrier T_{cold} will do the same. A BHE model describing this temperature decrease is presented by Stojanović *et al*. [2005]. The model takes into account factors such as borehole depth, ground conditions and initial ground temperature. The result, given in Table 3 and Fig. 3 is derived from a calculation of SPF reduction over time for a new residence located in Bromma/Stockholm. The borehole depth is considered to be 70 m. A more detailed description of the calculations and data is presented by Akander *et al.* [2007].

Table 3. A comparison of SPF and supplied electricity between year 1 and year 50.

	Year 1	Year 50	Change (%)
SPF	2.99	2.93	2.0
Supplied electricity	3609.5 (kWh)	3683.5 (kWh)	2.1

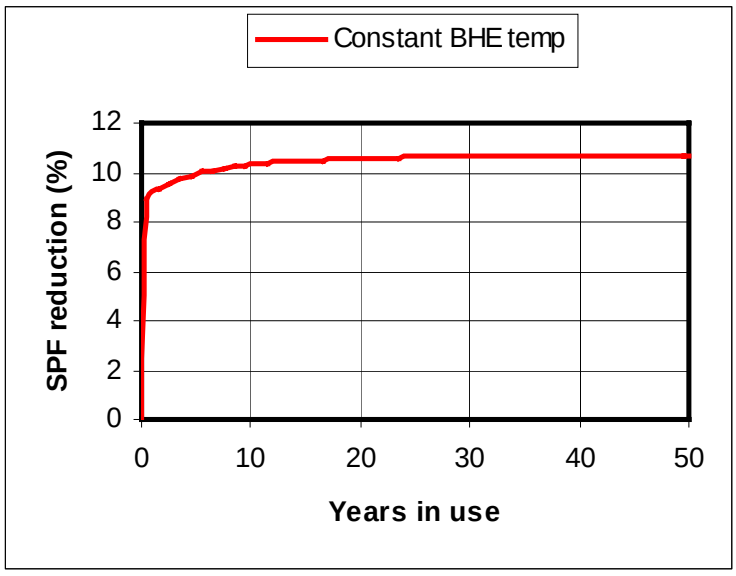

Figure 3. SPF reduction over time.

The complex BHE model is not yet applicable for the LMS Bygga Villa tool. However, the complex BHE model will be "simplified" by using regression analysis for various locations and borehole depths.

6 DISCUSSION AND CONCLUSIONS

In the first case, a number of different damage-/lifetime functions have been used for service life calculations. These are partly developed in Sweden, partly in an environment close to the conditions in Sweden, which justify the use of the functions in this application. This statement is strengthening by the fact that the results of the service life analysis are close to the common assessments of service life on the building component in question. Nevertheless, in general damage-/lifetime functions are developed in different research projects with different prerequisites, so one must be cautious when adopting these functions in service life performance analysis. Some of these are based on dose-response functions, which are functions that are not convenient for service life calculations since there is no direct link between the response and the loss of performance [Haagenrud 1997]. This is solved by adding a performance requirement to the dose-response function, which then will be valid as a damage function and thus, suitable in service life calculations. The tricky part is to define the performance requirements. Another difficult part is to collect and unify environmental data, appropriate for the use in service life calculations. A problem is that the various data is collected by different institutions for different purposes. Data is also presented in different formats, not always manageable. One example is transformation of environmental data from one "geographical level" to another. Another example is whether point sources of pollution should be included or not in an application such as LMS-Bygga Villa.

There is an ongoing discussion about the cooling effect in boreholes. The discussion is on, whether recharging is economical justified or not. This case shows nevertheless that the cooling effect is almost negligible for a single borehole of correct depth. It is true that the SPF of the heat pump system is heavily reduced during the first year in operation. But the fact that this effect is taken into account in the design of the system and that the performance loss is only 2.0 % the next 50 years in operation does not motivate recharging of the borehole. Transformed into economic terms the magnitude of the reduced performance during the 50 years in operation corresponds to 1-year operation cost. During this time the heat pump is probably replaced by a new and more effective one or by a complete different heating system.

7 FUTURE WORK

The development of LMS-Bygga Villa tool will continue. The main focus in the near future will be on development of a user-friendly interface and development of an economy module in which the user will be able to compare different maintenance actions in terms of life cycle costing. Along with the development of a user friendly application follows development of a GIS module in which mainly environmental data such as meteorological data, geological data, pollution data, etc. can be stored and presented. Another part of the near future work will be on development of a simplified borehole model applicable for LMS-Bygga Villa in which different heating distribution system and borehole depth is taken into consideration.

T 72

ABSTRACT

Elevators or lifts form the vertical transportation spine of modern high rise buildings. Safety and convenience being two critical issues, it is important to identify the associated risk factors. To complement the technological advancements of system design and greater users' expectation, there is a noted absence of maintainability aspect which not only ensures efficient system performance but also lowers the total life cycle cost through smooth operation and minimal maintenance. To address this knowledge gap, this research was undertaken to identify, analyse and quantify serious defects prevalent in the vertical transport system of commercial buildings of Singapore.

From detailed case study at five commercial buildings, total 114 types of common defects were identified for five main components including machine room, car, hoistway, landing and pit. Out of them, 28 were graded as significant by 40 experienced facility managers in a five pomt Likert scale in terms of frequency of occurrence, and adverse effect on: economy, system performance and safety & comfort. Comprehensive defect analysis established that inadequate or careless maintenance was the main cause for most of them. This study provides foresight of the long term effect of the decisions made during design, construction and operation-maintenance stage and forms the basis of good practices for efficient and safe functioning of highly maintainable vertical transport system. This generic method is applicable for any other building services.

1 INTRODUCTION

Elevators or lifts form the vertical transportation spine of modern high rise buildings. Since the invention of safety gear by Elisha Otis in 1953, elevators have undergone significant improvement especially in related areas such as: traffic handling, control systems, traction systems and vibration dampers. As modern elevators are complex equipment designed, produced and installed under stringent regulations, they are inherently safe. However in spite of a safety factor as high as 16, ISO certification of most of the manufacturers / installers, elevators and escalators related accidents kill about 30 and seriously injure about 17,100 people each year alone in the United States and 50% of the victims are trained elevator mechanics [McCann 2004].

Safety rules [ISO 2004] are focused at various types of accidents with lifts: shearing, crushing, falling, impact, trapping, fire, electric shock, damaged material, accidents due to wear or corrosion (Staal & Quackenbush 1998). Among the prevalent problems such as over speeding of car, uncontrolled low speed, car moving before door is closed etc, the most common hazard is fatal fall through elevator shaft due to opening of lobby door on pressing of call button before the car arrives [Vlahovic 1990]. Moreover equipment shutdown incurs in expensive over time 'callbacks' and inconvenience to the users. Such malfunctioning can be prevented by efficient maintenance practices [NEII 2007].

In spite of regular inspection according to elevator maintenance checklists [Schloss 1998], defects are prevalent. From extensive literature review it was established that to complement the technological advancements of system design and greater users' expectation, there is clear need for a better understanding of maintainability aspect to ensures efficient system performance and lower total life cycle cost through smooth operation and minimal break-down. Causes and long term effects of defects need to be addressed explicitly in design guidelines and maintenance handbooks. This research was undertaken to identify the defects common in the vertical transport system in commercial buildings of Singapore and to rank the significant one based on the scientific quantification of their seriousness. This study focuses on traction type passenger elevators generally found in high-rise commercial buildings.

2 RESEARCH METHODOLOGY

2.1 Data Collection

In order to obtain a preliminary idea of common maintenance problems in vertical transport system, major components were listed from available literature for a systematic site investigation. In the first phase of data collection, an in-depth field survey was conducted in five commercial towers. Discussion with facility managers (FM) and maintenance personnel was followed by expert walk-through and photo documentation of all permissible areas to investigate elements such as the machine room, car interior etc. The defects were analyzed with the help of information provided by FMs, past maintenance records of the buildings under study and the knowledge gained through the literature review [McKain 1999; O'Donoghue & Jarboe 2007; SAC 2000; Strakosch 1986] were elicited.

From preliminary analysis, a defect was observed to have adverse effect on (1) economy, (2) system performance; and (3) safety & comfort. These factors contribute to the level of seriousness of a defect and were considered to establish the significance of a defect. A frequent defect might have insignificant effect, while a very serious defect may occur rarely. For example, closing of car door while user are getting in and out of the car is common but the force exerted causes only nudging effect, while false opening of a lobby door when there was no elevator car is rare but can cause fatal fall through hoistway. The three major impacts were defined as:

- Economic loss: considerable financial damages sustained as a result of the defect, e.g. call back if users are caught in a stalled car due to deactivated safety switches or faulty circuits.

- System performance loss: here the system performs significantly below normal operating efficiency due to the defect, e.g. repeated opening and closing of car door.
- Safety & comfort loss: affected safety of the users and maintenance personnel as a result of the defect, e.g. opening of fire lift car door in fire floor if the lobby smoke detector is faulty.

The defect data related to major components and sub-components of vertical transportation system was collated in a detailed survey questionnaire. In a face to face interview, 40 experienced facility managers (FM) were asked to indicate the frequency of the defect in a five point Likert scale, where, 1 = 'rare', 2 = 'sometimes', 3 = 'quite often', 4 = 'very often' and 5 = 'always'. In order to estimate the impact of each defect, the respondents were asked to indicate the significance of the defects in terms three consequences also in a five point Likert scale, where, 1 = 'Nil', 2= 'Slight', 3 = 'Moderate', 4 = 'Serious' and 5= 'Very serious / fatal'. Among five major components, the questionnaire for elevator hoistway is shown in Appendix A as an example.

2.2 Data Analysis

Mean ratings for determining the level of seriousness of the defects were calculated from the feedback received. Mean rating for frequency was defined as $\overline{X}_{FR}$, while the same for impacts on four aspects, namely, economy, system performance, and safety & comfort were denoted by $\overline{X}_{EC}$, $\overline{X}_{SP}$ and $\overline{X}_{SC}$ respectively. For each defect, the mean rating was calculated by a general formula (Equation 1). Using statistical tool SPSS 12 (Statistical Package for the Social Sciences), T-test was carried out to identify the significance of each mean. The midpoint test value of 3 (by definition) was assigned to measure whether the defects have a significantly large enough mean with $p<0.005$.

$$\text{Mean frequency of occurrence } \overline{X} = \sum_{i=1}^{5} i \times n_i \Big/ \sum_{i=1}^{5} n_i \qquad (1)$$

Where, i = frequency rating and n_i = number of responses for i-th rating

3 RESULTS AND DISCUSSION

3.1 General Observation

Most of the commercial buildings in Singapore are accessible by elevator.. Geared traction elevators are used generally up to 20 storeys, while gearless express type is common for taller buildings. Misuse and vandalism such as banging on door, repeated pressing of buttons, littering and forceful opening of lobby door were observed, in lift lobby and car interior. These are accessible to users. Most of the system related defects were attributed to poor installation quality or mishandling during maintenance which could have been prevented by cleaning and proper lubrication of machinery.. Causes of defects were grouped into: (1) design-specification (D); (2) construction-installation (C) and (3) maintenance (M).

3.2 Survey Results

The summary of survey results illustrating the prevalent defects and their significance is presented in Tables 1 – 5. A total of 114 defects related to five major components of vertical transportation system were identified, out of which 28 were found serious and among those 11 were referred by FMs as frequent and 14 occurs in two or more categories. Economy, system performance, and safety & comfort were affected by 14, 14 and 9 defects respectively. Few defects which are not significant but contribute to overall maintainability were captured by three generic categories, namely, design, construction and maintenance. As an example, defects in hoistway are discussed in details

Table 1. Significance of defects in machine room

Sub-comp.	*Defects in machine room*	*Cause*			$\overline{X}_{FR}$	$\overline{X}_{EC}$	$\overline{X}_{SP}$	$\overline{X}_{SC}$
Significant defects (7 nos.)								
Controller	(1) Lift jam (stalled car)			M		2.62	3.10	3.15
	(2) Uncomfortable motion / jerky landing		C	M	2.29		2.80	3.15
	(3) Long waiting time (>30sec)	D		M	2.28			
Governor Machine	(4) Vibration during travel due to governor rope worn/ uneven tension/ not strong	D		M			2.90	
	(5) Intermittent fault difficult to detect`	D	C	M		2.65		
---	(6) Poor workmanship. E.g. Brake rod not secured to plate / uneven		C		2.51			
---	(7) Mishandling. E.g. under / over lubrication			M		3.08		
Other defects (30 nos.)								
Machine Room	(1) Dirty with rubbish, carbon dust, lubricant; (2) Insufficient lighting (<200 lux at floor level); (3) Water seepage through wall / ceiling; (4) Overheated (>38°C) machines in stuffy room; (5) Inadequate clearance around machines & control panel							
Controller	(6) Transformer noisy / dirty; Inverter cooling fan dirty / dusty, (7) Intermittent faults/ fire from overused/ burnt resistor, (8) Noisy bearing; (9) Dirty machine with leaking cover/ oil seal							
Traction machine	(10) Oil level is too low or high; (11) Oil level gauge blurred / faulty; (12) Faulty brake; (13) Noise and vibration by worn out, dry secondary sheave bearing/ groove; (14) Machine bed isolation rubber worn; (15) Main rope worn; (16) Carbon brush holder loose/ damaged							
Tractn. motor	(17) Bearing noisy; (18) Overheated motor, (19) Cooling fan dirty / noisy							
Brake assembly	(20) Vibration and jerky emergency stops; (21) Brake drum scratched, burnt lining; (22) Incorrect clearance of plunger stroke; (23) Brake rod is not secured to plate; (24) Brake lever uneven; (25) Brake slips excessively for emergency stop; (26) Brake shaft collar clearance out/ screw loose; (27) Levers jammed/ slippery							
Governor Machine	(28) Noisy operation; (29) Oily / dirty machine							
---	(30 Faulty design. E.g. less clearance, long waiting							

Table 2. Significance of defects in lift hoistway

Sub-comp.	*Defects in hoistway*	*Cause*			$\overline{X}_{FR}$	$\overline{X}_{EC}$	$\overline{X}_{SP}$	$\overline{X}_{SC}$
Significant defects (7 nos.)								
Guide rail	(1) Noisy vibration due to excess movement in guide / roller shoe over slippery rail			M	2.00			
Wire rope	(2) Wrong tension in rope causes wear & tear		C	M				1.82
	(3) High vibration. car hitting at top or bottom	D			1.84	2.71		2.59
	(4) Corrosion of rope	D	C				2.60	
---	(5) Faulty design. E.g. Limit switch v. close to governor rope (over conservative design)	D						2.06
---	(6) Poor workmanship. E.g. Rope socket is slanted or with bullock-clip in the wrong position causes wrong tension in wire rope		C		2.52	2.44	2.75	
---	(7) Mishandling. E.g. Oil spillage			M		3.08	2.74	
Other defects (6 nos.)								
Governor	(1) Updown switch roller jammed/ misaligned; (2) Limit switch & gov. rope too close							
Guide rail	(3) Separator beam, rail bracket dirty with rubbish; (4) Slippery by oil spillage							
Shaft	(5) Not covered by hatch; (6) Water seepage							

Table 3. Significance of defects in lift car

Sub-comp.	*Defects in lift car*	*Cause*		$\overline{X}_{FR}$	$\overline{X}_{EC}$	$\overline{X}_{SP}$	$\overline{X}_{SC}$
Significant defects (6 nos.)							
Car Interior	(1) Wear and tear with time: discolouration, dents, , worn flooring, worn off buttons, missing / blurred message /certificate plate	D	M	4.73	3.23		
Car Door	(2) Door jam/ stuck		M		3.55	4.08	
	(3) Repeated opening and closing		M			4.17	
	(4) Incomplete opening and closing		M		3.51	3.74	
	(5) Door closing on moving users as PE eyes or multi beams not aligned to detect movement	C	M				3.93
---	(6) Design specification sensitive to vandalism. E.g. Car operating panel (COP) dirty/ delaminated/ with buttons which are loose / jammed / without light / unable to register call. Easy opening of emergency exit at top	D		4.46			
Other defects (34 nos.)							
Car Top	(1) car top rope socket wrongly placed/ slanted / hitting; (2) Misfit rope wedge; (3) Excessive movement in car guide roller shoe; (4) Safety gear/linkage oily& dirty or dry & noisy; (5) Low overhead without warning sign; (6) Dirty with debris, lubricant						
Car Bottom	(7) Overload switch / cell jammed; (9) Compensation cable not firmly secured; (10) Safety gear jammed/ missing parts/ inadequate clearance; (11) Travelling cable not firmly secured; (12) Lower surface is dirty with cobwebs; (13) Excessive movement of guide shoes / roller						
Car Interior	(14) Dirty / damaged light diffuser; (15) loose /noisy false ceiling, noisy fan; 16) Architectural finishes hindering maintenance.						
Car Door	(17) Banging; (18) Linkages worn; (19) Door shoe is worn/ inaccurate clearance / loose; (20) Door sill is bulging; (21) Speed mismatch with lobby door (time lag); (23) Door jamb loose / rusty / stopper missing; (24) Car safety shoes hitting / noisy						
Door operator	(25) Door motor is slanted or causing vibration; (26) Door motor belt tension loose / worn; (27) Door motor chain/ sprocket/ wheel is loose / worn out and dry; (28) Faulty micro switch is unable to prevent door opening within unlocking zone; (29) Faulty mechanical lock; (30) Car door bar / hanger roller is dirty/ worn / rusty						
Travelling	(31) Lift levelling with landing > 5mm; (32) Jerk, vibration, noise						
---	(33) Poor workmanship. E.g. Loosely fitted false ceiling						
---	(34) Mishandling. E.g. damaged micro switch.						

Table 4. Significance of defects in lift pit

Sub-comp.	*Defects in pit*	*Cause*		$\overline{X}_{FR}$	$\overline{X}_{EC}$	$\overline{X}_{SP}$	$\overline{X}_{SC}$
Significant defects (3 nos.)							
----	(1) Dirty with rubbish or lubricant		M	3.42		3.10	3.40
	(2) Compensation cable/ sheaves misaligned	D	C		2.84		3.43
	(3) Noisy compensation cable		M	1.62	2.75	2.79	
Other defects (1 no.)							
----	(1) Damaged switch / light						

Table 5. Significance of defects in lift landing

Sub-comp.	*Defects in landing*	*Cause*	$\overline{X}_{FR}$	$\overline{X}_{EC}$	$\overline{X}_{SP}$	$\overline{X}_{SC}$
Significant defects (5 nos.)						
Landing door	(1) Rubbing/ large gap (> 10mm) in panel	D C M			3.28	3.68
	(2) Catch device roller worn/ hitting/clearance out	D M		2.78		
Lift Landing	(3) Hall button damaged/ no light/ loose/ jam	D M	4.18	3.08		
---	(4) Poor workmanship. E.g. misaligned door roller wears easily	C			2.75	
---	(5) Mishandling. E.g. jammed mechanic's access switch by forceful use of other key	M		3.08	2.74	
Other defects (8 nos.)						
Landing door	(1) Closing on moving users / no self-closing; (2) Door roller worn/ rusty/ clearance out/jammed; (3) Weight wire pipe damaged/ missing/ loose; (4) Lock contact worn / clearance out; (5) Shoe worn / clearance out; (6) Missing /damaged rubber stopper					
Smoke detector	(7) Missing/ damaged detector unable to stop lift reaching the fire floor					
---	(8) Faulty design. E.g. Sensitive finishes used in lobby with heavy use, inferior make of lock, clutch shoe wear off easily					

3.3 Discussion

For four sub-components of hoistway, a total of 13 common defects were identified from the first phase of data collection, among which seven were found to be significant for their impacts (Table 2). Excessive noise and vibration in guide rail during lift travel was found to be a frequent issue due to excess movement in guide or roller shoe. Careless maintenance is not only responsible for oil spillage during lubrication but also for wrong size of roller shoe. As mentioned earlier, elevators are manufactured under stringent ISO certification, it can be realized that misfit shoe is a result of replacement, not a manufacturing defect. This same logic is equally applicable to misaligned socket or improper wedge size causing wrong tension in rope. Overloading can be considered as an example of misuse rather than inadequate design consideration in this case. Vibration in hoisting rope was reported to occur quite often, but more than being frequent it has major implication on economy and comfort. The distress caused to users actually results in complaints and costly callbacks. Ropes get corroded due to undue stress and water seepage through hoistway. Both have the root cause of poor workmanship either during installation of lift or construction of lift shaft. All of these four significant defects mentioned had poor workmanship as common cause. This fact was further illustrated by the fact that it was graded as the most frequent defect. It is in agreement with the general understanding that quality control at site is not as strict as of factory. As a result the systems performance is highly affected since commissioning incurring higher maintenance cost. Limit switch too close to governor rope was an example of over conservative design. It creates uncomfortable emergency stops. Wrong maintenance practices such as oil spillage during lubrication or misalignment of machine parts was observed to affect system performance seriously, and have highest impact on cost.

From the present study, it was established that among many defects in vertical transport system, most of the defects can be prevented by considering three major maintainability criteria, namely, design and specification, construction or installation, and operation & maintenance (O&M). Few defects may have more than one cause. It is important to know at which stage what are the defects arise so that the appropriate preventive measures can be taken to improve the maintainability. It was found that among 28 significant defects, 12 were design related, 10 were due to faulty installation or poor construction quality and inadequate O&M practises were responsible for 19 defects. The maintenance quality was largely subjective with regard to cleanliness and lubrication.

3 CONCLUSIONS

The study had identified 28 persistent defects out of total 114 defects commonly occurring in five major components of vertical transportation system. Mishandling of components during regular maintenance including improper lubrication and inadequate cleaning was detected as the most common cause for majority of the defects. From the analysis based on feedback provided by 40 experienced FMs regarding: (1) frequency of occurrence of various defects and (2) seriousness of the defects in terms of their adverse effect on economy, system performance and users' safety & comfort, it was established that the most important contributing factors for maintainability is good maintenance, next comes good design and material specification, followed by workmanship during construction or installation. This comprehensive defect analysis was aimed to help the designers, contractors and facility managers to realize the long term effect of their decisions made and form the basis of an enhanced maintainability to promote good practices for efficient and safe functioning of highly maintainable vertical transportation system. Further, this may provide a simple guideline for FM to achieve and as well as owner to enjoy lower life cycle maintenance cost of building services. This generic research method can be applicable for any other building services.

APPENDIX A: Sample questionnaire for defects in hoistway

DEFECTS FOR ELEVATOR HOISTWAY			**Grading for Frequency**	**Grading for Impacts**		
Sub-component	**Description of defect**	**Probable Causes of the Defect**	**1= Rare 2= Sometimes 3= Quite often 4= Very often 5= Always**	**1=Nil 2= Slight 3=Moderate 4=Serious 5=Very serious**		
				Econ	**Sys**	**Sfty.**
Governor	Up-down switch roller jammed/ worn/ misaligned [M]	−Intermittent fault due to circuit breaks −Dust / dirt deposit into the hoist way				
	Limit switch too close to governor rope [D]	−Wrong selection of design factor				
Guide rail	Noisy vibration due to excess movement in guide / roller shoe [M]	−Guide / roller shoe of the wrong size −Slippery rail due to oil spillage during lubrication				
	Separator beam, rail bracket dirty with rubbish [M]	−Vandalism (rubbish thrown by users) −No cleaning after regular maintenance				
	Slippery by oil spillage [M]	−Careless lubrication				
Shaft	Not covered by hatch [M]	−Removal of cover during careless maintenance				
	Water seepage [C]	−Poor workmanship of building structure				
Hoisting rope	Excessive vibration / car hitting at top or bottom [D]	−Overloading of car −Wrong tension in rope if 3-fold instead of 4-folds				
	Wrong tension in wire rope causes wear & tear [C, M]	−Overloading of car −Rope socket is slanted / hitting / socket bullock-clip is in the wrong position −Wedge of wrong size				
	Corrosion of rope [D, C]	−Stress corrosion, hoistway not dry,				
-----	Design defects [D]	−Faulty design or poor specification				
-----	Construction defects [C]	−Poor workmanship during installation				
-----	Maintenance defects [M]	−Mishandling during careless maintenance				

[D] Defect caused by poor design or material specification
[C] Defect caused by poor workmanship during construction / installation
[M] Defect caused by inadequate or careless maintenance

Optimal Maintenance Plan by Minimizing Life-cycle Cost Including Deterioration Risk

ABSTRACT

This paper shows deterioration models due to carbonation in consideration of uncertainty to estimate the initiation and the rate of corrosion, and to analyze the structural capacity and serviceability of RC members, i.e. shear capacity, bending strength and width of severe spalling/cracking of columns or beams with corroded reinforcing bars based on simple formulas formed through the past experiments.

Then, the failure and severe spalling/cracking probability during earthquakes and the deterioration risk of members in specified years from construction could be evaluated by this method proposed in this paper.

In addition, by applying immune algorithm to minimization of life-cycle cost including the deterioration risk, the optimal maintenance plan and semi-optimal solutions with high diversity of reinforced concrete members could also be found in a single analysis and a case study is finally conducted to prove the effectiveness of this system.

1 INTRODUCTION

Generally, structural members, beams, or columns whose reinforcing steel components are corroded by carbonation or chloride attack are appropriately repaired/retrofitted after investigating the cause of corrosion. However, few studies discuss how an optimal maintenance plan can be envisaged beforehand to minimize the life-cycle cost (LCC) of a structure, including the deterioration risk caused by earthquakes. Therefore, there is a need for a system that can be used to determine a maintenance strategy to minimize the LCC in terms of structural capacity and serviceability. In this paper, we describe a system that can estimate the LCC, including the deterioration risk (induced by carbonation), of an RC beam or column resulting from failure and severe spalling/cracking during earthquakes (Fig.1). In addition, we analyze the ability of an immune algorithm (IA) capable of searching for semi-optimal solutions with high diversity to find the optimal maintenance plan.

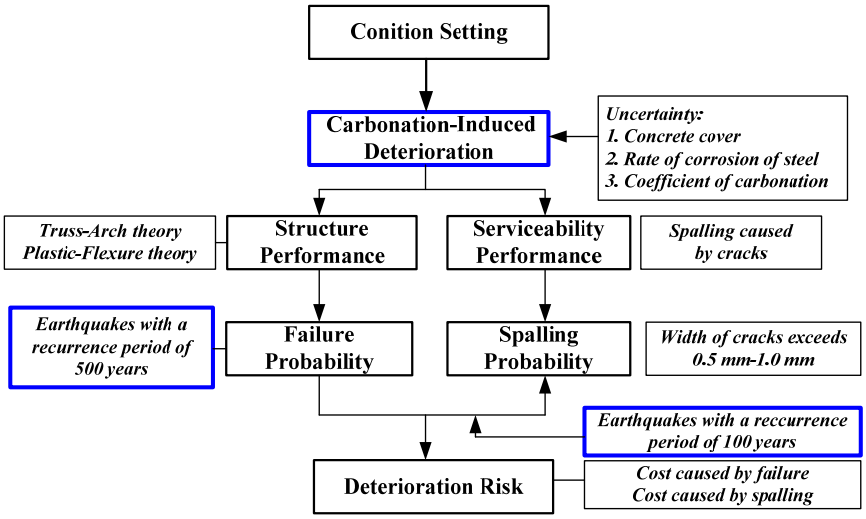

Figure 1. Flowchart depicting how deterioration risk induced by carbonation is evaluated

2 EVALUATION OF DETERIORATION RISK AND LCC

2.1 Deterioration Model

2.1.1 Carbonation

In this paper, the process of corrosion of the reinforcing steel due to carbonation is modeled on the basis of a previous research [Seiichi & Toyoaki 2004].

2.1.1.1 Initiation stage. This stage is defined as the time period required for corrosion to begin. Under steady hygrometric conditions, the depth of carbonation increases in proportion to the square root of time; therefore, the depth of carbonation, C, can be expressed in millimeters as follows:

$$C = A\sqrt{t} \quad \text{.....(1)}$$

where A = carbonation coefficient in mm/year$^{0.5}$, and t = time of exposure in years.

Based on previous investigations, when the carbonation front reaches the surface of the steel, it can be assumed that corrosion has been initiated [AIJ 2004]. This paper considers the uncertainties with regard to the carbonation coefficient and concrete cover induced by the environment or construction conditions to calculate by using Monte Carlo simulation the probability that the corrosion of the outermost reinforcing steel layer has been initiated. In the simulation, corrosion is considered to have occurred when the probability of corrosion initiation exceeds 10%. In the probabilistic analysis, the carbonation coefficient and concrete cover are treated as lognormal random variables with coefficients of variation of 45% [Taichiro *et al.* 2006] and 20% [Yoshitaka & Taketo 2005], respectively.

2.1.1.2 Propagation stage and former period of acceleration stage. The propagation stage is defined as the period from corrosion initiation to cracking initiation of the concrete surface. The former period of the acceleration stage is defined as the period from crack initiation to spalling initiation of the concrete surface. Based on a model developed previously [Seiichi & Toyoaki 2004], the rate of corrosion in these two stages is assumed to be same, and this rate is treated as a lognormal random variable with a mean equal to 0.06%/year (percentage weight loss) [Seiichi & Toyoaki 2004] and a coefficient of variation of 50% [Toshiaki et al. 2005].

2.1.1.3 Latter period of acceleration stage. In the latter period of the acceleration stage, the concrete surface spalls severely so that the concrete cover is almost unable to prevent the steel from corroding. In this paper, the latter period is characterized by severe spalling, which is regarded as an increase in the crack width in excess of 1.0 mm; the corrosion in a 1.0 mm crack can be quantified as follows:

$$w_c = 0.141 \exp(1.078d/\varphi) \times x \quad \ldots\ldots(2)$$

$$r = \frac{400 w_c}{\rho_s \varphi_o} \quad \ldots\ldots(3)$$

where w_c = corrosion of steel in mg/mm^2; x = crack width in millimeters; d = concrete cover in millimeters; φ = diameter of steel in millimeters; φ_o = diameter of steel without corrosion in millimeters; ρ_s = density of steel in mg/mm^3 (7.85 mg/mm^3); and r = corrosion of steel in percentage weight loss (%).

Based on previous researches [Seiichi & Toyoaki 2004, Toshiaki *et al.* 2005], the rate of corrosion at this stage is equal to the rate of corrosion of steel without any concrete cover and is treated as a lognormal random variable with a mean equal to 0.14%/year (percentage weight loss) and coefficient of variation of 50%.

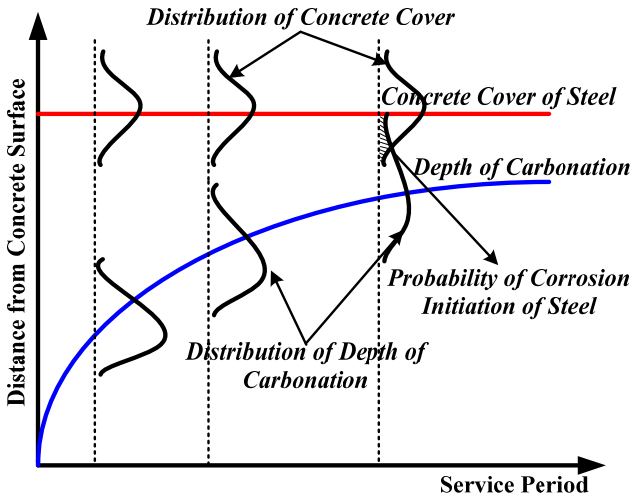

Figure 2. Evaluation of the probabilityof corrosion initiation

2.1.1.4 Carbonation suppressive effect of finishing. Because finishing can prevent the concrete surface from coming into contact with CO_2, it could also suppress carbonation. In this paper, if the material of finishing is composed of cement, the depth of carbonation can be estimated as shown in Eq.4 based on the concept of an equivalent concrete cover [AIJ 2004].

$$C = A\sqrt{t} - M_{eq} \quad \ldots\ldots(4)$$

where M_{eq} = equivalent concrete cover in relation to the thickness of finishing in millimeters.

If the material of finishing is made up of a polymer mixture, we must use Eq.5, which includes a material aging factor dependant on ultraviolet radiation, rain, and wind, to estimate the depth of carbonation [AIJ 2004].

$$C = A(\sqrt{t + R^2} - R) \quad \ldots\ldots(5)$$

where R = resistance of carbonation in relation to year and the coating thickness in year$^{0.5}$.

2.2 Probability of Failure and Spalling

2.2.1 Capacity degradation of beam and column

2.2.1.1 Shear and flexure capacity. In this paper, two major causes of the reduction in capacity due to corrosion are considered. The first cause is the degradation of the yield stress of the reinforcing steel. In the case of general corrosion, the yield stress of reinforcing steel can be estimated as [JCI 1998]

$$\sigma_y = \sigma_{yo}(1 - 2.17r / 100) \quad \ldots\ldots(6)$$

where σ_{yo} = yield stress of reinforcing steel without corrosion and r = corrosion of steel in percentage weight loss (%).

The second cause is the degradation of the ultimate bond stress of the reinforcing steel and concrete, and it can be estimated as [JCI 1998]

$$\tau_{bu} = \tau_{bo} \times exp(-0.0607r) \quad \ldots\ldots(7)$$

where τ_{bo} = ultimate bond stress without corrosion.

The shear capacity of an RC beam or column in the case of bonding failure or stirrup yielding induced by corrosion can be estimated by a previously developed model [Chien-Kuo *et al.* 2007], which in turn is based on the truss-arch theory associated with Eq.(6) and Eq.(7). The flexure capacity can be estimated by the plastic flexure theory associated with Euler-Bernoulli beam theory and Eq.(6) [Chien-Kuo *et al.* 2007].

2.2.1.2 Shear demand. The shear demand of an earthquake with a recurrence period of 500 years is defined as the shear force caused by an earthquake and the vertical loading , Q_{DS}.

$$Q_{DS} = Q_L + \alpha \times Q_E \quad \ldots\ldots(8)$$

where Q_L = shear force caused by vertical loading; Q_E = shear force caused by the earthquake; and α = an additional factor.

2.2.2 Structure performance and failure probability

Using the capacity and the shear demand of an RC beam or column obtained based on 2.2.1, the shear performance index, D_V , and the flexure performance index, D_M, are defined as follows:

$$D_V = \frac{min(V_{bu}, V_u)}{Q_{DS}} \quad \ldots\ldots(9)$$

$$D_M = \frac{2M_u / L}{Q_{DS}} \quad \ldots\ldots(10)$$

where L = length of beam or column. If $D_V \leq 1.0$, shear failure is implied. If $D_M \leq 1.0$, flexure failure is implied.

Clearly, D_V and D_M decrease and approach the value of the limit (equal to 1.0) with the passage of time, as illustrated in Fig.4. In this paper, the rate of corrosion of reinforcing steel is treated as a random variable and Monte Carlo simulation is used to calculate the distributions of D_V and D_M. Then, the area of the distribution below the limit value can be evaluated and defined in terms of the shear failure probability, P_V, and flexure failure probability, P_M, respectively.

2.2.3 Serviceability performance and spalling probability

It is generally perceived that the serviceability performance of RC structures is affected when spalling is caused with the formation of a crack with a width in excess of 0.5–1.0 mm [Dimitri V. & Mark G. 2003]. The limit quantity of corrosion resulting in spalling can be estimated by Eq.(2) and Eq.(3). Therefore, when the quantity of corrosion of the outermost reinforcing steel component in the RC beam or column exceeds the limit quantity, spalling can be assumed to occur on the surface of the concrete. Monte Carlo simulation is used to evaluate the spalling probability, P_S, similar to how it was used in the case explained in 2.2.2. When an earthquake with a recurrence period of 100 years occurs, it is reasonable to expect that a higher spalling probability caused by carbonation would lead to a higher expected cost of serviceability failure.

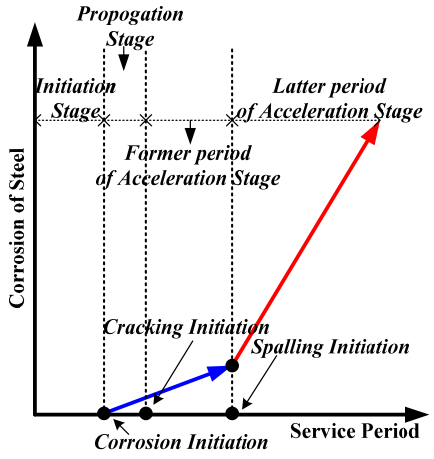

Figure 3. Stages of deterioration caused by carbonation

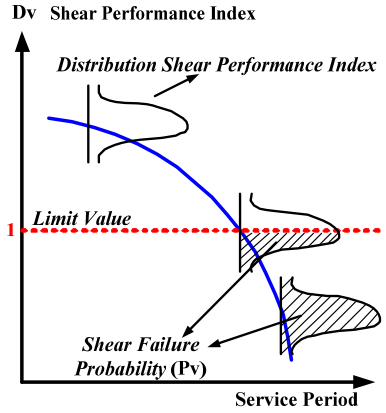

Figure 4. Definition of shear failure probability

2.3 Deterioration Risk and Life-cycle Cost

2.3.1 Deterioration risk of service period

In this paper, the deterioration risk of a specified service period, E, is estimated as

$$E = \int_0^T \frac{1}{(1+k)^t} \times (C_f \times (P_M + P_V) \times v_f + C_s \times P_s \times v_s) dt \quad \ldots\ldots (11)$$

where C_f = cost of failure; C_s = cost of severe spalling/cracking; v_f = annual probability of an earthquake with a recurrence period of 500 years (if a Poisson distribution is assumed, 0.2%); v_s = annual probability of an earthquake with a recurrence period of 100 years (if a Poisson distribution assumed, 1%); T = specified service period; k = discount rate.

2.3.2 Life-cycle cost

Besides the deterioration risk stated in 2.3.1, the construction cost, retrofitting cost, and repair cost must also be considered. Therefore, the LCC, C_T, is defined as

$$C_T = C_I + \Sigma(C_{Rep} \times \frac{1}{(1+k)^{t_{Rep}}}) + \Sigma(C_{Ret} \times \frac{1}{(1+k)^{t_{Ret}}}) + E \quad (12)$$

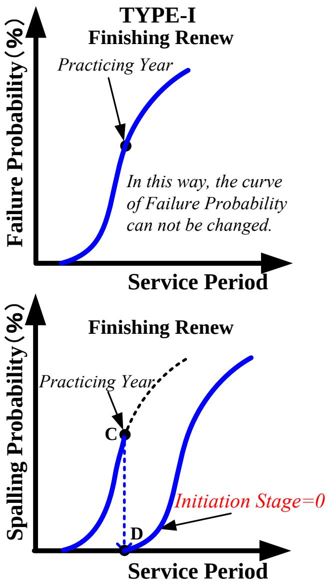

Figure 5. Setting of repair/retrofit

where C_I = construction cost; C_{Rep} = repair cost; C_{Ret} = retrofitting cost; t_{Rep} = year of repair; t_{Ret} = year of retrofitting.

2.4 Maintenance Strategy

The selection of repair/retrofit techniques significantly affects the lifetime performance of an RC beam or column. In this paper, three repair/retrofit techniques are considered. Moreover, in order to improve the computing efficiency of the immune algorithm to find the optimal maintenance plan, the model illustrated in Fig.5 is used to directly reflect the effect of the maintenance strategy on the failure probability and spalling probability.

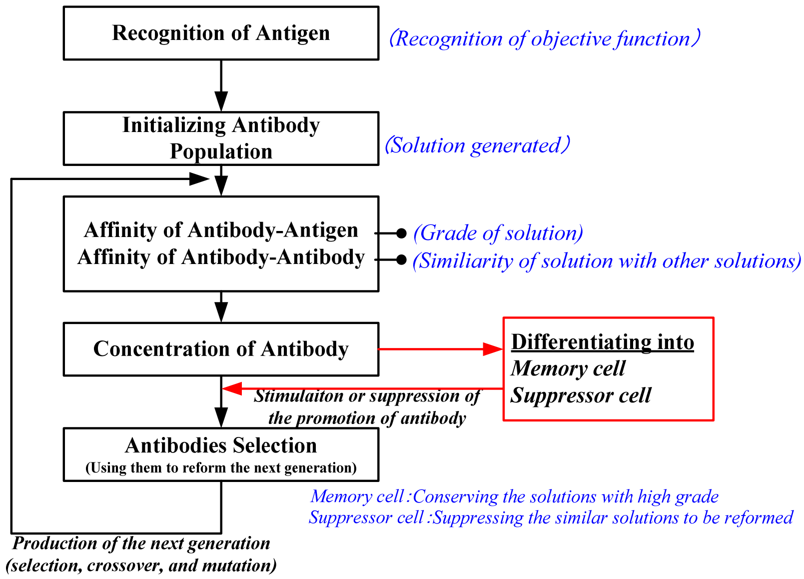

Figure 6. Flowchart showing computing procedure in IA

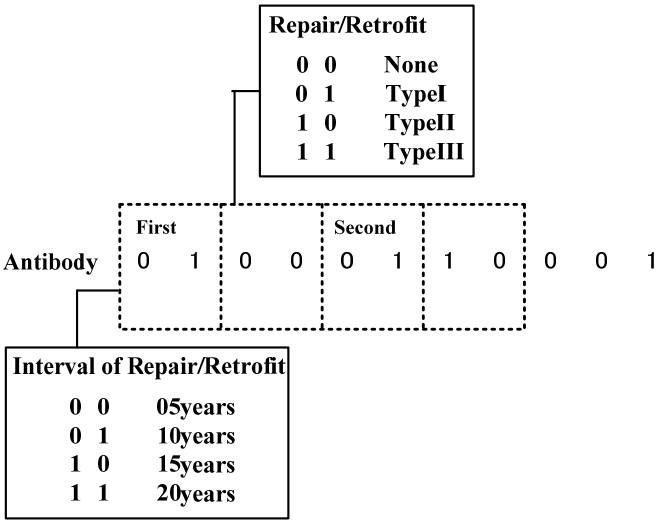

Figure 7. Code of an antibody

3 IMMUNE ALGORITHM

The immune algorithm [Toshio *et al.* 2005], which emulates the biological immune system, is mainly composed of the genetic algorithm (GA), which is used to reform solutions/antibodies of the next generation, memory cells, which are used to conserve higher-affinity solutions/antibodies, and suppressor cells (T-cells), which are used to suppress the re-seeking of higher-affinity solutions conserved in memory cells, and proposed to solve optimization problems.

3.1 Computing Procedure

[Step 1] Recognition of antigen. Antigens and antibodies correspond to objective functions and associated feasible solutions. In this algorithm, memory cells are used to conserve higher-affinity solutions/antibodies, which can be regarded as a set of feasible solutions. In addition, objective/antigen and solutions/antibodies are defined as LCC (C_T) and maintenance plans of an RC beam or column in this research, respectively.

[Step 2] Randomly initialized antibody population. Similar to the GA developed by Manabu [Manabu & Takafumi 2001], the initial population of antibodies utilizing a multi-variable binary-code string is generated randomly. In this paper, four bits are used to express one repair/retrofit work including the method (2 bits, 2^2 kinds) and time (2 bits, 2^2 kinds) this method was planned, as illustrated in Fig.7. Further, each maintenance plan has a maximum of ten repair/retrofit works; therefore, 40 bits are built in one antibody.

[Step 3] Calculating affinity of antibody-antigen or antibody-antibody. In this paper, the inverse of the LCC is used to express the affinity of the antibody v and the antigen, as shown in Eq.(13). Clearly, the greater the affinity, the lower is the LCC caused by the antibody v and its higher grade.

$$\Phi_v = \frac{1}{C_T} \quad \text{.....(13)}$$

The affinity Ψ_{vw} between antibodies v and w is defined as the ratio of the similarity of binary code strings in them. Note that $0 \le \Psi_{vw} \le 1$, and when $\Psi_{vw} = 1$, the antibodies v and w are identical.

[Step 4] Calculating concentration of antibody. The concentration Θ_v is used to express the similarity of the antibody v with other antibodies, as shown in Eq.(14)

$$\Theta_v = \frac{1}{N}\sum_{\omega=1}^{N}\pi_{v\omega} \quad \text{.....(14)}$$

where N = the number of antibodies. If $\Psi_{vw} \geq T_{\pi 1}$, $\pi_{vw} = 1$; otherwise, $\pi_{vw} = 0$; $T_{\pi 1}$ = user-defined threshold value that illustrates the allowable difference between two antibodies.

In this algorithm, as the concentration increases, the higher probability is selected as the memory cell and suppressor cell.

[Step 5] Antibody differentiation into memory and suppressor cells. If the concentration Θ_v of the antibody v exceeds the user-defined threshold value T_{II}, the antibody v becomes a candidate memory cell. Then, candidate memory cells are chosen for differentiation into a pool of memory cells in the order of the affinity of antibody-antigen and into a pool of suppressor cells in the order of the concentration.

[Step 6] Stimulation or suppression of antibody promotion. In this paper, we use the affinity of the antibody-suppressor cell, Ψ_{sv}, to suppress the creation of similar antibodies. Therefore, if Ψ_{sv} exceeds the user-defined threshold value T_S, the antibody will be eliminated. In addition, in order to add and maintain the diversity of the next generation of antibodies, those antibodies that have a high expected value based on Eq.(15) are chosen to create the next generation by the GA method (including selection, crossover, and mutation).

$$E_v = \Phi_v \prod_{s=1}^{S}(1-\Xi_{vs}) \quad \text{.....(15)}$$

where S = number of suppressor cells. If $\Psi_{vw} \geq T_{\pi 2}$, $\Xi_{vw} = \Psi_{vw}$; otherwise, $\Xi_{vw} = 0$.

3.2 Diversity of Solution/Antibody [Toshio *et al.* 2005]

In this paper, we use the concept of entropy to estimate the diversity of a solution/antibody. First, the diversity of the locus j of an antibody in the same generation $H_j(N)$ can be expressed as shown in Eq.(16). Then, the average value of $H_j(N)$ is estimated by Eq.(17) to represent the diversity of the generation. It could be said that the higher the $H(N)$, the higher is the diversity.

$$H_j(N) = -\sum_{i=1}^{L} p_{ij} \log p_{ij} \quad \text{.....(16)}$$

$$H(N) = \frac{1}{G}\sum_{j=1}^{G} H_j(N) \quad \text{.....(17)}$$

where N = number of antibodies in one generation; G = number of loci in one antibody; L = number of symbols in one locus; p_{ij} = probability of the symbol i appearing in the locus j.

4 CASE STUDY

The optimal maintenance plan for the columns (outside column) [details in Chien-Kuo *et al.* 2007] coated with mortar (Coating-1) and those coated with resin (Coating-2) on the first and sixth floors of a twelve-story RC building are analyzed by the method proposed in this research to prove its suitability. The parameters required for the analysis are listed in Table 1, Table 2 [June & Haresh 1997, Mark G. & Dimitri V. 2003], and Table 3.

The LCC, failure probability, and spalling probability of the columns without maintenance are illustrated in Fig.8. According to the results, when the same finishing material is used, the spalling probability curve of the column does not change with the floor considered. However, because a higher floor has a lower shear demand, the failure probability of the column on the sixth floor is smaller than

that on the first floor. Moreover, we observe the same phenomenon with regard to the LCC. The optimal maintenance plans for columns coated with resin are found by this system and illustrated in Table 4 and Fig.9. When compared with the LCC without maintenance, the optimal maintenance plans yield a definite and effective improvement, irrespective of which floor the column belongs to.

Furthermore, the diversity of the solution/antibody is used to prove the effectiveness of this system and is shown in Fig.10. In the figure, besides the diversity of the memory cell (if in GA, the best 10 are chosen) (SAH), the diversity of each generation is also expressed. With reference to the diversity of solution/antibody in one generation (SH), IA shows more intense variation than GA. Due to the high intensity variation of diversity, IA can suppress similar solutions and does not easily resort to local-solution searching. In other words, IA does not converge to one solution by the original adjustment mechanism (suppressor cells). In addition, the diversity of the memory cell increases with the generation and lasts until the end of the analysis. It also can be said that IA has the ability to research semi-optimal solutions with a high diversity in a single analysis.

Table 1. Parameters for the estimation of deterioration

Compression strength of concrete (kN/mm^2)	25
Thickness of mortar (Coating-1,mm)	20
Thickness of resin coating (Coating-2, mm)	0.05
Carbonation coefficient ($mm/year^{0.5}$)	7.57

5 CONCLUSIONS

In this paper, we described a system that can estimate the deterioration risk of carbonation caused by earthquakes. We also applied the immune algorithm to minimize the LCC, including the deterioration risk, and find the optimal maintenance plan for an RC beam or column. According to the results of the case study, besides the optimal maintenance plan, semi-optimal solutions with high diversity are also provided in a single analysis. In other words, the system can obtain multiple maintenance plans with high diversity, thereby allowing a user to select the suggestion he/she finds most appropriate.

T 72

ABSTRACT

Reinforced concrete buildings which for various reasons have completed or are about to complete their life cycle have become one of the most important issues of the decade. To demolish these buildings and to rebuild new ones that meet new requirements is one option to solve the issue. However construction and demolition waste to be generated during this process cause environmental loads. Another option is to lengthen life cycle of these buildings by appropriate repair and maintenance techniques.

For the long period re-use of the existing building stock and especially for some particular reinforced concrete buildings which reflect architectural characteristic of modern time, it is essential to achieve repair and maintenance techniques without faults and problems. In order to succeed in doing this process, identifying the nature and cause of the damage is a precondition. In this study, the deteriorations formed in reinforced concrete buildings and their causes have been explicated systematically. Current repair and maintenance techniques developed for rehabilitation have been emphasized. In this context, the stages conducted during the rehabilitation process of reinforced concrete buildings/monuments have been presented in a scheme format. The efficiency of the architects and conservators has been tried to determine during the process. The conservation of modern architectural heritage will be ensured by application of this process without fault. At the same time, reassessment of existing building stock and prevention of demolition waste will be an environmental approach.

1 INTRODUCTION

Reinforced concrete buildings which for various reasons have completed or are about to complete their life cycle have become one of the most important issues of the decade. To demolish these buildings and to rebuild new ones that meet new requirements is one option to solve the issue. However construction and demolition waste to be generated during this process cause environmental loads. In many countries, the large volumes of construction waste strain landfill capacities and leads to environmental concerns. Another option is to lengthen life cycle of these buildings by appropriate techniques. For the long period re-use of the existing building stock and especially for some particular reinforced concrete buildings which reflect architectural characteristic of modern time, it is essential to achieve repair and maintenance techniques without faults and problems. In this context, there is a lack of methodology for the rehabilitation process of reinforced concrete buildings/monuments, which requires interdisciplinary studies (engineering, architecture, conservation).

In this study, the deteriorations formed in reinforced concrete buildings and their causes have been explicated systematically. Current repair and maintenance techniques developed for rehabilitation have been emphasized. In this context, the stages conducted during the rehabilitation process of reinforced concrete buildings/monuments have been presented in a scheme format. The efficiency of the architects and conservators has been tried to determine during the process.

2 REASONS AND DAMAGES WHICH REQUIRE THE REHABILITATION OF REINFORCED CONCRETE BUILDINGS

The term of “rehabilitation” is used in architectural field as “adaptive-reuse” and “re-functioning”. The term is also used in engineering field as a comprehensive term to include all the concepts of “repair”, “upgrading”, “retrofitting” and “strengthening” [Fukuyama & Sugano 2000]. Rehabilitation application is a more complex method both in terms of architecture and engineering compared to the construction of a new building. In order to succeed in doing the rehabilitation application without faults and problems, identifying the nature and cause of the damage is a precondition.

Apart from the human factors such as the designer, contractor and user faults manifesting through the design, decisions, selections and applications, there are various factors such as climatic, physical, chemical, biological, mechanical, and geological which directly or indirectly impact and cause damage to buildings [Gaudette *et al.* 1995; Ersoy 2004; Ekinci 2004; Ahunbay 1996; Cosgun *et al.* 2002] [Table 1].

Human factors which lead to the deterioration of buildings:

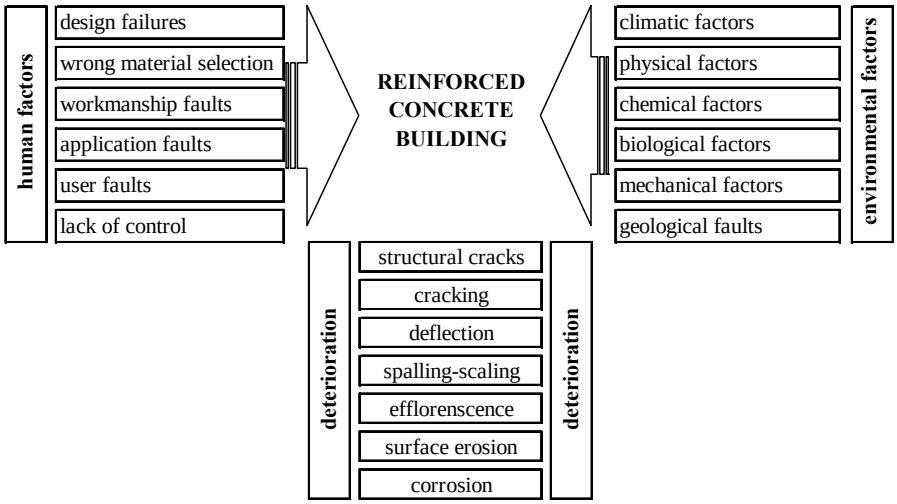
- Design failures: Disregarding user needs and environmental data during the planning and sizing of the space in the building, structural design failure caused by using the wrong or inappropriate system, and inadequate work on detail,
- Wrong material selection: Due to lack of knowledge by the designer, the contractor or the user in terms of building materials, the building materials were not of the appropriate type and standard,
- Workmanship and application faults: Inadequacy of the contractor in terms of project reading, knowledge of building materials and construction techniques,
- User faults: Ignoring the necessary maintenance and repairs, unconscious repairs,
- Lack of control: Failure to comply with the specifications, standards and regulations at the design, workmanship and application and lack of an effective audit system.

Environmental factors which lead to the deterioration of buildings:

- Climatic factors: Rain, wind, thermal differences, humidity, sun,
- Physical factors: Impact, Friction, UV rays, polluting impacts,

- Chemical factors: Oxide impact, air pollution, impact of chemical materials,
- Biological factors: Plants, insects and micro organisms,
- Mechanical factors: Vertical loads, horizontal loads such as wind and earthquake,
- Geological factors: Impact of underground water, soil structure.

Table 1. Types of deteriorations in reinforced concrete buildings and their factors



Types of damage seen in reinforced concrete buildings caused by human and environmental factors are as follows: Structural Cracks, Cracking, Deflection, Spalling, Efflorescence, Surface Erosion and Corrosion [Gaudette *et al.* 1995; Coney 2007]:

- Structural cracks can result from temporary or continued overloads, uneven foundation settling, temperature changes or design inadequacies.
- Cracking occurs over time in virtually all concrete. Sulphate attack which may come from the environment or from one or more of the concrete constituents also leads to the forces that eventually crack the concrete. Cracks vary in depth, width, direction, pattern, location.
- Deflection is the bending or sagging of concrete beams, columns, joists, or slabs, and can seriously affect both the strength and structural soundness of concrete. It can be produced by overloading, by corrosion, by inadequate construction techniques.
- Spalling is the loss of surface material in patches of varying size. It occurs when reinforcing bars corrode or water absorbed by porous aggregate freezes, thus creating high stresses within the concrete. As a result, chunks of concrete pop out from the surface. The surface weakness encourages scaling, which is spalling in thin layers.
- Efflorescence is a white, powdery stain produced by the leaching of lime from Portland cement, or by the practice of adding lime to whiten the concrete. Also stains can be produced by alkali-aggregate reaction, which forms a white gel exuding through cracks and hardening as a white stain on the surface.
- Erosion is the weathering of the concrete surface by wind, rain, snow, and salt air or spray. Erosion can also be caused by the mechanical action of water channelled over concrete.
- Corrosion, the rusting of reinforcing bars in concrete, can be a most serious problem. Normally, embedded reinforcing bars are protected against corrosion by being buried within the mass of the concrete and by the high alkalinity of the concrete itself. This protection, however, can be destroyed in two ways. First, by carbonation, which occurs when carbon dioxide in the air reacts chemically with cement paste at the surface and reduces the alkalinity of the concrete. Second, chloride ions from salts combine with moisture to produce an electrolyte that effectively corrodes the reinforcing bars. Cracking, spalling, deflection are frequent results of corrosion.

3 REPAIR AND MAINTENANCE TECHNIQUES OF REINFORCED CONCRETE BUILDINGS

The architectural significance of the building, its age, existing condition, structural system and whether it is located in an earthquake risk area, are priority factors in taking the decision for rehabilitation. In this context, evaluation studies of the current condition of reinforced concrete building are completed. After the preliminary examination consists of reviewing the current situation and building's documents the analysis study is carried out. This study includes, soil surveys, determining the quality of the reinforced concrete, statically evaluation of the building, and re-functioning studies. If the dimension of the building elements and the quality of the reinforced concrete is adequate, then it may be enough to do only repairs and conservation. However if the study shows the reinforced concrete not to be of adequate quality, then a comprehensive rehabilitation may be required. According to the determined strategy, the project and planning goes ahead using one or more of the available methods.

In the conservation of reinforced concrete, the key issue is whether the existing material can be repaired and conserved or whether it must be replaced. The concrete and the structure must be investigated to develop repair options and strategies. Laboratory analysis of the concrete to be repaired is an important part of the investigation. All repairs of existing concrete require proper preparations to provide a clean, sound surface to which the repair can adequately bond. During the repair existing reinforcement may be also required cleaning, priming, and painting with a rust-inhibitive coating. The repair area should be reinforced and mechanically attached to the existing concrete. Reinforcement materials can include regular steel, epoxy-coated steel, or stainless steel, depending on the conditions. Preparing trial repairs and mock-ups permit evaluation of the designs of the aesthetic acceptability [Gaudette *et al.* 1995].

Various repair methods, available today, reduce the rate of corrosion of embedded reinforcing and associated concrete deterioration. One method is cathodic protection. Cathodic protection is intended to reduce the rate of corrosion of embedded steel in concrete, which in turn reduces overall deterioration. Another technique to protect concrete is realkalization. Other methods include flooding with a corrosion inhibitor or, more aggressive, removing the concrete cleaning the exposed steel coating with a epoxy and covering the new concrete, and then sealing. Concrete deterioration is heavily influenced by moisture penetration; rehabilitation may also entail application of a decorative surface coating or a clear penetrating sealer, if appropriate. These water-resistant coatings and sealers should be breathable and alkali resistant. If specific components in reinforced concrete structures are beyond repair, replacement components can be cast in place to match historic ones. As with surface repairs, placement and finishing will dictate how well replacement concrete matches the historic concrete [Gaudette *et al.* 1995].

Especially in areas of high earthquake risk, comprehensive rehabilitation works are required for reinforced concrete buildings. Many rehabilitation techniques were investigated recent 20 or more years to apply to both pre-earthquake and post-earthquake rehabilitation. The expected performance level of the building following the earthquake (operational, immediate occupancy, life safety, collapse prevention) and the earthquake hazard levels impact the selection of the techniques [FEMA 356 2000];

- Operational level: Backup utility services maintain functions; very little damage.
- Immediate occupancy level: The building remains safe to occupy; any repairs are minor.
- Life safety level: Structure remains stable and has significant reserve capacity; hazardous non-structural damage is controlled.
- Collapse prevention level: The building remains standing, but only barely; any other damage or loss is acceptable.

Methods and elements used in the comprehensive rehabilitation of existing reinforced concrete buildings are as follows [Fukuyama & Sugano 2000]:

a. Infill existing frames
- Cast-in-situ reinforced concrete wall
- Precast concrete or steel panel
- Concrete blocks or brick infill

b. Brace existing frames
- Steel or reinforced concrete brace
- Post-tensioning cables

c. Place side walls
- Cast-in-situ reinforced concrete wall
- Precast concrete panel

d. Jacket existing members
- Steel encasement
- Steel straps
- Cast-in-situ reinforced concrete

e. Provide back-up structure
- Reinforced concrete or steel peripheral frames
- Reinforced concrete or steel buttresses

f. Wrapping existing members
- Fibber sheets
- FRP (Fibber Reinforced Plastic) sheets

Another concept to reduce seismic response is to use base isolation systems. For base isolation [Fukuyama & Sugano 2000]:
a. Rubber bearing systems
b. Friction pendulum systems are presently available.

4 REHABILITATION PROCESS PROPOSAL

Rehabilitation process of reinforced buildings/monuments which require contributions of conservators, architects and engineers has been proposed on the basis of above explications. Main stages and sub-stages of the rehabilitation process proposal and the methods and tools that will be used to reach the activities/results have been illustrated in scheme format [Table 2].

At the first column of the scheme seven main stages of the process; preliminary examination, analysis, determination of strategy decision, planning and preparation of project, control of project, application and control have been displayed. The sub-stages have been presented at the second column. Methods and tools that will be utilized during rehabilitation applications have been displayed at the third column. At the last column, activities and/or results of the stages have been presented. Sub-stages and methods/tools should be chosen according to the architectural significance of the building, its age, existing condition, structural system and whether it is located in an earthquake risk area within the framework of the proposed scheme.

During the implementation of the process -sub-stages, methods/tools and activities/results- the efficiency of the architects/conservators display differences. The efficiency of the architects/conservators during the rehabilitation process is highlighted in the proposed scheme in grey tones. Architects/conservators play most efficient role during -preliminary examination, determination of strategy decision, planning and preparation of project, control of project and control- main stages. Architects/conservators also play most efficient role during the re-use study and control sub-stages.

Table 2. Rehabilitation process proposal for buildings/monuments:

MAIN STAGES	SUB-STAGES	METHODS/TOOLS	ACTIVITIES AND/OR RESULTS	
PRELIMINARY EXAMINATION	**Pre-observation of existing condition**	Determination of visual construction damages		
	Determination of authentic architectural features			
	Investigation of original construction and repair documentations	**Archive research**	**1** Determination of structural damages (Determination of cracking and deflection causes, determination of building components that lost bearing capacity)	
ANALYSIS	Soil surveys (Inspection Hole)	Soil Profile , Ultimate strength , Allowable soil pressure , Settlement analysis , Unit weight of soil , Modulus of shear , Modulus of bulk, Poisson ratio, Modulus of elasticity , Soil fundamental period , Wave velocity P and S , Site Seismic Hazard	**2** Determination of non-structural damages (Determination of cracking caused by corrosion, Determination of shrinkage cracking, Determination of the segregated zone, concrete deteriorations)	
	Determination of material quality	Core sample, Ultrasonics and rebound hammer readings, Determination of rebars diameter and location with pachometer and cover meter, Petrographic evaluation, Chemical analysis		
	Evaluation of building structure	Preparation of structural survey, Determination of accordance with new requirements and regulations of structural system	**3 Determination of re-use alternatives** (continuity of original function, new function possibilities)	
	Re-use study	**Preparation of building survey, Determination of new functioning potential, Determination of conformation of new function to the project, Aboriginal cost analysis**		
DETERMINATION OF STRATEGY DECISION	**Strategy Decision**	**Analysis Result Report Determination of expected performance level of the building** (operational, immediate occupancy, life safety, collapse prevention)	**Repair & Conservation**	Comprehensive rehabilitation strategy: **1** Rehabilitation with seismic resistant techniques **2** Rehabilitation with seismic isolation techniques **3** Rehabilitation with mix techniques (seismic resistant &seismic isolation)
PLANNING AND PREPARATION OF PROJECT	**Selection of material & technique**	**Organization of specialists and technical team**	**1 The Re-Use (Architectural) project**	
	Preparation of necessary detailed drawings		**2** Retrofitting (Static) project	
	Preparation of work plan		**3** Mechanical project	
	Cost analysis		**4** Electrical project	
CONTROL OF PROJECT	**Determination of conformation to related regulations and specifications**	**Academic and professional organs Local and state organs**	**Approval for the application**	
APPLICATION	Taking measures for technical safety	**Organization of technical team**	**Rehabilitated building/monument**	
	Preparation of the building			
	Technical operations	**Conservation methods**		
		Addition of new footing Strengthening of existing footing Infill existing frames Brace existing frames Place side walls Jacket existing members Provide back-up structure Wrapping existing members Rubber bearing system Friction pendulum system		
	Control	**Organization of team**		
CONTROL	**Control of material**	**Academic and professional organs**	**Approval for the use of building**	
	Observation on site	**Local and state organs**		

Efficiency of architects :	**most efficient**	less efficient	non-efficient

CONCLUSION

The proposed scheme will contribute to regularize the rehabilitation process of reinforced concrete buildings/monuments if implemented under the supervision of experts (engineers, architects and conservators). Looking for new solutions and adding new components to the buildings/monuments during the rehabilitation process, in order to bring the buildings to contemporary up to the standards, is acceptable. However, rehabilitation techniques such as the jacketing of the structural system can cause a loss of space because of increased size. This may affect the functional performance of the building to be subjected to rehabilitation. This situation may lead to the decision to demolish these buildings. Because of these reasons optimum solutions should be chosen for sustainability of old reinforced concrete buildings.

The architectural significance of the building, its age, existing condition, structural system and whether it is located in an earthquake risk area are priority factors in taking the decision for their rehabilitation and repair/maintenance techniques. During the analysis non destructive evaluation (NDE) methods have to be preferred. In this context, after evaluation studies of the current condition of the building, if the load resisting system and concrete quality is adequate, then it may be enough to do only repairs and conservation. Otherwise, a comprehensive rehabilitation may be required which needs the contributions of engineers, architects and conservators. According to the determined strategy, the re-use project and planning goes ahead using one or more of determined available methods. It is expected that this proposed rehabilitation process will make available to re-use old reinforced concrete buildings/monuments and it will guide for their rehabilitation.

Service Life Prediction Tools for Buildings' Design and Management

Bruno Daniotti [1]
Sonia Lupica Spagnolo [2]

T 72

ABSTRACT

Service Life Prediction is necessary to evaluate Life Cycle Costs and Life Cycle Assessment for a sustainable construction process. In order to provide a specific time schedule for a sustainable building maintenance, Politecnico di Milano has developed a specific method for Service Life Prediction based on the correlation between users' requirements and measured decays of building components' performance characteristics.

The report deals specifically with the definition of tools and methods to control indoor quality with a performance based approach, which analyses the existing link between user's needs and technological requirements. The performance loads' distribution for functional-technological elements is defined through computational models which relate predicted indoor conditions to technological performance specifications. The stage of technological design has to be supported by methods for calculating and by laboratory or in-site tests. The time behaviour of building components is simulated using time dependant environmental models, thanks to the correlation between performance characteristics' decay (measured by lab programmes) and the conditions established by users' requirements.

The paper reports on the activities undertaken by the Research Group on Durability of Building Components, at Politecnico di Milano's, for the development of operative tools for Service Life Prediction, thanks also to the cooperation inside the Italian research network for durability, born in the framework of the international links with CIB and ISO.

1 INTRODUCTION

A sustainable building process requires to control and to plan the use of material and economic resources necessary during its all life cycle. Designers' choices should be oriented towards building components and products characterised by an economically reasonable Working Life, i.e. which require sustainable maintenance activities, considering the predicted Service Life. In this optics Building Science is fundamental to furnish suitable information to designers to make such choices.

The Durability of Building Components Group of Politecnico di Milano is undertaking some researches to set up methods for building components' evaluation of durability, applying them to building materials and components for external walls. In particular, an experimental programme with a technical solution belonging to the external not load-bearing walls' family has been planned in collaboration with the Swiss technical experimental laboratory of the "Scuola Universitaria Professionale della Svizzera Italiana" (SUPSI) in Lugano. Both accelerated ageing proofs and real exposition ones have been conducted in two different climatic contexts: Milan and Lugano. Thanks then to the comparison between accelerated and natural ageing results it was then possible to evaluate the so called "time re-scaling factor" bringing to the definition of Reference Service Life, in particular, of the external protecting covering layer. Through, eventually, to this factor it is, in fact, possible to say that a certain number of accelerated cycles corresponds to a certain number of years of natural (real) ageing.

2 DEVELOPMENT OF METHODS FOR THE APPRAISAL OF BUILDING COMPONENTS' DURABILITY IN DESIGN PHASES

In 2003, with the co-financing of Ministry of Instruction, University and Research, in Italy a pluriannual research on "Methodologies of planning and evaluating durability of buildings components for sustainable production processes" started: the proposed research programme has developed methodologies for Service Life Prediction of some building components, belonging to the classes of external walls, external casings, continuous and discontinuous coverings.

In this programme, six research units of as many Italian university centres are involved: Politecnico di Milano, Politecnico di Torino, University of Naples, University of Palermo, University of Brescia and University of Catania. Thanks to this collaboration, it has been created a meaningful methodological-experimental reference for the developing of a national net of systematic experimentations on building components' durability both in technological laboratories (tests of accelerated ageing in standard conditions) and in outdoor environment (tests on out-exposed specimens in real conditions of use).

The chief objective of the Italian research network is to develop interoperable modular ICT tools (SW/ Web Services) focused on Service Life and maintenance issues and take into account the knowledge acquired on Service Life prediction methods to plan maintenance and inspection. Such tools have to allow to plan and manage works, responding to the demands and requirements of Designers, Maintenance Planners, Real Estate and Facility Managers and contributing to drive designing choices in civil application from a sustainable point of view.

Thanks to the cooperation among the six Italian research units, Service Life prediction tools will receive input data from a set of the national regionalized information sources, through an ad hoc structured (in conformity with ISO-DIS 15686-8) Reference Service Life Database [Daniotti & Lupica Spagnolo 2007], contemplating also a performance evaluation for feedback of Service Life data from practice.

A particularly meaningful and innovative aim of this research is also to determine conventional performance limits for each building's component in order to recognize the end of Service Life, providing, moreover, an method as suggested by ISO standards.

Moreover, the purpose is to provide a graduate acquaintance of durability, contributing to the international research of CIB and also developing ISO standards in this field through the Italian National Agency of Standardization (UNI). With this aim, in 2006 the Italian standard

That's why, deepening the evaluation methods indicated by ISO 15686 Durability of Building Components Group of Politecnico di Milano has contributed to the developing of methods for the appraisal of building components' durability, useful for the prevision of Service Life and of reliability propensity in the design step. As a first result, this activity carried to the emanation in 2006 of the Italian standard UNI 11156 "Valutazione della durabilità dei componenti edilizi (Appraisal of building components' durability)".

The studied methods are:

– Evaluating building component's reliability method, which can be applied starting from a careful examination of component's design through a functional and technical analysis of the design itself.

  This analysis is developed evaluating the four components of reliability (functional, executive, inherent and critical) and following precise procedural indications. The average of the four calculated reliabilities' values is then assumed as propensity to reliability of the building component's spontaneous duration [Daniotti et al. 1990].

  The evaluation of reliability propensity method can be applied to the technical designing of buildings, according to three opportunities of use.
  - The first opportunity concerns the conception and designing moment of a technical element, trough the optimisation of the four components of reliability, as a useful tool for the "design for durability" and in order to limit designing pathology risk.
  - The second one is about technical element's choosing criteria for its correct use inside a specific building intervention. The application of the esteeming reliability method proposed by DBCG allows the evaluation of reliability propensity at the time of building components' Service Life through this comparison with known components: esteems are the more reliable the more building components (belonging to that repertory) are examined.
  - The third opportunity is to act for buildings' retraining, suggesting design interventions for each functional building's part; this is possible only keeping into consideration evaluations about reliability propensity made on the existing, according to the proposed method.

– "Failure Modes and Effects Analysis (FMEA)": through a systematic analysis of the building organism decomposed in its fundamental components, this method concurs to give precious information in the perspective of a maintenance planning. Its application produces an exhaustive list of all the sceneries of degradations that could be possible in the various steps of building process [Daniotti 2006].

– evaluation of building components' Service Life method: it provides on one hand to obtain, through an experimental programme, Reference Service Life values and, on the other hand to adopt these values as input data for ESL's calculation in the considered context of exposition, of production, of use and of maintenance.

  Among this last family of methods, the Factor one gives an easy contextualization of Reference Service Life values of building components outside the system and the specific context of design. This method is considered one of the main international references within ISO for the valuation of building component's Service Life in the specific conditions of use.

  Politecnico di Milano's research suggests for this method some criteria in order to make more objective and scientifically validated the values attributed to each single factor [Re Cecconi & Iacono 2005]. In this optics, in structuring the Reference Service Life Database, it appears very

important to create grids for every introduced RSL value in order to describe precisely the reference condition and to help the user in calculating the ESL through the Factor method [Daniotti & Lupica Spagnolo 2008].

Eventually, the Performance Limits Method (PLM) has been developed because Service Life prevision must necessarily be based on a performance concept. The aim is to correlate directly building component's Service Life to environmental performances (thermal and hygrometrical comfort) of the space that the components themselves delimit; this allows accomplishing a durabilistic analysis on the capability to maintain during their Service Life the performances for which such components were thought, planned and realized.

2.1 The Factor Method

About the Factor Method, the research group has defined some criteria in order to make as more objective and scientifically validated as possible values given to each single factor. In fact, ISO 15686 has provided a very simple method for evaluating Service Life, the Factor method: thanks to seven deterministic factors, this method tries to model aleatory phenomena, such as climatic agents. That's the reason why the scientific community has showed the necessity to improve the method, through two ways to proceed:

- The first way is based on a probabilistic approach and uses the same equation proposed by ISO standard, but treating factors as aleatory variables. The DBCG's proposal is based on the use of triangular distributions of ISO factors, adopting Montecarlo method for solving the equation [Re Cecconi 2004]. Aleatory variables' use describes better the complexity of decay and provides both the Service Life and an esteem of data's reliability: it is possible to obtain an evaluation of duration with precise probabilistic guarantees. Despite this, the Factor method still remains too subjective.
- The second way to proceed is to adopt guiding grids, which can drive the designer in assigning values to each factor. These grids, obviously, cannot avoid the subjectivity in calculating Service Life, but they move it in the moment of grid creation: that's why grids should be built by experienced people belonging to the building sector, such as manufacturers themselves. In this way grids remove subjectivity during the esteeming factors phase, making it proper even for not experienced people [Re Cecconi & Iacono 2005].

2.2 The Performance Limits Method (PLM)

Durability of Building Components Group has, therefore, developed a method based on the evaluation of durability as the esteem of building component's performance decay till a limit of acceptability: the Performance Limits Method.

This method consists of the five following fundamental moments:
- definition of performance targets;
- individuation of requirements and specification of performances that the component must supply;
- translation of performance specifications into technical functional characteristics;
- individuation of the performance thresholds for Service Life;
- evaluation of Service Life.

The analysis of the performance and functional decay is fundamental to model the degradation phenomena through a linked chain relation: i.e. Agents-Actions-Effects-Degradation (see figure 1).

Once this functional decay relation has been developed for specific components of the assembly, these relations are useful for the designer to verify, for each component, the relevant agents and actions that can cause degradation and performance decay.

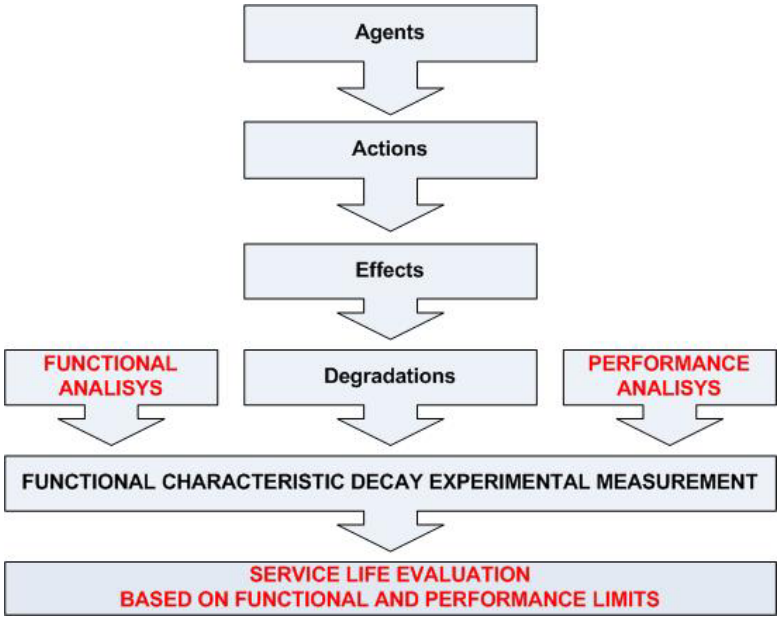

Figure 1. Analyses scheme for building components' durability evaluation.

The durability evaluation derived from results of experimental work gives information on products' Service Life related to environmental conditions, and is useful to help optimise designers' choices for components and component finishes.

The input data for modelling is based on the decay of functional characteristics measured through ageing tests. The experimental Service Life evaluation method reported in paragraph 3 is an application of this method: an analysis of trends for loss of performance characteristics between differently finished components was completed. This was specifically carried out for paint coatings based on acrylic and vinyl resins that are typically used to protect cementitious-based wall renderings.

The component's behaviour over time was measured in regard to the decay of their functional characteristics and degradation phenomena.

Currently, this method represents a valid help when it is necessary to evaluate Service Life in relationship with a precise performance decay.

2.3 Evaluation of the Gravity of Decays and Damages

As a result of the international collaboration between Politecnico di Milano and CSTB (Centre Scientifique et Technique du Bâtiment) a proposal for the evaluation of gravity (Criticality) and the risk consequent to decays and damages has been defined.

The proposed methodology introduces tools and guide lines in order to lead the designer across this investigation, individualizing a hierarchy of the innumerable sceneries returned from FMEA (Failure Modes Effects Analysis) method. These sceneries allow the designer to esteem the more or less gravity of determined sceneries, with temporal indications regarding the frequencies of these phenomena.

With this aim, two indexes were introduced:

a) IG_1 (functional index): to correlate the decay to the no more guaranteed function at the end of a series of events which lead to the not operation of functional elements (or of entire technical solutions);
b) IG_2 (maintenance index): to correlate the decay to the complexity of maintenance required to re-establish the correct initial working.

3 EXPERIMENTAL EVALUATION OF RSL: ONE CASE STUDY

The international standards ISO 15686 introduce a general evaluation methodology divided in two steps:

- the experimental evaluation of Reference Service Life (RSL);
- the prediction of Estimated Service Life (ESL) for the design stage.

The method to predict Reference Service Lives of building components, (i.e. the period of time, after installation, during which a building component meets or exceeds performance requirements in normal conditions of use and maintenance), has been divided into the following five main points:

- definition: of user requirements and of agents influencing building's behaviour (ageing agents, location, etc.), the characterization of building material, etc;
- preparation: identification of degradation agents, mechanisms and effects, choice of performance characteristics and evaluation techniques, feedback from other studies;
- pre-testing: session in order to check mechanisms and loads and to verify the choice of characteristics and techniques;
- exposure and evaluation phase: short term exposure and long term exposure degradations are compared;
- analysis and data elaboration.

Applying this procedure since 1996 a research programme has been developed at Politecnico di Milano: the aim of this research is to evaluate Reference Service Life of external not load-bearing walls with double masonry, thermal insulation inside and two different kinds of protecting covering layers. The criteria followed to choose this technical solution was to opt for a traditionally widespread solution in the building market so that results and considerations could have been more interesting and more immediate to be verified.

3.1 Accelerated Ageing in Laboratory Proofs

Accelerated proofs in laboratory started first of all with not protected masonries and then with protected by paints masonries: the aim was to study the behaviour of external layers of masonries subjected to artificially reproduced climatic stress. For this reason, four specimens at one time were fitted in the climate chamber, with external surface turned toward the centre of it, just in front of the origin of ageing agents stress.

The whole ageing cycle lasts 6 hours and 25 minutes (including transition phases) and is structured as in the following table.

Table 1. Accelarated ageing in laboratory: used cycle

Phase	*Temperature (°C)*	*Relative humidity (%)*	*Duration (minutes)*
Rain	20	95	60
Freeze	-20	95	90
Humid heat	55	95	60
Dry heat + UV	30	40	80

Masonries were then periodically subjected to not destructive characterization proofs: visual inspections of paint's aspect and, through weighting, measurement of residual water; moreover, at the end of ageing period some destructive proofs through core boring were conducted: determination of plaster's compressive strength, adhesion between external plaster and bricks, plaster's porosity, water absorption, vapour diffusion resistance and microstructure.

3.2 Natural Ageing Proofs in Outside

The same elements tested in accelerated proofs were reproduced and exposed toward South for a natural external ageing both in Milan and in Lugano, cities with similar climatic conditions but with different pollution levels [Daniotti & Lupica Spagnolo 2008]. In doing that, two different inclinations were used: the vertical one at 90° and the sloping at 45° one, which, according to ISO normative, should accelerate the natural ageing.

In order to evaluate the damaging during time for the different specimens has been defined a classification of decays through a dimensional scale (from 0 to 3), based on a photographical analysis:
DL0: intact protecting layer;
DL1: local cracks or broken swellings;
DL2: many microcracks and cracks;
DL3: torn bubbles, detaching and saline crystallisation of the surface.

This kind of classification allows analytical comparisons during time and can be then used in implementing diagnostic card in order to define inspection ways for these solutions. Thanks then to the comparison among damaging levels found both in Milan and in Lugano for the two slops, it is possible to sum up the following considerations:

- ageing of sloped at 90° specimens is quite similar for the two localities of exposition; the only important difference is for VL90 specimens (V= vinylversatic resin, L=low concentration of resin) because they are more damaged in Milan than in Lugano;
- ageing of sloped at 45° specimens is faster than ageing of sloped at 90° ones.

In order to correctly interpret the results obtained, climatic data of the two different cities during the exposition period were studied, noticing that in Lugano the quantity of rain is higher and that in Milan values of pollution (PM10, SO_2 and NO_2), solar radiation and medium temperature are higher than in Lugano [Daniotti & Lupica Spagnolo 2008]. As a consequence of these considerations, vinylversatic paints degrade themselves more quickly in Milan than in Lugano because of thermal stresses.

3.3 Comparison Between Accelerated Ageing Results and Outdoor Natural Ageing Ones for Reference Service Life's Evaluation

Comparison between accelerated ageing results and outdoor ageing ones (analysed on the surface through optical microscope) gave the possibility to define the time-rescaling factor and, eventually, the Reference Service Life for the considered paints. In fact, specimens covered by high concentration of vinylversatic resin paints show the same levels of damaging after 150 cycles in laboratory and 4 years of outdoor natural exposition: presence of many torn bubbles and detaches. It is then possible to quantify the time-rescaling factor: 150 of the accelerated used cycles correspond to 4 years of natural exposure. Moreover, considering the performance decay evaluation of the external water protecting layer, quantified through water absorption measurements, it was possible to state that the Reference Service Life for Vinylversatic paints with low concentration of resin is 4 years.

The experimental programme is still going on in order to quantify Reference Service Life also for the other tested paints, but, in summary, it can be already asserted that:

- acrylic paints show a better protection than vinylversatic ones;
- high concentration of resin increases the protection.

5 CONCLUDING REMARKS

Service Life evaluation methods described by ISO 15686 still need precise tools for their application and, most of all, for obtaining reliable predictions. Following this guiding principle, Politecnico di Milano has been working to develop new tools for durability's evaluation and to improve existing ones: on one hand Durability of Building Components Group has defined a method to determine

building components' reliability propensity while on the other hand it is developing Service Life planning thanks to RSL's definition based on a performance approach and ESL's evaluation applying enhanced Factor methods.

Eventually, to make the application of these methods possible and to share results coming out from undertaken researches, a Reference Service Life Database is going to be developed, chief tool for the actual use of such evaluating Service Life methods.

ABSTRACT

In accordance with the principles of "sustainable development" and "performance-based building", building components are expected to maintain their required performance levels over their service life. This is typically achieved through the use of planned maintenance interventions. However, providing relevant management of building components likely requires both the identification and evaluation of the most critical degradation scenarios. Failure Modes and Effects Analysis (FMEA), is a method developed in the 1970s in the industrial domain, and has more recently been adapted to the construction domain as a mean to identify all the possible degradation scenarios. From all the available results obtained from the FMEA, the most critical scenarios are established on the base of a further analysis of the criticality of these scenarios, so obtained through a FMECA ("C" for criticality). In this paper, two variations of methods are proposed to complete the criticality analysis. The first method is based on the formalisation with expert's system of the relation between elements, environment, functions and degradation in order to perform FMEA. The second one is based on unifying and aggregating relevant service life data in order to obtain the service of building component in a given environment. This paper provides: (1) An overview of the FMECA method; (2) A brief review of the state-of-the-art on FMECA research for and application to the construction domain; (3) Method based on expert's system to perform FMEA (4) Method of service life prediction of building components based on FMEA; (5) Application of the FMECA in a maintenance planning project of building facades.

1 INTRODUCTION

Building components are expected to maintain their required performance levels over their service life (SL). This notion is in accordance with the principles of sustainable development [Charlot-Valdieu & Outrequin 1999] and those of the "performance-based building" as espoused in the PeBBu project [Lee & Barrett 2003]. Over the life of a building component, its' performance levels depend, on the one hand, on the quality of the design and, on the other hand, on the quality of the maintenance affected during its SL. Research has evidently been completed in these both areas; however in this paper emphasis in placed on the SL of building components as it relates to the management and planning of maintenance.

The management and planning of maintenance of building components focuses on information, of two types: (qualitative and, quantitative information). Qualitative information regroups the knowledge of the structure and the function of the building component, as well as the phenomena that deteriorate the component, the causes of these phenomena and their possible consequences. Among all available methods of failure analysis (e.g. hazard and risk analysis, failure tree, butterfly knot, etc.), the failure modes, effects and criticality analysis (FMECA) seems to be the most appropriate for obtaining such type of qualitative information.

In this paper, a succinct presentation of the FMECA method is provided followed by a brief overview of the state of the art on FMECA research as applied to the construction domain. Given that different building components may be comprised of similar materials, functions and degradation scenarios, an evident idea is to formalise the commonality among components such that the process of conducting a FMEA can be automated; this approach is presented in a subsequent section of the paper. The quantitative information necessary for the management and the planning of maintenance are, on the one hand, information related to the SL of the building component and the duration of the respective degradation phenomena and, on the other hand, information on the cost of the maintenance or repair actions. A method that allows obtaining these durations is presented and the final section offers information on a project in which FMECA is used within a maintenance management model for building facades to help plan maintenance actions.

2 AN OVERVIEW OF THE FMECA METHOD

The FMECA is a method that is used to identify all possible degradation phenomena of a given building component in a specified in-use environment. The in-use environment relates to the specific context in which it is used, namely its function, performance requirements and environmental factors affecting its long-term performance. As well, it permits determining the series of degradation phenomena, referred to as degradation scenarios, associated to a particular component and environment. For each degradation phenomenon that is identified, the causes, consequences, and related damaged functions of the building components is determined; in this manner, the failure modes of the building component may be then determined.

Historically, the FMECA was developed in the 1970's in the development of nuclear arms domain and thereafter, in the aeronautical domain [Dyadem Press 2003]. This method has since been widely used in different industrial fields such as the aerospace, chemical, automotive fields as well as in the highly critical field of design of nuclear power plants. At the present time, this failure analysis method is one of the most universally used in the industrial domain.

Before undertaking an FMECA, it is essential to have in-depth knowledge of the building component being analysed; that is to say, have knowledge of the elements and materials of which the components is comprised, the functions ensured by this building component and its in-use environment. This may entail categorising several sub-environments (e.g. for a façade component, defining external and internal

environments) and the corresponding environmental agents (e.g. rain, temperature, thermal shock, etc.) associated to each of these situations. This knowledge may be obtained by first completing a component constituent analysis and thereafter, a functional analysis of the building component. To facilitate this first step in the analysis, certain databases have been developed [Talon 2006] that provide information on: (1) environmental agents (regroups all environmental agents that may compound the primary environments of building components); (2) function of building components (regroups all generic functions ensured by building components) and; (3) degradation phenomena (regroups 120 generic degradation phenomena).

The results of FMEA are quite often summarized in an FMEA table in which the information is typically provided in five columns: (1) functions identified during the functional analysis, (2) elements of the building components identified during the constituent analysis, (3) degradation phenomena appropriate to the component and function, (4) causes of these degradation phenomena and, (5) consequences arising from theses degradation phenomena as these relate to the function as provided in the first column. A same degradation phenomenon can cause damage to several different component functions and can also generate other degradation phenomena. For this reason: (1) there is as many lines in the FMEA table as there are {function, phenomenon} pairs and, (2) FMEA is necessarily an iterative process. Specifically, in an initial review all information "triplets" (i.e., environmental agents, functions, elements) are searched and subsequently, in a second review, the degradation phenomena generated in the first review likewise searched, and so on, until all degradation scenarios that lead to failures of the building component are identified.

Given that FMEA is a systematic process, it is capable of being exhaustive in identifying degradation phenomena; however, the quality of the result depends directly on the knowledge level of those expert seeking to use it for failure analysis of building components and their related degradation phenomena.

An example of FMEA carried out for a solar panel is provided by Talon *et al.* [2004]; it provides details of the different phases of analysis including constituent and functional analysis, and FMEA.

The "C" in FMECA corresponds to criticality analysis; this analysis is one that completes FMEA. The intent of carrying out such an analysis is to estimate the consequences of failure arsing from each degradation phenomenon or degradation scenario, as the case may be. This then permits classifying the consequences of failure by degree of criticality such that these can then be used to determine which maintenance actions are most important to complete.

Generally, the degree of criticality corresponds to the product of three criteria: (1) the likelihood of occurrence of the phenomena, (2) the level of significant related to the consequence of failure of the component and, (3) the degree of detectability of failure [Faucher 2004]. Each of these criteria is typically assessed with quotation grids that are scales varying from [0; 10]. Several variants of this formulation are used when two criteria [Sctrick & Goussy 2003] or five criteria [Department of Defence 1980] are considered, or when the criteria product is replaced by a weighted product [Sahraoui 2006] or by fuzzy inferences [Bowles & Pelaez 1995].

3 BRIEF STATE OF THE ART ON FMECA RESEARCH FOR AND APPLICATION TO THE CONSTRUCTION DOMAIN

A succinct review of different approaches in the construction domain that are based on FMECA is presented here in which information is provided on the use of FMECA in different international projects carried out in the past 9 years; a more detailed description of this state of the art is provided in [Talon *et al.* 2006].

The approach adopted by the Aspen Research Corporation [2002] is based on carrying out FMECA in order to qualitatively and quantitatively explain the degradation mechanisms of double-glazed

insulated glass (IG) units. This study corresponds to a Department of Energy (US) project entitled: "An Insulating Glass Knowledge Base". This knowledge base of the more critical failure modes of IG units provides behaviour models so as to determine the characteristics of accelerated short-term exposure tests to be used in validating these models.

At the Building Research Establishment [Barlett & Clift 1999] the use of FMECA is integrated in a global approach for the improvement of the supply chain of buildings during their whole SL cycle. In this context, FMECA is used as a method for identifying the more critical failures of the supply process. In this way, this approach allows supplying a "Reliability Centred Maintenance" program that aims to optimize the process reliability. As such, it provides descriptions of corrections actions or modifications required during either the management or during design phases.

In the context of a project led with cladding manufacturers, the Centre for Window and Cladding Technology [Layzell & Ledbetter 1998] applied FMECA to study cladding failures at the elemental, system, and building process level. The aim of this study was to improve cladding quality during the design phase and to facilitate the inspection and survey actions during the installation phase.

The SP Swedish National Testing and Research Institute [Carlsson *et al.* 2002] applies a method quite similar to FMEA, referred to as the Initial Risk Analysis (IRA). IRA is completed in order to determinate possible failure modes of solar panels. The aim of this study was to qualitatively define the parameters that influence the durability of the building component. These parameters were then studied by completing ageing tests on specific components of the assembly. The development of mathematic models and their correlation with experimental test results allowed assessing the SL of the solar panels. This study was completed in the framework of an international project entitled: "Durability assessment methodology development" (International Energy Agency Task 27 Proj. B1).

The approach undertaken by the Polytechnic of Turin [Pollo 2003] was improvement of the SL of building components from the design phase and consisted in combining three methods: FMEA, "Life Cycle Cost", and "Maintenance Cost Planning". This method aimed to: (1) foresee the degradation rates of components when taking into account their in-service use; (2) improve their maintenance, and; (3) optimise their global cost over their SL.

The approach proposed by Wyatt [Wyatt 2005] consisted in integrating FMEA and the fault tree method into the control and audit procedures for assessing building performance. The FMEA is used to identify any possible errors made during the building design phase.

In France, the Cemagref [Peyras 2002] integrates FMEA in a novel method for the management of dams; this method combines a knowledge base of ageing mechanisms and a database of ageing history of dams that facilitate the failure diagnosis for a specific dam. FMEA allows developing the knowledge base by, on the one hand, structuring expert opinions relevant to the ageing of dams and, on the other hand, by establishing the cause-effects relations and possible degradation scenarios.

4 METHOD BASED ON AN EXPERT SYSTEM PERFORMING FMEA

The objectives of an expert system are to assist FMEA by computer in order to:

- Accelerate the "time consuming" phases of the study;
- Obtain a better formalisation and reuse of existing information such as degradation phenomena, results of previously performed FMEA on other building components;
- Build and to feed the knowledge base on environmental agents, functions, materials, and degradation scenarios.

The use of an ontological approach, which is simply a formal model that allows expressing assertions in a structured manner, permits thereafter to render the model "computable". Ontology is a formal representation of a system from a certain point of view, a specific perspective. Such a representation

provides details of concepts of the system and the interactions or interrelations that exist between concepts [Gruber 1993]. For instance, one can study a low-emissive, double-glazed, insulated glass unit in its environment, from the point of view of its thermal properties or its thermal performance. Once the model is developed, it is then possible to capitalize on different aspects of knowledge of the unit as different "instances" of this model, and in so doing, ensure that this knowledge is completely structured and hence, computer accessible. These instances are expressed as for example:

My **component** Frame *is composed of* **material** "Aluminium". My **component** "Frame" *has as a* **function** to be watertight. My **Environment** External *contains* the **environmental agent** Humidity, Gas, UV, rain, etc.…

An example of providing information on the interrelation between concepts one may have:

The **Environment** External is in contact with the **component** Frame…

In the example, words in bold face are concepts of which the model is comprised, those in italic give the relation between concepts, and underlined words are specific instances of the model). Hence, the set of "instances" allows describing a building component on which one wants to perform the FMEA. Figure 1 provides an example of a generic building component model.

The various "instances" that together describe the product form the basis on which one identifies the possible set of degradation scenarios according to the information one can extract and thereafter, studies the consequences of these scenarios.

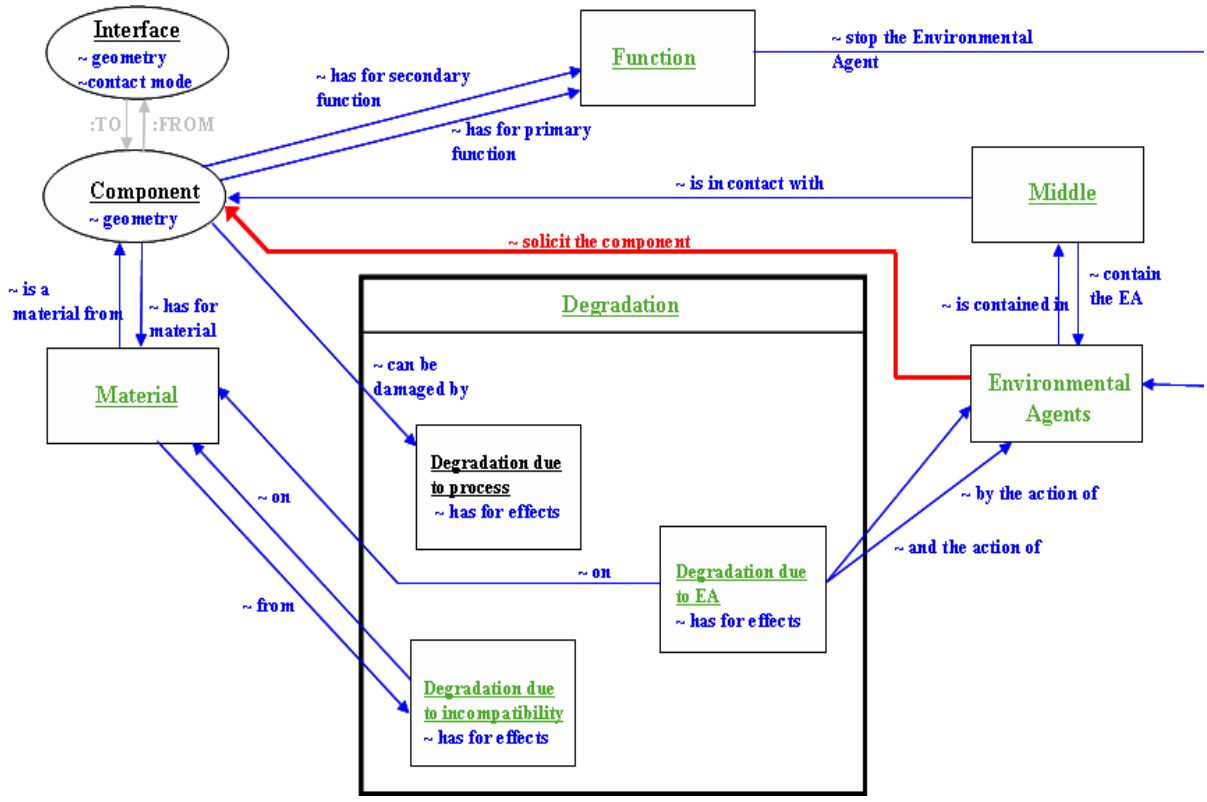

Figure 1. Description of the ontological-based product model from which FMEA can be performed on building components.

5 METHOD OF SERVICE LIFE PREDICTION

This paragraph provides a summary of a method based on FMECA that assesses the SL of building components; this SL estimate is essential information for the planning of maintenance of buildings.

This method uses all available data collected from several sources. The intent of the assessment process is to obtain the SL of a given building component in a given environment when all degradation phenomena and degradation scenarios implicated in the deterioration the functions of this building component during its SL are taken into account.

Two key practical elements must first be considered when retrieving SL data for a given building component and complimentary environment data. Data is: (i) not often available and, on the other hand, data does not necessarily have an acceptable level of quality. Given this situation, the following two-phased approach was proposed as a means to render the information useful: (i) the first phase is used to assesses the quality of each collected data set and; (ii) the second phase consists in combining all collected data of acceptable quality in order to obtain a harmonized data set that regroups those sets that together reflect the maximum consensus among the data sets, and an indicator of the quality of concurrence of the service life data.

The second phase may be formalised as a procedure. The process is initiated by carrying out research for all relevant SL data related to the given building component and its intended in-use environment. Thereafter, an assessment of the quality of each of the collected data sets is completed. Should the quality of the data be acceptable, then the entire collection of SL data is transformed into a plausibility format that allows categorising the different types of available data as being, e.g., derived from expert opinion, based on statistics, or extracted from a probabilistic method of SL estimation. Thereafter, the SL data set is harmonised using data fusion rules. From this process, the quality of concurrence of the SL data is obtained and related data quality indicators are provided (i.e., values for belief, Smets's probability, and plausibility functions respectively [Talon 2006]).

In the case where the quality of the SL data collected is not acceptable, research is then focused on the degradation phenomena identified during the FMEA and information on the duration of the phenomena is sought. Similar steps are then taken in this portion of the process: the quality of collected data is reviewed; data is transformed into a plausibility format, data is harmonised; the quality of the concurrence of the data is provided in terms of the data quality indicators. Finally, the results are aggregated at the phenomenon level in order to obtain the SL of the building component, thus taking into account all the degradation scenarios of the component. Specifically, for each degradation scenario identified from FMEA, the duration of each phenomenon of which the scenario is comprised is assessed. The duration of each scenario is then equal to the sum of the durations of its constitutive phenomena. The same assessment process is completed for all identified scenarios. Finally, the service life of the building component corresponds to the minimum value of durations extracted from these degradation scenarios. The proposed method for SL prediction is provided in more detail by Talon in [Talon 2006].

6 APPLICATION OF FMECA IN A MAINTENANCE PLANNING PROJECT FOR BUILDING FACADES

This project focuses on the development of a Markovian-based, building façade maintenance management (BMM) model that permits the optimization of maintenance planning, and introduces software that permits a user to initiate building maintenance actions. The intent was to provide building managers who are faced with having to maintain their buildings assets more efficiently, with a tool that could reduce the short and long-term costs of maintenance and rehabilitation. In essence, the BMM software can either optimize maintenance planning actions based on an expected maintenance budget or determine the budget required to maintain the façade to a minimum acceptable level of performance. An overview of the project is provided in [Kyle et al 2008] and a schematic of the primary components of the software is given in Fig. 2; details in respect to the Markovian approach to façade maintenance management is given in Lacasse et al. [2008]. The façade was first considered in development of the BMM software given that it is a significant element of the building envelope and of the building itself.

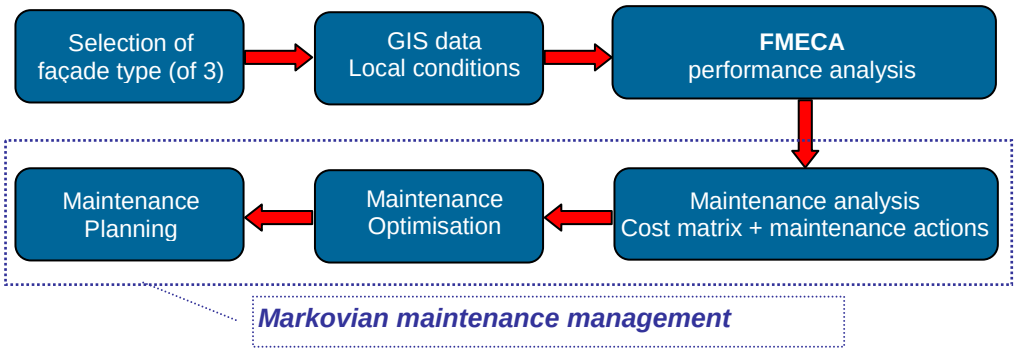

Figure 2. Schematic key project components of BMM model [Lacasse et al 2008].

The BMM model is built on several parts, however one of the key components is FMECA and performance analysis of the façade and related components; the several steps of this process are provided in Fig. 3 [Lacasse et al 2008]. The first step consists of developing a façade component criticality index. This is based on outcomes of a FMECA and permits determining the relative importance assigned amongst the different façade components, as proposed by [Talon 2006].

The basis for determining component criticality resides with understanding the criticality of the different degradation scenarios. Since the criticality of the different degradation scenarios is known and given that a degradation scenario may affect various components, the component criticality is equal to the maximum scenario criticality of the component, or simply:

$CC_j = \max (C_{r_{ij}})$ criticality of component *j*

where $C_{r_{ij}}$ represents the criticality of degradation scenario *i* affecting component *j*. Once the degree of criticality of the component is known, classifying components in respect to their relative degree of criticality is given by the ratio of the component criticality to the overall criticality of the façade system comprised of a number of components, i.e.:

$IC_j = CC_j / \Sigma CC_n$ degree of importance of component *j*

where, CC_j is the criticality of component *j* and ΣCC_n represents the sum total of criticality for *n* components of the system.

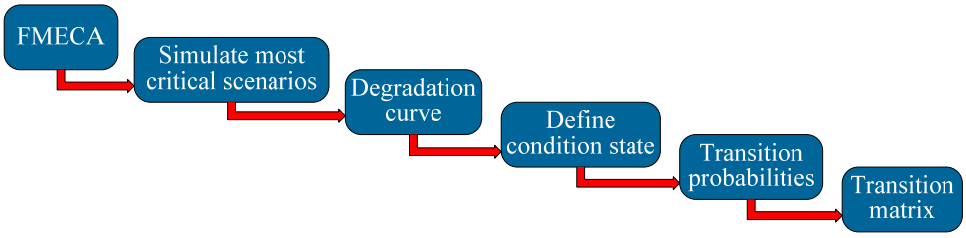

Figure 3. Description of performance analyses and development of Markov condition state matrices for service life estimation.

Given that building managers do not necessarily dispose of unlimited budgets for maintenance actions, only the most critical set of components are further analyzed by simulation of the deterioration process. These simulations provide degradation curves of the change in condition state of façade components as a function of time. The different condition states are then defined ensuring that it is possible to observe these conditions during an inspection. The condition state matrix provides information on the likelihood of a component remaining or changing state at given inspection intervals. Thereafter, the transition probabilities that correspond to the different sates are deduced that in turn permits obtaining the transition matrix. Such a matrix permits estimating the service life of components, or assembly of components, through an analysis using the Markovian model.

7 CONCLUSIONS

FMECA has been shown to be an essential method for failure analysis in the planning of maintenance and maintenance management of built assets. Indeed, this method allows obtaining a broad range of qualitative information (phenomena, causes, consequences) useful for planning maintenance. It provides a hierarchy of and direction for maintenance and repair actions to be undertaken by providing the real causes of degradation or failure. This method is also the basis, on the one hand, of an expert system for performing FMEA, representing a primary advantage for the efficient use of this method and, on the other hand, of quantitative methods for assessing the service life of building components, this latter item, essential information for planning maintenance. The wide range of different applications based on FMECA as well as its use in a maintenance planning project for building façades helps illustrates the relevance of this method in the construction domain.

Condition Assessment of a 63-year Old Reinforced Concrete Structure Exposed to the North Sea

Robert E Melchers [1]
Chun-Qing Li [2]
Mark Davidson[3]
Shangtong Yang[4]

T 72

ABSTRACT

This paper describes the condition of a reinforced concrete balustrade consisting of some 1000 individual beam elements all exposed similarly to the hostile marine environment of the North Sea at Arbroath, Scotland since 1943. A comparison is made of the condition of the original construction with the condition of repairs carried out in 1968 and in 1993. It is shown that the 1943 construction shows very little corrosion-induced cracking and little rust staining even though it does not appear to be of high construction quality. Only a very low percentage of the balustrade beams have been replaced. In contrast the beam installed in 1968 and later in 1993 show very considerable and large concrete cracks directly attributable to the corrosion of the longitudinal reinforcement, even though the concrete is of a higher quality and density.

A detailed condition survey and statistics of crack sizes are presented in the paper. It is found that the higher corrosion resistance of the 1943 concrete is generally consistent with the concrete electrical resistivity measurements but the degree of corrosion of the reinforcing bars is inconsistent with chloride penetration measurements. The results are compared with the very few observations available in the literature for ageing concrete structures in marine environments. The results cast doubt on the conventional wisdom that chloride content at the reinforcement correlates well with reinforcement corrosion.

1 INTRODUCTION

It is well known that chloride is the predominant cause for the corrosion of reinforcing steel in marine concrete structures. What is less known however is to what extent the chloride (content) affects the corrosion, in particular the corrosion process. One measure widely used is the critical ratio of chloride to hydroxide ions for corrosion initiation with acceptance levels defined largely arbitrarily [Bentur et al. 1997]. However, the mechanisms involved in corrosion process including the propagation phase continue to be poorly understood [Melchers and Li 2006]. Although there are many structures with high degrees of reinforcement corrosion after only a few years service, there are also some isolated cases of no apparent occurrence of corrosion even after long exposure periods including in normally highly aggressive environments [Lukas 1985, Lau et al. 2007]. Relevant to these observations is that some laboratory experiments have shown that although corrosion initiation can occur quite early but that there may not be continued active corrosion until much later [Francois and Maso 1988, Li 2002].

Unfortunately, there are very few older reinforced concrete (RC) structures exposed to marine exposure conditions for which detailed investigation have been reported [Lau et al. 2007, Poupard et al. 2006, Liam et al. 1992, Weibenga 1980, Gjorv and Kashino 1986, Polder and de Rooi 2005]. This means that direct comparison to more recent concrete structures is difficult in general. One case that does allow such comparison is available at Arbroath, Scotland, where there is a 1.5 km long RC promenade railing exposed directly to the North Sea. Particularly during winter storms seawater washes over the railing. Importantly, the railing consists of 244 nominally identical sections each composed of 4 precast concrete railing beams set in cast-in-situ posts (Figure 1). There are therefore nearly 1000 nominally identical 'samples'.

Figure 1. Typical (part-)section of the RC promenade railing showing the four precast railing beams, the cast-in-situ central support and the left end-post.

Initial construction of the promenade railing was in 1943. It has been estimated that about 1% of 1943 the railings were replaced in. 1968 and about 10% in 1993. Unfortunately details of the original 1943 design and concrete and reinforcement properties and those of the replacements in 1968 are not available. recent sand laboratory observations show that the 1943 beams contain four 6 mm diameter bars with a nominal (but highly variable) cover of about 20-25 mm. The 1993 beams contain only two bars (16mm) on the vertical axis with 25mm cover. The 1968 beams are similar except that the bars were coated with a commercial zinc-rich primer. Also, the concrete used in the 1993 beams was air-entrained, apparently to counter problems with freeze-thaw behaviour.

These observations and details were considered to present a good opportunity to obtain some further insight regarding reinforcement corrosion of essentially similar concrete elements exposed to similar

marine environment conditions but for concretes with considerably different ages. The comparative study of these elements is the purpose of the present paper.

2 CONDITION SURVEY

The structure was surveyed in detail during the summers of 2003 and 2006. Matters recorded included overall condition, and rack size, length and depth, concrete blistering and spalling. The extent of exposed reinforcement and evidence of repairs (such as patching) were noted also. Table 1 presents an abbreviated summary of crack size.

Visual examination of the surface texture of the three types of beams revealed considerable differences. The 1943 beams all have a rough surface with some external wear and some deterioration of once sharp edges (Figure 2). Close examination showed that these beams were constructed using aggregates of widely varying size and the concrete also contains a significant amount of crushed seashells. These were identified both by their characteristic shapes and through testing with a very fine application of hydrochloric acid.

Table 1 Summary of crack sizes in 2003

Bay No.	Origin year	Crack Size (mm)			
		A	B	C	D
11-14	1993	3-7	3-7	3-8	3-7
16	1993				
21-24	1993	0-10	3-10	6-19	5-12
47	1993	8	8	3	12
48	1993	12	15	10	20
57	1968/93?	5	12	10 (11)	10
59	1993 ?		10		
60	1993	12	15	12	12
61	1993	5	5	6	10
62	1993	3	3	3	5
63	1993	10		5	
64	1993			5	
79	1993	10	7	2	2
87	1993	4	1	4	4
102	1993	10	2	3	
113	1968	5	7	3	10
118	1993	-	12	7	12
126	1968	8	7		
212	1943?			2	

Figure 2. Typical condition and surface roughness of 1943 (left) concrete railing beams.

Only about 2% of the 1943 railings still in existence in 2003 showed minor (hairline) cracking and minor local spalling. In contrast, most of the 1968 and 1993v replacement railings are badly cracked longitudinally. There is clear evidence within the cracks of very heavy corrosion of the reinforcement steel (Figure 3).

Figure 3. Typical crack pattern in 1993 railing beams

For the 1968 and the 1993 concrete beams the exterior surfaces generally show a smooth and dense surface texture. This suggests a well-graded concrete mix at the surfaces. They also show sharp edges. This suggests a good quality concrete. Rebound hammer tests were carried out at three locations (centre and towards the ends of each beam) on surfaces rubbed smooth using a carborundum stone for randomly selected samples of each beam type. Table 2 shows the results. These tend to be consistent with the superficial observation of surface density for the 1943 and 1968 beams. However, the 1993 beams appear to have rather lower than expected rebound results. This could be the result of the use of an air-entraining agent for the 1993 concrete.

Table 2. Rebound hammer results

	Construction		
Position	1943	1968	1993
1 (mean of 10 tests)	41.1	47.4	42.5
2 (mean of 10 tests)	38.4	47	41.4
3 (mean of 10 tests)	42.1	47.4	38.4
Average	40.5	47.2	40.7

Microscopy observations of the 1993 concrete showed a considerable number of voids (Figure 4). These are likely to be also the result of the use of an air-entrainment agent. The imposed grid is 10

mm. A resin was used to reveal more clearly the cracks, voids and aggregate. The image has been modified to give greater intensity and contrast. It shows a high degree of good cement bond.

The 1943 beams show some localized blistering and spalling of the concrete cover but no serious cracking. Hairline cracks offset from the centreline were observed. These are likely to be the result of the corrosion of the 6mm reinforcing bars relatively close to the exterior surface. The 1943 beams show about 5% of the with localized patch repairs. However, many exhibited some degree of minor rust staining on the exterior surfaces. These various observations suggest that very localized corrosion initiation had occurred for many of the 1943 beams but that by 2003/6 it had not yet progressed to the stage of inducing spalling of the concrete cover. Most the 1968 and 1993 replacement beams, on the other hand, showed severe longitudinal cracking with very large crack openings (Figure 3). Only some 25% of these beams remained uncracked in 2003/6. Moreover, nearly all of the longitudinal cracking was of considerable crack size, much more than would be expected according to the standard linear damage model. This suggests that damage and hence cracking increases gradually with age after corrosion initiation [Bentur et al.1997].

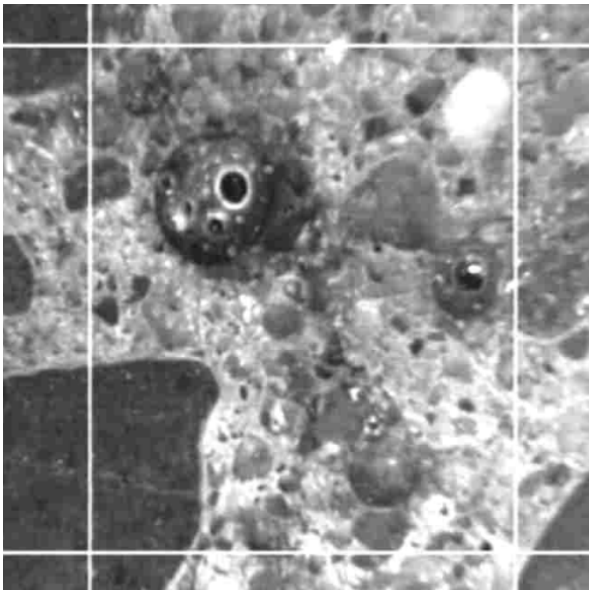

Figure 4 Micrograph of a typical section of concrete in the 1993 beams

3 CRACK STATISTICS

Maximum crack size as a function of period of exposure and year of construction are shown in Table 3 as at 2006. It is interesting to note that there is clearly some artificialness owing to to the usual preference in measurements for discrete sizes. Nevertheless, it is clear that the 1943 beams show much lower overall crack sizes also that many of these beams uncracked. In contrast, the 1968 and 1993 beams show a very substantial number of cracks and most of these are of large size. The considerable difference between the crack sizes indicates that it is highly unlikely that it is due to randomness in cracking, as has been suggested for reinforced concrete structures generally [Bamforth 1999]. Table 1 shows that of the 22 sections (i.e. 88 beams) reconstructed in 1993, only 22 beams have survived to 2006 without significant cracking. Moreover, the data from 2003 and the 2006 surveys shows that of the 1993 beams, about 9 beams failed during this time interval. This can be interpreted as an annual failure rate of about 0.5%. The failure of 66 beams from 1993 to 2006 suggests that the remaining 22 beams could be expected to fail in 3-5 years, that is 2010 or so.

Table 3. Frequency of maximum crack size

Maximum crack size (mm)	1943	1968	1993
0	222	0	0
1	4	0	1
2	18	1	5
3	2		10
4			7
5		3	9
6			5
7		1	6
8		2	2
9		1	2
10		2	11
11			
12		1	7
13			1

Similarly it is estimated that for the 2 beams still remaining from 1968 these can be expected to fail by about 2008 and by 2010 all the replacement beams are likely to have failed. The failure rate from then on will be that for the 1943 beams. This can be estimated from the period 1993-2006 if it is assumed (since as noted no records are available) that in 1993 all defective beams, both from 1943 and from 1968, were replaced. If this was done, there would then have been no defective beams left in 1993 and all failures evident in 2003/6 date from that time.

Chloride profiles and concrete resistivity are also being investigated as part of the present investigation and will be reported separately in due course. However, it is noteworthy that the chloride contents for the 1943 and the 1993 beams were similarly high at the reinforcement and that both were much higher than that for the 1968 beams, despite the considerable differences in exposure period for these three classes of beams.

4 DISCUSSION

Using the conventional the bi-linear damage model as a guide for the progression of corrosion with time in RC structures, it might have been expected that both the 1968 and the 1993 beams display a range of crack sizes since the model suggests that damage is a linear function of time after crack initiation and active corrosion has occurred, and cracking should be consistent with damage. Clearly, this expectation is not evident in the observations, even for the population of 1993 beams. This raises the possibility that the linear damage model is not quite correct - recently it has been proposed that the corrosion propagation stage of reinforcement corrosion is much more complex than indicated by the linear damage model [Melchers and Li 2006].

Table 4 gives a summary of the estimates of the corrosion rates, concrete densities and resistivity and chloride profile results. It shows that although the 1943 beams are surviving much longer than the beams constructed in 1968 and in 1993, this durability is not consistent with the lower or similar density and lower or similar permeability of the 1993 beams. Given their long exposure periods, the chloride concentrations at the surface of reinforcement could be expected to be greater for the 1943 beams than for the others, yet this is not the case. Moreover, the conventional thinking about the influence of chloride penetration on corrosion activation (e.g. Bentur et al. [1997]) suggests that the 1943 beams should have failed much earlier than their replacements. The statistics clearly indicate that this is not the case. One measure that is consistent with the loss rates of the 1943 and 1993 beams are the concrete resistivity readings. However, since the exposure conditions for all beams was and remains essentially similar, it might be expected that the concrete resistivity should reflect concrete density. It is surprising, therefore, that this is not the case.

Table 4 Overview of consistency between corrosion and physical properties.

	Corrosion loss rate*	Minimum cover (mm)	Superficial Concrete density	Rebound hammer	Chloride profile	Concrete resistivity
1943	≤ 0.16%	20-25	medium-good	medium	deep	very high
1968	~ 2.3%	20-25	good	higher	1/3 of others	medium-high
1993	~ 5.8%	20-25	good (a)	medium (a)	deep	low

* proportion of beams failed per unit time of exposure; ** from polarization resistance
(a) air-entrained concrete

Similar inconsistencies between chloride content, density and resistivity and durability have been reported by others. For example, Lukas [1985] reported long service lives for road bridges in Austria despite harsh exposure conditions and heavy use of de-icing salts. Lau et al. [2007] found little sign of reinforcement corrosion, despite around 40 years of exposure and only about 23-40mm concrete cover for more than 1000 reinforced concrete cylinder bridge piles exposed in the marine tidal zone in southern Florida. This was a 'striking' contrast with the performance of some other conventional reinforced concrete marine substructures in the same area. They noted high levels of chlorides at the reinforcing bars after 40 years exposure although this resulted only in minor rust staining and little evidence of preferential chloride penetration along cracks.

The above observations and comparisons show clearly there remain a number of issues for further exploration and research. This is despite the view in some quarters that the corrosion of reinforcing bars in concrete is reasonably well-understood and that its control involves mainly the achievement of good quality concrete and high resistance to chloride diffusion [Polder and de Rooi 2005]. The long-term field observations described herein, together with those reported by others [Lukas 1985, Lau et al. 2007], all indicate that in real structures chloride penetration to the reinforcing bars may not be very indicative of the initiation of reinforcement corrosion. It appears to be also not well-correlated with the rate of corrosion. The conventional view, that in order to achieve greater durability of reinforcing bars it is necessary to have greater and/or denser concrete cover is not fully supported by the present observations or those for the Florida piers. It follows that there are still important questions to be answered as to what influences are important and to what extent and duration in the initiation and progression of reinforcement corrosion. Evidently, more fundamental research into the precise mechanics and causes of reinforcement corrosion is required.

5 CONCLUSION

Many of the approximately 1000 reinforced concrete promenade railing elements constructed around 1943 and exposed to a harsh North Sea sea-spray environment for over 63 years show little evidence of reinforcement corrosion However the elements constructed more recently in 1968 and in 1993 show very serious reinforcement corrosion. As a reult they exhibit extensive considerable corrosion damage asuch as wide longitudinal cracking.

The 1943 concrete elements show remarkably good corrosion resistance for their concrete density and rebound hammer measurements, even though these are not consistent with concrete electrical resistivity measurements. Moreover, corrosion of the reinforcing bars was found to be inconsistent with chloride penetration measurements. Overall the observations are not consistent with the usual understanding of the role of chloride concentration and corrosion propagation. It is suggested that despoite decades of investigation of the problem, more detailed research is required to improve understanding of the role of chloride in the long-term corrosion of reinforcement bars.

ACKNOWLEDGEMENTS

The support of the EPSRC (EP/E00444X/01) and the Australian Research Council is appreciated. Mr McCoughlan performed the 2003 field survey and carried out some testing as part of a final year Honours project at the University of Dundee, Scotland.

ABSTRACT

Maintenance of building façades should be an on-going process. However, maintenance prioritization issues are often neglected due to the lack of available tools to assess susceptibility to deterioration. Key components of the façade system most in need of maintenance interventions ought to be identified to prevent premature failure of façade components, to sustain the health and safety of the occupants, and to maintain the serviceability of the system over its service life. The effects of moisture and other climate effects on the deterioration of façade components are known. Likewise, water penetration of the façade from wind-driven rain to the interior causes damage, mould growth and degradation of thermal performance. Knowledge of the combined effects of wind, moisture and thermal loads permits determining the response of the wall, that in turn allows evaluating the hygrothermal performance, dilation at panel joints, susceptibility to water penetration, or the product of combined responses that act to deteriorate the façade system. The most severe combinations most likely to deteriorate the facade can then be determined and thus provide a basis for prioritizing maintenance programs for buildings. The process can be used to establish the risk of deterioration from climatic effects among different types of walls for a given building façade, between the level of risk among different buildings in a given climate, or for comparing the relative effects of similar facades located in different climate zones. This paper provides an overview of a project focused on developing a GIS-based framework for evaluating building façade performance and maintenance prioritization. Climate effects are discussed in relation to wall response and expected damage arising from the deterioration of façade components is given. Loss in functional performance of components is examined and the consequences of these losses are related to maintenance interventions.

1 INTRODUCTION

1.1.Background

Maintenance of high and medium-rise building façades should be an on-going process. Maintenance prioritisation issues are often neglected due to the lack of available tools to assess vulnerability to climatic effects and susceptibility to deterioration. Key components of the façade system most in need of maintenance interventions ought to be identified to prevent premature catastrophic failure of any of the façade components, to sustain the health and safety of the occupants, and to maintain the serviceability of the system over its service life.

The effects of moisture and other climate parameters on the deterioration of façade components is well known; spalling of masonry caused by freeze-thaw action, spalling and degradation caused by salt migration, damage due to expansion of materials or components; loss of adhesion or rupture of jointing products from joint movement. Likewise, water penetration of the façade from wind-driven rain to the interior causes failure of interior finishes, damage to gypsum plasters, mould or mildew growth and degradation of the thermal performance of insulation.

Knowledge of the combined effects of wind, moisture and thermal loads on the façade system permits determining the response of the wall, be it metal-glass curtain walling, stone or brick masonry veneer, prefabricated concrete panel, or other types of wall assemblies. This in turn allows evaluating the response of the wall to climate loads, including the hygrothermal performance, dilation at the panel joints, susceptibility to water penetration or the product of combined responses that act to deteriorate the façade system. Hence evaluating climatic effects in combination with wall response permits establishing the most severe combinations most likely to deteriorate the facade and thus provides a basis for prioritising maintenance scenarios for high-rise buildings. It is proposed that this process can be used to establish risk of deterioration from climatic effects among the different walls for a given building façade, between the level of risk among different buildings in a given climate, or for comparing the relative effects of similar facades located in different climate zones.

Evaluating risks of deterioration of building components from climate effects on buildings in different geographical locations requires the integration of environmental loads to the location of the buildings; given the previous studies completed in this area, it was thought that this would best be achieved through the use of a Geographic Information System (GIS).

1.2.Related Studies

An overview of the use of GIS in the building domain is provided in Haagenrud [2005] and in which a select number of studies are identified that served as a basis for the development of the current project. These include:

Wood-Assess [*Haagenrud* 1999a] and *MMWood* [Haagenrud 1999b; Haagenrud 2001] – These EU-projects combined European resources to develop methods and technologies for the assessment of the conservation state of wooden heritage buildings and mapping of environmental risk factors to these built assets. A condition assessment protocol was first developed and methods for continuous measurements of moisture and temperature in the microenvironment of buildings established in *Wood assess*. Thereafter for the *MMWood* project, these methods were extended to whole buildings in which estimates of environmental exposure of wood components were determined; for example the effects driving rain were based on the European standard EN 13013-3 [*p*EN 1999]. A PC-based pilot version of the assessment protocol was implemented on a GIS platform that can store, integrate and further process text, pictures, maps and related data.

LIFECON [Haagenrud 2004, Hallberg 2005] – A Life cycle based Maintenance System (LMS) was developed as a generic software tool to aid the documentation, inspection and maintenance management of cultural buildings, infrastructures and the built environment. The GIS-based

technology is open, object oriented and modular, can be extended to any type of built asset and includes management of component functionality during the life cycle of the asset. The LIFECON project is a specific implementation of the LMS for concrete infrastructure assets. Validation of LMS system was demonstrated by application for environmental characterisation of and performance analysis on a concrete bridge located in Fäeltskärsleden, Norway. The technology was also adapted to a municipality in Norway responsible for administering 8800 rental objects in which the system was used to document buildings information, building condition, maintenance costs, and maintenance planning and optimization information.

This paper provides an overview of a project to develop a GIS-based framework for the evaluation of façade performance and maintenance prioritisation, for high and medium-rise buildings with consideration of the likely environmental loads. A brief review of related studies and project methodology is provided, as is information on key project components, including: a Geographical Information System (GIS) based MMS interactive database for climate information, and building data; a Markovian-based, building façade maintenance management (BMM) model.

2 APPROACH

A schematic providing an overview of the approach adopted for the GIS-based assessment method as applied to building cladding systems is provided in **Figure 1**. Emphasis has been placed on characterising key climate variables such as moisture, thermal, wind and other loads for any given location in Canada. Evaluating climatic effects in combination with wall response provides a basis for setting maintenance priorities given that damage and deterioration can bring about loss in performance of the functional elements of the wall system. The process is used to establish risk of deterioration among the different walls for a given building façade, between the level of risk among different buildings in a given climate, or for comparing the relative effects of similar facades located in different climate zones.

The schema for the proposed GIS-based implemenation of the building façade performance and maintenance prioritisation framework is given in Figure 2 and consists of a GIS-based interactive database for climate information and building data (described in following section), the climate response module, maintenance condition and forecast module, and the National Maintenance Management System (NMMS). The web accessible GIS provides access to building data, as derived from the NMMS, climate data, and climate loads that are derived from climate data, and the climate response and field data module. Additional information on the climate response module and the building façade maintenance condition and forecast module are provided in a subsequent section. The NMMS is administered by the Real Property Branch of Public Works and Government Services Canada and is responsible for managing over 300 buildings across Canada.

Development of the identified tools will permit building managers to rate the relative applicability of various façade systems to particular geographic locations. System and material selections that more closely tie to the expected climatic loadings will result in reduced deterioration rates and should produce heightened thermal efficiency and performance of envelope systems. The project will help designers avoid design choices that can cause adverse indoor environmental conditions by evaluating the likelihood of water penetration into facades and examining the potential for propagation of mould and mildew. The net result provides for location specific designs and selections of façade materials and insulation that result in reduced energy consumption and extend life expectations of the components and wall assemblies in service.

Façade types considered in the framework include:

- Metal-glass curtain wall;
- Brick masonry veneer (stone and); and
- Prefabricated masonry and concrete panel.

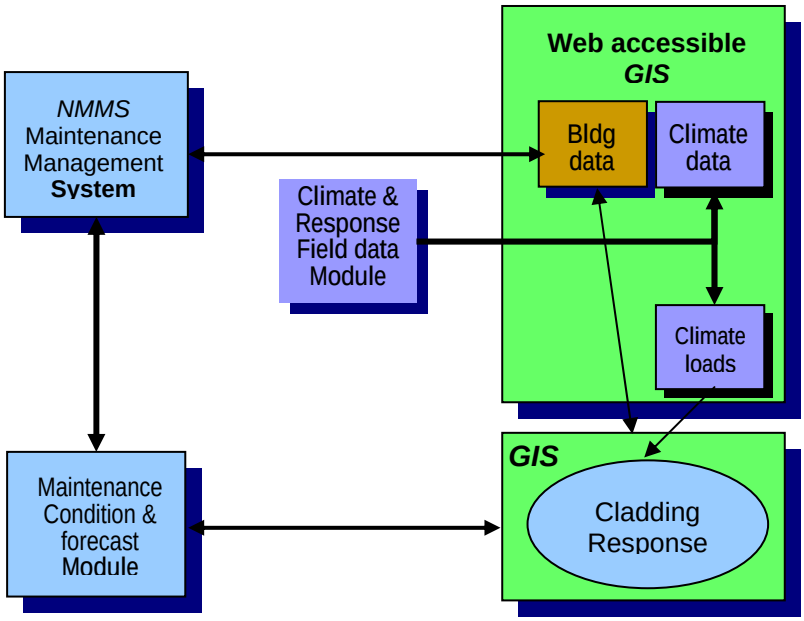

Figure 2 . Schema of proposed GIS-based implemenation of framework for evaluation of building façade performance and maintenance prioritisation

3 DEVELOPMENT OF GIS-BASED MMS INTERACTIVE DATABASE FOR CLIMATE INFORMATION, AND BUILDING DATA

The GIS-based MMS contains performance, damage, and durability models to make probabilistic predictions of changes in the state of the cladding or estimates of the service life due to prevailing conditions or some actual or planned event, such as an extreme climate event or maintenance interventions. These performance, damage, and durability models require information. A GIS approach was selected as the means of obtaining the necessary integration of climate- and building-related information in a geographical context. The GIS system comprises a national geographic base of

Canada and additional details for specific cities of interest. The system contains several databases including, but not limited to: a historical climate database, topographical data in the form of large scale topographic information for large parts of Canada and small scale data for urban areas, and database of built assets such as roads, bridges, and specifically buildings from real property databases. The web accessible GIS system integrates these several databases and provides the basic input to the cladding response models. These cladding response models feed input to the tools used for assessment and prioritization, discussed in subsequent sections. The basic architecture and relationship of the GIS portion to the rest of MMS system is illustrated in **Figure 2**.

The GIS data can be grouped under three general categories: climate-related data, building-related data, and physical data (e.g. topographic or hydrological data). These types of data are kept separately but the GIS is used to integrate the various databases. Only the climate-related data is discussed in this paper. The information incorporated into the GIS can be broadly categorized into two abstract types: gridded (mapped) data and point data. Point data can be essentially viewed as a tuple, the first two parts of the tuple locating the third part or element in two-dimensional space (and perhaps time). A latitude, longitude, and elevation can be considered to be a point whereas a table consisting of latitudes, longitudes, and elevations is a gridded data set. The distinction is arbitrary but useful since, for example, data regarding individual buildings or large amounts of historical weather data from a meteorological station can be considered as point data. Viewing the source of information as point data permits transforming, deriving, and exporting large of amounts of data to the cladding response models. Examples of gridded data, best viewed in a map form, are mean annual rainfall or mean wind speed.

As conceived the GIS system, shown in **Figure 3**, has the following capabilities:

Display a map — The primary purpose of this mode is to display gridded data. In this mode, a rough appreciation of the climate loads or risks can be obtained and measures of performance, risk, or condition state can be assigned to assets within the portfolio.

Display charts/graphs/roses/reports — In map mode, specific points can be selected, for example, a single building. Additionally, specific climate data can be attached to a particular building, such as hourly weather data from nearby meteorological stations. At this level more detailed climate loads can be determined, wind-driven rain on a particular façade for example.

Export data files — This mode of interaction is similar to the “Display” mode except that in this mode data files can be created from the database and exported for use in the performance and damage assessment models described below. The GIS data can be transformed or derived from the original data or used directly.

3.1.GIS Climate-Related Data

One of the objectives of this project is to render specific climate data in a form suitable for inclusion in either hygrothermal simulation models or damage index models. Hence, the climate is the primary information from which derivative climate parameters are developed. It also provides the basic information to determine the microclimate on a building façade. For example, given the geographical positioning of a site several scenarios are possible for determining the appropriate macro- or meso-scale data source or sources to obtain climate data that is most suited for the circumstances. i.e. use:

1. The nearest hourly meteorological station.
2. A nearby local weather station.
3. A very local station such as an instrumented building or a portable weather station.
4. A surrogate station with similar characteristics deemed appropriate.
5. Nearby stations extrapolating, interpolating or generating the required climatic information.
6. Long-term climate data (if the model can use long-term data) or interpolate, extrapolate from long-term climate data

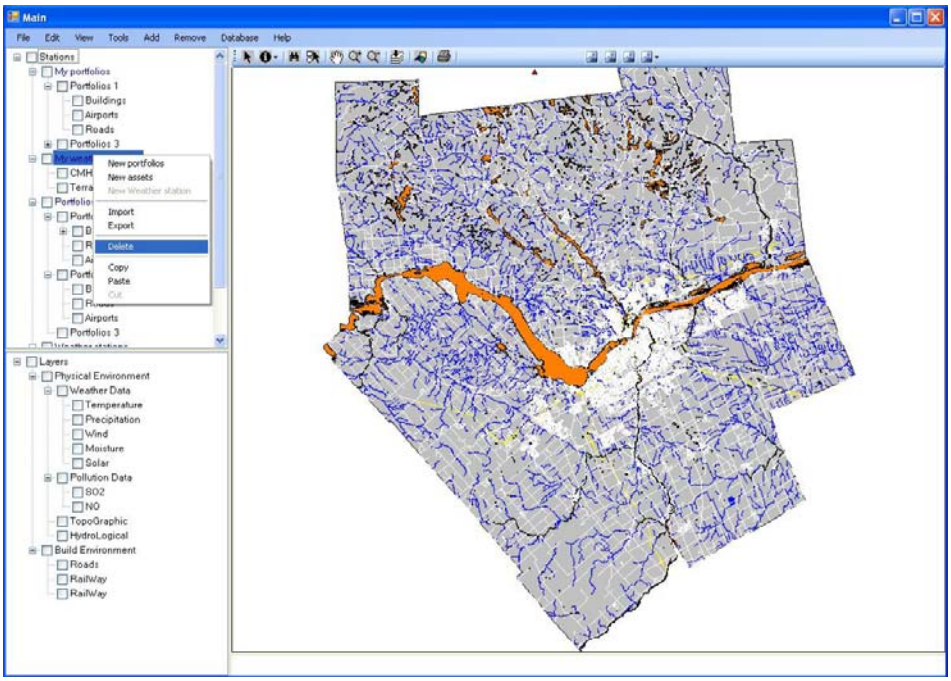

Figure 3. Basic GIS-MMS interface, display in map mode.

Thus after determining the appropriate source of information for a particular building asset the weather loads can be estimated. Various types of climatic information can be generated depending on the specific cladding response model utilised. For example, hygrothermal simulation models generally equire hourly weather data spanning over several months or years; energy simulation models, hourly data from either typical years (e.g. Weather Year For Energy Calculations or Typical Meteorological Year) or weather records from meteorological or local weather observation stations; a freeze-thaw model may only require the mean number of freeze-thaw cycles per year. Other models require information such as yearly, monthly, or daily data such as daily range, monthly averages. In all cases however the type of climatic information needed is historical. The GIS-MMS system provides a seamless method for determining the required climatic data for the appropriate models.

The GIS system allows the climate data to be accessed on a variety of time-scales, annual means, for example, to hourly data at the finest useable time-scale. Finally the required local or meso-scale climate data can be reduced through ancillary or helper applications to a micro-scale. These applications, through theoretical, empirical or numerical (e.g. computational fluid dynamics) models, make use of the building-related and physical data to reduce the scale of the climate-related data to the micro-scale: i.e. to bring the weather to the façade.

4 DEVELOPMENT OF RISK-BASED ASSESSMENT AND PRIORITISATION FRAMEWORK FOR FACADE BMM

The risk-based assessment and prioritisation framework for the facade BMM is based on two modules; the:

- Cladding response module that imparts information on the effect of environmental loads (climate or interior loads) on wall assemblies or specific components of the assembly; may also provide information on deterioration or damage of specified components over time.
- Building façade maintenance management (BMM) and forecast model.

Each of these is briefly described in turn.

4.1.Cladding Response Module

The cladding response module is comprised of several models that are either applications built on top of the GIS platform or stand-alone applications linked to the GIS. These models take input in the form of loads from the GIS and export the results to the maintenance management and forecast models. Some typical models that could be linked to the GIS include:

- Hygrothermal simulation (e.g. 1-D hygIRC [Cornick 2003])
- Energy simulation (e.g. DOE-2 Building energy analysis program [Mukhopadhyay 2006]
- Masonry freeze-thaw index [Mukhopadhyaya 2005]
- Scheffer's climate index for wood decay [Scheffer1971]
- Atmospheric corrosion models for metals [Roberge et al 2002]
- Masonry brick metal tie corrosion [Hegel and Lissel 2005]
- Jointing product (sealant) durability model [Lacasse et al. 2002]

4.2.Building Façade Maintenance Management (BMM) and Forecast Model

The Markovian-based, building façade maintenance management (BMM) model permits the optimization of maintenance planning, and introduces software that permits a user to initiate building maintenance actions. The intent was to provide building managers who are faced with having to maintain their buildings assets more efficiently, with a tool that could reduce the short and long-term costs of maintenance and rehabilitation. In essence, the BMM software can either optimize maintenance planning actions based on an expected maintenance budget or determine the budget required to maintain the façade to a minimum acceptable level of performance.

A schematic of the primary components of the software is given in **Figure 4**; details in respect to the Markovian approach to façade maintenance management are given in Lacasse et al. [2008]. The façade was first considered in development of the BMM software given that it is a significant element of the building envelope and of the building itself.

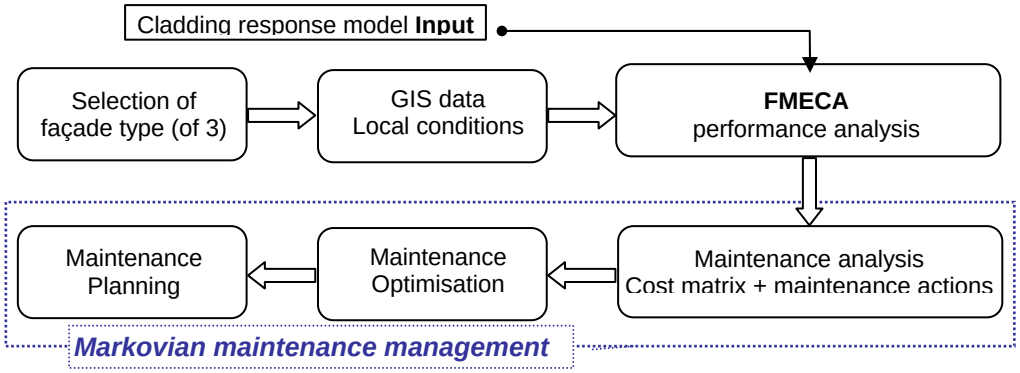

Figure 4. Schematic key project components of BMM model [Lacasse et al 2008].

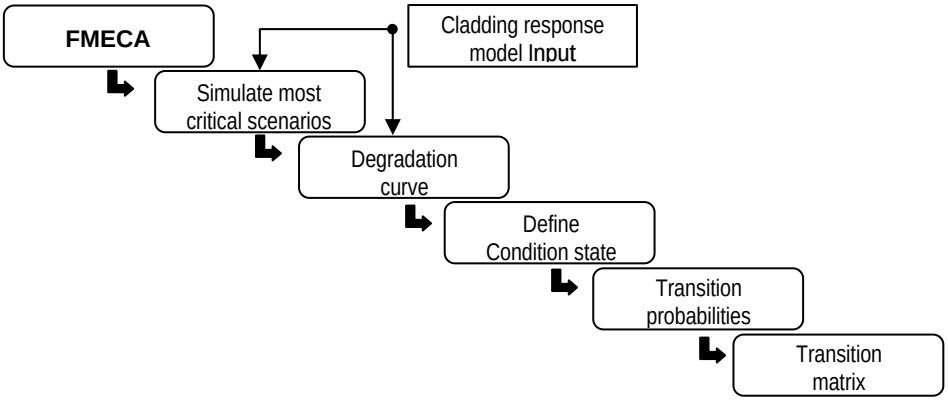
The BMM model is built on several parts, however one of the key components is Failure Mode Effects and Criticality Analysis (FMECA) and performance analysis of the façade and related components; the several steps of this process are provided in **Figure 5** [Lacasse et al 2008]. The first step consists of developing a façade component criticality index that is based on outcomes of a FMECA. This permits determining the relative importance assigned amongst the different façade components, as proposed by [Talon 2006]. The basis for determining component criticality is described in more detail in Lacasse et al [2008].

Given that building managers do not necessarily dispose of unlimited budgets for maintenance actions, only the most critical set of components are further analyzed by simulation of the deterioration process. These simulations provide degradation curves of the change in condition state of façade components as a function of time. The different condition states are then defined ensuring that it is possible to observe these conditions during an inspection. The condition state matrix provides information on the likelihood of a component remaining or changing state at given inspection

intervals. Thereafter, the transition probabilities that correspond to the different sates are deduced that in turn permits obtaining the transition matrix. Such a matrix permits estimating the service life of components, or assembly of components, through an analysis using the Markovian model.

Figure 5. Description of performance analyses and development of



Markov condition state matrices for service life estimation.

5 SUMMARY

An overview is provided of a project focused on developing a GIS-based framework for the evaluation of building façade performance and maintenance prioritization. Climate effects are discussed in relation to wall response and expected damage arising from the deterioration of façade components is given. Loss in functional performance of components is examined and the consequences of these losses are related to risk as measured in terms of potential cost of maintenance interventions.

ACKNOWLEDGEMENTS

The authors are indebted to the Program of Energy Research and Development (PERD), part of the Office of Energy Research and Development, together with their respective organisations for funding of this project. Additionally, the authors would like to thank other contributors to this effort in particular, Mr. Denis Richard, Principal, Intempco Controls, and those from the GIS directorate of PWGSC, CMHC and NRCan who supported this project.

ABSTRACT

The building envelope restoration and retrofitting suffering from rising moisture problems is one of key issues in sustainability of buildings, considering that moisture effects indoor air quality, energy consumption and durability of building materials and components. New tools are needed for the ability of building, its parts, components and materials to resist the degrading action of moisture over a period of time. In this work, an integrated methodology for the moisture protection of buildings against rising damp is proposed. This methodology includes real experimental data, phenomenological mathematical modelling and simulation. This methodology contributes to the prognosis of masonry moisture content, as well as to the decision-making on compatible restoration materials.

1 INTRODUCTION

Moisture causes a number of structural and aesthetical problems in buildings. The effects of moisture can be combined with other deteriorating factors such as air pollution and/or environmental loads (such as frost) and create an even more aggressive condition. Apart from creating structural, aesthetical problems, moisture can cause degradation of indoor quality, since it enhances the development of mould, and mildew, and favourable conditions for biological attack of a building. It also increases the relative humidity of the indoor environment, and decreases the thermal insulation of the building, causing increase of buildings energy requirements.

There is a wide agreement that the management of moisture in its various forms is essential for buildings to be durable, safe and energy efficient. One of the main mechanisms of moisture transfer is capillary rise of ground moisture. The capillary rise kinetics is indicative of materials susceptibility to decay factors and can provide important information for the selection of compatible building materials. In addition the frontiers of moisture analysis for buildings involve the development of computer software tools and underlying methods capable of modelling all types of moisture flows through buildings. Indeed, there are many facets to the moisture issue and many approaches to modelling [PATH, 2004].In this work an integrated methodology for the protection of buildings against rising damp phenomenon is proposed. This methodology includes retrieval of experimental data, and thereafter, phenomenological mathematical modelling and simulation of moisture transport effects. With the aid of this methodology materials moisture content can be assessed. Moreover appropriate restoration materials for masonries suffering by rising damp phenomenon can be assessed before their real application, contributing to the maintenance of such structures.

2 DATA/ MODELLING

A first stage for the realisation of this methodology is carrying out a basic laboratory experimental study, focused on chemical, mineralogical, and microstructural characteristics of building materials, e.g. determining porosity, bulk density and average pore radius of porous moisture susceptible materials. Concerning the phenomena of water transport in porous materials, two processes are of importance: capillary rise and drying kinetics

For the study of the kinetics of capillary rise of moisture, variations of capillary height to time are recorded for each material. A first-order kinetics model is proposed, in which the equilibrium moisture height, derives from Jurin law, based on materials average pore radius [Karoglou et. al. 2005a]. The concept of capillary height time constant is introduced for the first time. The first order kinetic model is fitted to experimental data. The parameters of the proposed model result from an optimization technique to minimize the residual sum of squares between experimental and calculated values of capillary height. The model predicts successfully the capillary rise of water. The capillary height time constant is affected by the material characteristics. In Table 1 it is shown the capillary rise mathematical model.

Table 1. Capillary rise mathematical model

Properties	
H capillary rise height	(cm)

Factors affecting parameters	
material→ H_0	
environment→ρ, σ	

For the study of drying kinetics an experimental air dryer of controlled drying air conditions can be used. Environmental factors, such as air temperature, relative humidity, and air velocity affect drying; hence these factors are monitored in the experimental study. A first order kinetic model is used to describe the drying process. The model predicts successfully the experimental data. The drying time constant is a function of drying conditions and materials characteristics [Karoglou et. al. 2005b]. In Table 2 it is shown the mathematical model for drying.

Table 2. Drying mathematical model

c_2	(-)
c_3	(-)
Factors affecting parameters	
material→ c_0	
environment→ c_1, c_2, c_3	

In Figure 1 the effect of relative humidity and air velocity on the drying process of a plaster (PRL) is shown. As expected, there is an acceleration of the drying process due to the increase in air velocity from 1 to 8 m/sec. The effect of relative humidity is also very important as this decreases the drying rate as the relative humidity increases from 30 to 70%.

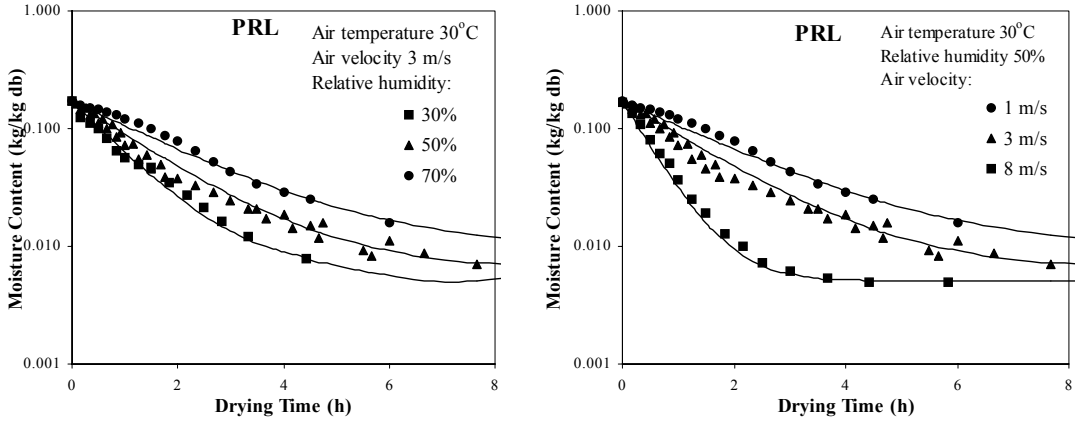

Figure 1. Effect of air relative humidity and air velocity at drying kinetics of a plaster

For the estimation of the moisture equilibrium of each material, moisture sorption (adsorption and desorption) isotherms, are defined. This is made using a water sorption analyser, obtaining materials sorption isotherms at three different temperatures. A modified Oswin equation is used to predict the

experimental data, for water activity in the range of 0-0.9 [Karoglou et. al. 2005c]. The governing equation for sorption, forming the basis for the mathematical model and definitions of the basic model parameters, is provided in Table 3.

Table 3. Water sorption mathematical model

Properties	
X_e moisture equilibrium	(kg/kg db %)
Factors	
T air temperature	(^{o}C)
α_w water activity	(-)
Equation	
$X_e = b_o \exp(\frac{b_1}{T})(\frac{a_w}{1-a_w})^{b_2}$	
Parameters	
b_0	(kg/kg db%)
b_1	(^{o}C)
b_2	(-)
Factors affecting parameters	
material→ b_0	
environment→ b_1 , b_2	

The equilibrium moisture content of the material is affected by temperature and humidity of the surrounding air. Thus, the equilibrium moisture content is higher at lower air temperature and at higher humidity levels. The equilibrium moisture content of various materials is presented at Fig. 2.

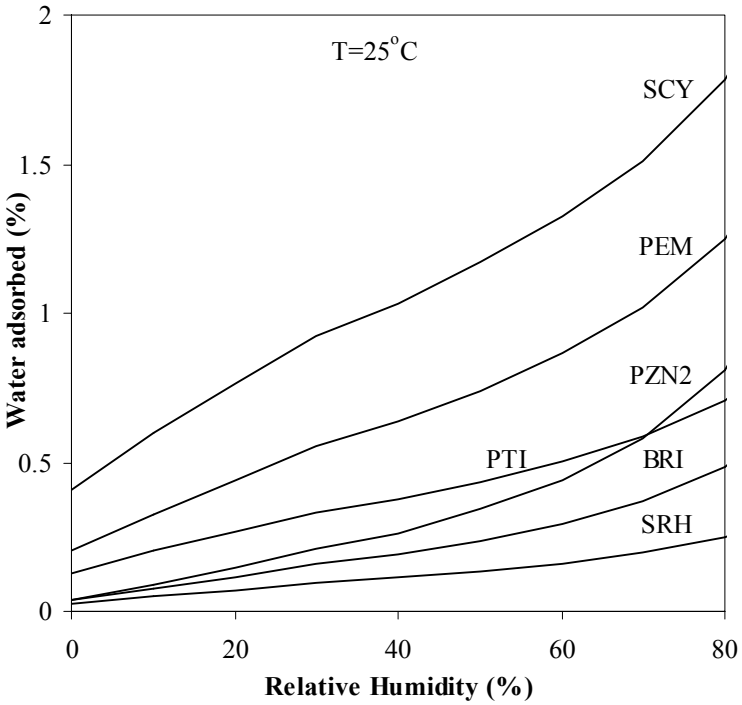

Figure 2. Isotherms of selected building materials at T = 25 ^{o}C (S: Stone, B: Brick; P: Plaster)

All the suggested phenomenological models predict the experimental data. A correlation between the parameters of the moisture transport model affected by materials characteristics and microstructural parameters is attempted. The primary objective of this work is the development of a general

phenomenological model that allows the prediction of all related hygroscopic properties, based on its microstructural characteristics. This approach is very significant, because permits the prediction of the hygroscopic properties of the material, when only experimental data related to the microstructure of the material is available or when there is no possibility to obtain experimental data [Moropoulou et. al. 2005].

3 SIMULATION

After data collection and modelling, a moisture transport simulator is developed (HygroScope). HygroScope is developed for a two-layer masonry wall, consisting of a wall substrate and a plaster layer of varying height and width. The masonry layer consists of one material (referred to as wall), either stone or brick, and the outer layer of a plaster with various compositions [Konstantopoulos et al. 2007]. Various plasters before their real application can be tested, like macro-porous plasters, which are suitable for the protection of masonry against rising damp. The simulator takes into account the: (i) moisture transfer mechanisms to and from the building (capillary rise, drying); (ii) wall configuration (materials and size); (iii) properties of the construction materials; (iv) seasonal regional meteorological data (air temperature, humidity and wind speed). It can calculate the: (i) seasonal wall moisture content along with the corresponding equilibrium moisture height; (ii) rate of capillary rise; (iii) rate of wall drying. The software application is developed using Visual Studio (2005) development software based on C+ programming language. The simulator is a combination of three basic components that include the: Database, Mathematical Model Library, and Graphical User Interface (GUI); each of these is briefly described below.

3.1 Database

Material and environmental data are stored in the database. The terms material and environmental data correspond to a collection of attributes that fully define a set of materials and a set of environmental conditions. For material data these attributes are: porosity, density, capillary saturation moisture, equilibrium moisture constant, drying constant, average pore radius, capillary time constant and the name of the material. For environmental conditions these attributes are the minimum and maximum temperature, moisture and air velocity values that appear in the specified environment, the date when the maximum for each of the above values is observed, daily observed temperature, moisture and air velocity conditions (365 values – one for each day) and the name of the location where these conditions dominate. Each material and environmental collection is stored in a separate XML file. The advantage of having a XML file format is that the user can change, if desired, the data files without necessarily running the application.

3.2 Mathematical Model Library

The second component is the mathematical model library embedded in the application. This library is the core of the simulator, since it brings into effect the methods and the principles previously described.

3.3 Graphical User Interface (GUI)

The third component, the Graphical User Interface (GUI), consists of four basic windows (screens) The GUI enables the user to interact with the database in various ways (create, delete and update information) and also create and manage simulation projects. It also permits the user to customize the application settings through the ‘settings’ window. The Simulation ‘project screen’ is given in Figure 3.

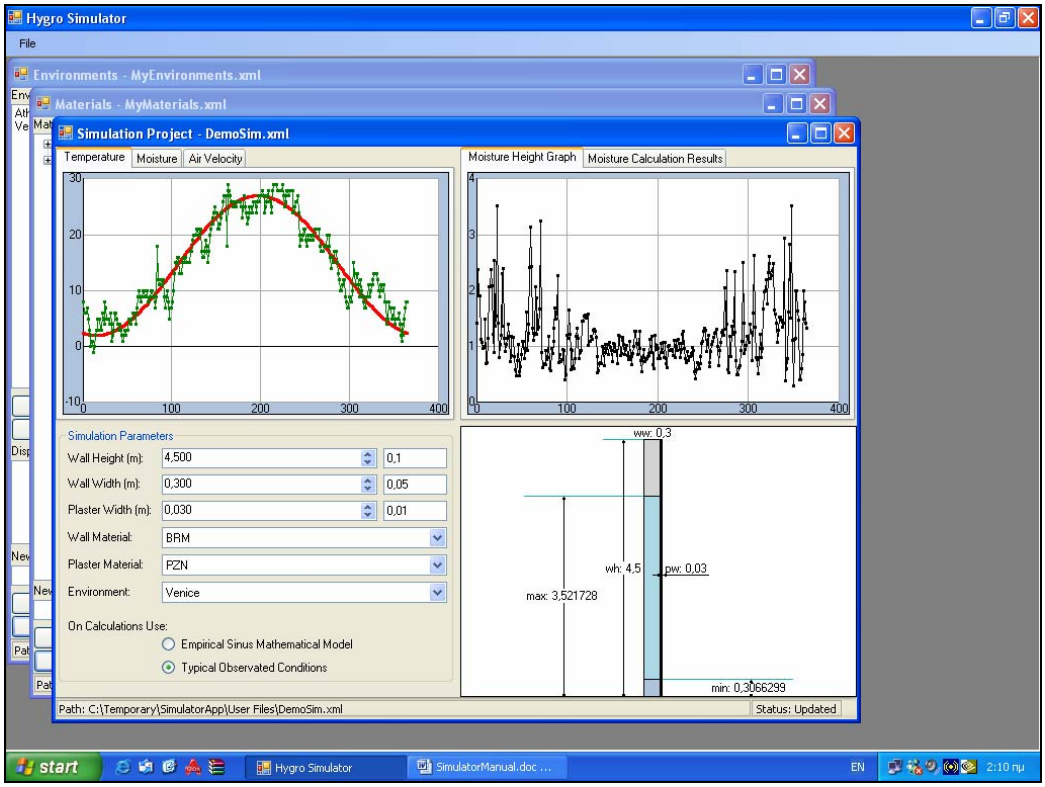

Figure 3. Simulation Project Screen

To initiate a new simulation project, the user has to select the File – New – Simulation Project menu. This starts a new blank simulation project and opens the relative window which will host the project. When the simulation project has been created or loaded the user will be able to see four different areas inside the window. In the bottom left area are located the controls with which the user can interact to manage the simulation project. After the desired values for these controls have been set, the simulator calculates the curve for the moisture height and presents it to the graphic area located in the upper right part of the window. This is the curve that depicts the height of the moisture (vertical axis) relative to time (horizontal axis) for all 365 days of the year. From this curve the user can also see the minimum and maximum heights of moisture during the whole year. On top of this graphic area are two tabs from which the user can switch between the curve view and the report view, where he can see the moisture height results of the calculations. In the lower right part of the window there is a graphic design of the wall with the plaster material attached.

This graphic design is in scale and shows the geometrical aspects of the wall – plaster. It also shows the minimum and maximum height of moisture during the year once the calculations have finished. In the upper left part of the window is another graphic area that shows the measurements curve and the proximal sinus curve of the selected environment. The user can select one of the three tabs on top of this graphic area to change among the temperature, moisture and air velocity curves. The current simulation project can be saved by accessing the File – Save (of Save As) menu. Each simulation project is saved in a separate XML file.

3.4 Case Study

With the aid of this methodology various restoration building materials can be assessed, with respect to properties related to their capability of retaining moisture, before their real application. The fundamental variable expressing the suitability of such materials is the variation of moisture height, which is the maximum height that moisture creeps on a vertical wall with respect to materials used for construction. A case study with respect to the ability of decision making on different restoration

plasters is stated below. It is considered masonry situated at Athens. The wall is constructed with a traditional hand-made clay brick, named as, BRM, has a height of 3.3 m and width 0.5 m. The plaster application width is equal to 0.03 m. The masonry suffers from rising damp. The question arising is what kind of restoration plaster should be used. Two different plasters are investigated. PZN, which is a traditional plaster and PEM, which is a macroporous plaster. The attributes for the afore-mentioned materials are shown in Table 4.

Table 4. Materials attributes

Properties	**BRM**	**PZN**	**PEM**
Porosity%	32.6	41.3	63.8
Average pore radius(μm)	2.02	0.52	33.2
Density (kg/m^3)	2.77	3.25	4.4
Capillary saturation moisture %	11.6	17	18.6
Equilibrium moisture content (%)	1.62	33.8	31.3
Drying constant (h)	2.62	2.77	3.13
Capillary rise constant (d)	1.39	3.54	0.04

With the aid of HygroScope (Figure 4), it is found that PEM reduces more moisture height in comparison to PZN. This can be justified comparing materials attributes. PEM presents higher porosity and very high average pore radius value. Moreover PEM contains hydrophobic substances, resulting at a very capillary rise rate and high drying rate due to the existence of macropores. Thus PEM is preferable to be applied, instead of PZN.

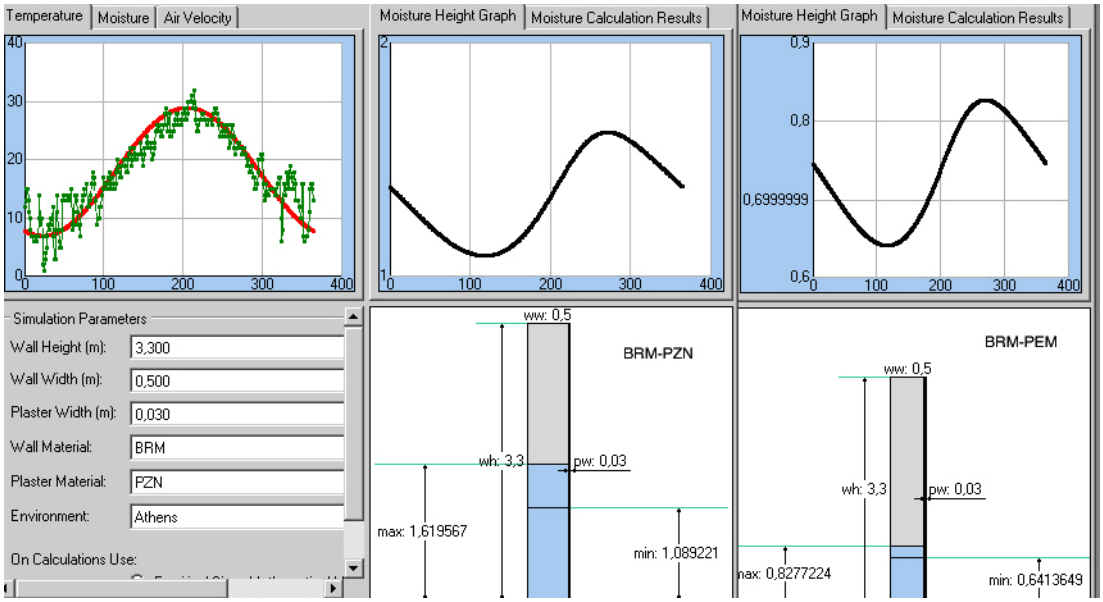

Figure 4. Simulation Project Screen for the two different plasters

4 CONCLUSIONS

Capillary rise of water is one of main moisture transfer mechanisms at buildings. In this work an integrated methodology to tackle rising damp problem is proposed. This methodology involves specific stages such as; conduction of basic experimental work, data modelling and simulating. The simulator supports satisfactory decision making concepts concerning the selection of the appropriate protecting strategy, e.g., plaster selection (material, size). With the use of this methodology, the

assessment of the effectiveness of restoration materials before their real application can be made, contributing to the maintenance of masonries suffering by rising damp.

ABSTRACT

Building managers are increasingly faced with having to maintain their building assets more efficiently whilst reducing the short and long-term cost of maintenance and rehabilitation. Several different systems employing a Markovian approach have been adapted to the bridge structure domain; fewer in the domain of buildings. The present paper describes a parallel approach to maintenance management used in bridge structures but adapted to the maintenance of building facades. The maintenance of several components of a concrete panel façade system is considered in the context of both yearly and longer-term maintenance planning. The significance of different components in relation to others in the system is determined by first conducting a Failure Mode Effect and Criticality Analysis (FMECA) on all façade components. The FMECA permits developing a component criticality index from which their relative importance is assigned amongst the different façade components. An optimization of different possible maintenance actions are considered in relation to the cost of specified actions to or replacement of components based on a multi-objective index. This index provides a means of relating competing maintenance objectives; that of controlling maintenance intervention costs and maintaining component condition ratings. It provides yearly maintenance costs of individual components for a given wall system over a long-term horizon that spans the life of the façade system.

1 INTRODUCTION

Building managers are increasingly faced with having to maintain their building assets more efficiently whilst reducing the short and long-term cost of maintenance and rehabilitation. In the domain of construction infrastructure, there exist several examples of infrastructure maintenance that employ the Markovian approach; examples can be found in the domain of roadway pavements [Nesbitt et al 1993; Durango-Cohen and Mandanat 2006], storm water sewerage works [Micevski et al 2002] and several related to the bridge structure domain [Cesare et al. 1994; Morcous et al. 2003; Morcous and Lounis 2006; Robelin and Mandanat 2007]. However there are fewer examples of the Markovian approach used in the domain of buildings although some useful examples include the work of Van Winden and Dekker (1998), Lounis and Vanier [2000] and that of Augenbroe and Park [2002].

~~DETERIORATION~~ Approaches to Maintenance Management of Building Components:

The Markov-based decision model for rationalising building maintenance, developed by Van Winden and Dekker (1998) was used at the strategic level for the planning of maintenance for buildings owned by a building society. The value of the model as a management instrument in estimating and allocating maintenance budgets was demonstrated in a pilot case of four (4) building elements, namely: masonry, pointing, window frames and painting. Modelling the deterioration of these components permitted determining the maintenance policy that ensured a specified average quality level at minimal cost. The intent of the study was to provide some estimate of life cycle costs to the building and as such, the study provides useful information related to methods of establishing cost matrices. However, there appears to be some missing information related to the allocation of costs.

Lounis and Vanier [2000] describe the development of a roofing maintenance management system that integrates an existing condition assessment module (i.e. *Roofer;* [Bailey 1990]), and performance prediction based on a Markovian model, with a multi-objective optimization scheme. The maintenance optimization includes the determination of the optimal allocation of funds and prioritization of roofs for maintenance, repair and replacement that satisfy: (i) minimization of maintenance and repair costs; (ii) maximization roof performance; and (iii) minimization of risk of failure. Compromise programming is used to solve the optimization problem and the system purports to provide building managers an effective decision support system that identifies optimal projects for repair and replacement whilst achieving satisfactory trade-offs between conflicting maintenance objectives.

Augenbroe and Park [2002] suggest that the building maintenance problem can be formulated as a Markov decision process. They indicate that the discrete Markov chain model aptly describes both the time-dependence and randomness of building system performance and thus can be used for systematic decisions regarding replacements of building components that affect the scope of yearly maintenance activities. Such an approach permits comparison of various maintenance policies on resulting maintenance costs and building quality. The authors also suggest that this approach gives insight into the relation between yearly maintenance costs and the quality of the building, both on short as well as a long term.

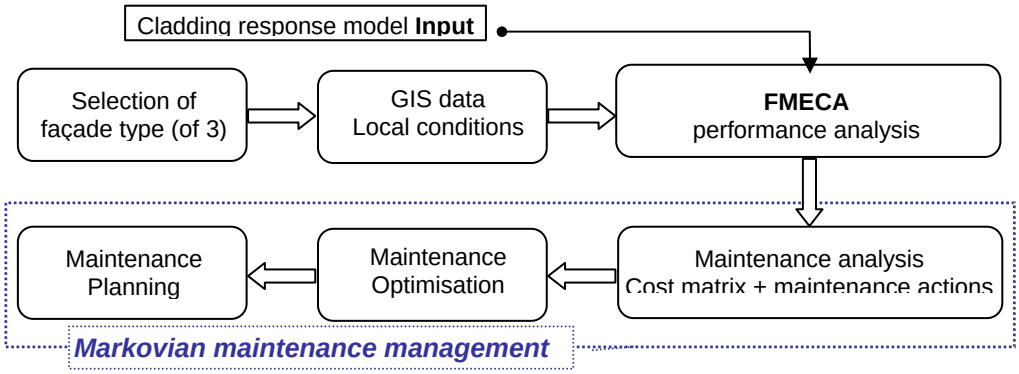
The present paper describes a parallel approach to the maintenance management of bridge desks initially postulated by Lounis and Vanier [1998] and on which the work of Lounis and Vanier [2000] on roofing was developed, of which a broader overview of the roofing project is provided by Kyle et al. [2002]. In this instance, these approaches have been adapted to the maintenance management of buildings facades and have also drawn upon the more recent work of Morcous et al. [2003] and Morcous and Lounis [2006].

2 PROPOSED MARKOVIAN-BASED, BUILDING FAÇADE MAINTENANCE MANAGEMENT (BMM)

The Markovian-based, building façade maintenance management (BMM) model permits the optimization of maintenance planning, and introduces software that permits a user to initiate building maintenance actions. The intent was to provide building managers who are faced with having to maintain their buildings assets more efficiently, with a tool that could reduce the short and long-term costs of maintenance and rehabilitation. In essence, the BMM software can either optimize maintenance planning actions based on an expected maintenance budget or determine the budget required to maintain the façade to a minimum acceptable level of performance. A schematic of the primary components of the software is given in Figure 1. The façade was first considered in development of the BMM software given that it is a significant element of the building envelope and of the building itself.

Figure 1. Schematic key project components of BMM model.

Consider for example, the maintenance of several components of a concrete panel façade system in the



context of both yearly and longer-term maintenance planning. The significance of different components in relation to others in the system is determined by first conducting a Failure Mode Effect and Criticality Analysis (FMECA) on all façade components. This permits developing a component criticality index from which their relative importance is assigned amongst the different façade components. An optimization of different possible maintenance actions can then be considered in relation to the cost of specified actions to or replacement of components. However, a means of relating competing maintenance objectives is required that controls maintenance intervention costs whilst maintaining component condition ratings.

3 O~~VERVIEW~~~~UTLINE~~ OF FMECA IN THE CONTEXT OF MAINTENANCE MANAGEMENT

Of the several parts of which is comprised the BMM model, one of the key components is Failure Mode Effects and Criticality Analysis (FMECA) and performance analysis of the façade and related components; the several steps of this process are provided in Figure 2. The first step consists of developing a façade component criticality index that is based on outcomes of a FMECA. This permits determining the relative importance assigned amongst the different façade components, as proposed by Talon [2006].

Given that building managers do not necessarily dispose of unlimited budgets for maintenance actions, only the most critical set of components are further analyzed by simulation of the deterioration process. These simulations reflect the change in condition state of façade components and thus the degree of overall deterioration over time. The different condition states are necessarily defined thereby ensuring that it is possible to observe symptoms of these conditions during an inspection. The condition state vector ($\boldsymbol{D}_t$), given in Figure 2, provides information on current condition; each element in this vector having S condition states, represents the estimated percentage of all like components in a particular condition state after time t, for which t, is expressed in transition periods, or e.g., periods

between inspection. The likelihood of a component remaining or changing state at given inspection intervals provides the transition probabilities ($p^{i,j}$), that is, probability of changing (or not) condition from state *i* to a lower state *j*, and for which the corresponding transition probability matrix (**P**) is obtained. Such a matrix (*S* x *S*), shown in Figure 2, permits estimating the service life of components, or assembly of components, through an analysis using the Markovian model. Given the present condition vector of a component ($\boldsymbol{D_t}$), the future condition vector ($\boldsymbol{D_{t+n}}$) can be obtained as: $D_{t+n} = D_t \times \mathbf{P}^n$, where n, is the number transition periods in the future.

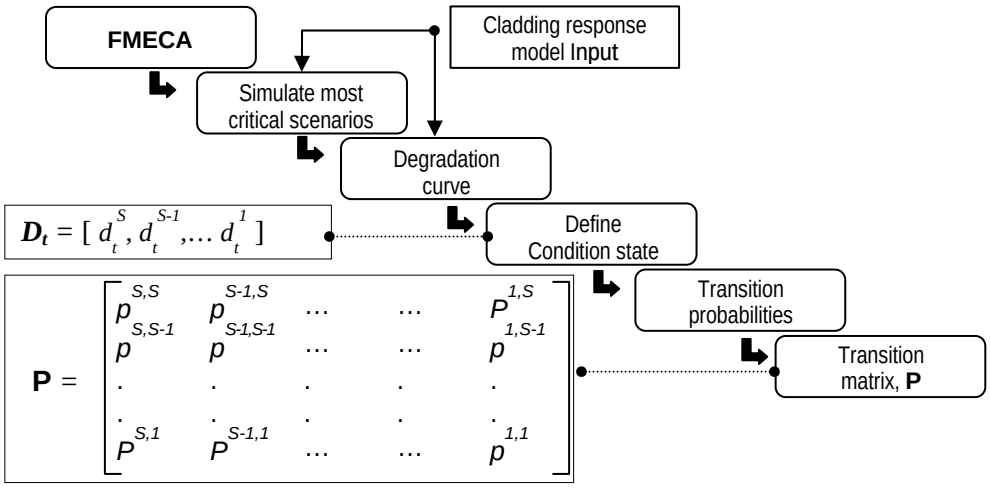


Figure 2. Description of performance analyses and development of Markov condition state matrices for service life estimation.

4 MANAGEMENT OF COMPONENT CONDITION STATE USING A MARKOVIAN METHOD

There are different maintenance actions that maintenance managers can take over the course of managing the façade component condition state. For example, the component might be repaired such that its condition can be maintained or it might be completely replaced. If repaired, consideration should be given to how amenable to repair the component. Can the component be repaired more than once? Then again, can the component be repaired indefinitely? Provided a component is readily accessible then repair is likely possible. However, it is unlikely that any building façade component can be repaired indefinitely so then repairs should be considered as actions capable of retarding the degradation process but ultimately not preventing the need for replacement at some time in the future. Hence a repair action undertaken on a component typically would not renew the component to its original condition state but the action would improve its condition to a stated higher level.

If, however, the component were replaced then its condition state would be renewed to that of a new component. A typical example of components in a building façade more likely replaced as opposed to repaired would be the insulated glass (IG) component of a window. The IG unit is either, functioning adequately (i.e. IG unit is transparent, and still holds an inert gas between glass lites), or its seal has failed and the unit is now clouded, as is evident by the presence of moisture on the interior glass lites.

As well, it may be decided that no maintenance action be taken, in which case the loss in performance over time would continue at the rate prescribed by the deterioration process.

For each of these actions (described as a maintenance vector, $\mathbf{M}_{ct}$), including the no maintenance action, there exist transition matrices that reflect the action taken (i.e. $\mathbf{P}_{ct}$) and associated with each of these a cost for repair or replacement, and perhaps in some cases, a cost for no action as well ($\mathbf{C}_{ct}$). The general stages in the maintenance action approach are provided schematically in Figure 3. Once the

consequences of maintenance actions are established, one can then consider optimization of maintenance actions.

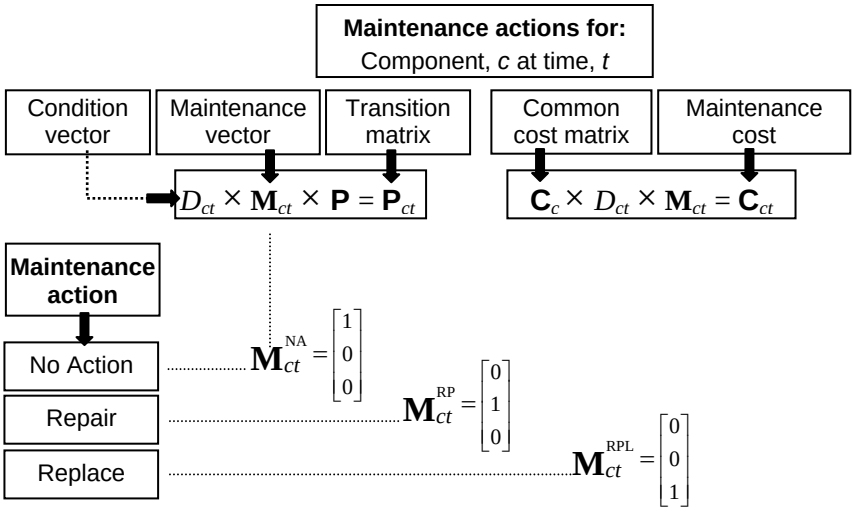

Figure 3. Description of maintenance analysis – possible choice of maintenance actions, associated maintenance vector, transition matrix and cost matrix.

5 OPTIMIZATION OF MAINTENANCE ACTIONS~~OF~~

An optimization of different possible maintenance actions considers three scenarios that relate aggregated component condition rating (ACCR) to a desired or available maintenance budget. These scenarios include:

- Maximization of component condition rating for a given annual maintenance budget.
- Minimizing the maintenance budget for a targeted condition state (aggregated condition state for all components)
- Use of multi-objective index when neither the budget is neither defined nor is the expected condition state – a compromise solution between maximisation of the budget and minimisation of the condition state over time.

The aggregated component condition rating (AACR) is derived from the a knowledge of the number of "sections" in any given condition state at a given time, a section being defined as a measurable part or portion of the entire set of sections that together form the representative "mass" for a given component type. As illustrated in Figure 4, at any given timer, *t*, component sections will be in their respective conditions state.

The multi-objective index (MOI), obtained from Morcous and Lounis [2006], with evaluation criteria, *i*, a set of criteria, *m*, and assuming the solution metric with $p = 1$, is given by:

$$MOI(x) = \left[\sum_{i=1}^{m} w_i \bullet \left| \frac{f_i(x) - \min f_i(x)}{\max f_i(x) - \min f_i(x)} \right| \right]$$

Where, w_i is the weight given to criteria *i*, $f_i(x)$ the value of objective function, and max $f_i(x)$ and min $f_i(x)$ the maximum and minimum values of the same function respectively. The choice of *(p)* indicates all deviations from the ideal solution are considered in direct proportion to their magnitudes Lounis and Vanier [2000]. If it is assumed that the competing objectives are budgeted maintenance cost and AACR (i.e. m = 2), then this index provides a means of relating competing maintenance objectives; that of controlling maintenance intervention costs and maintaining component condition ratings.

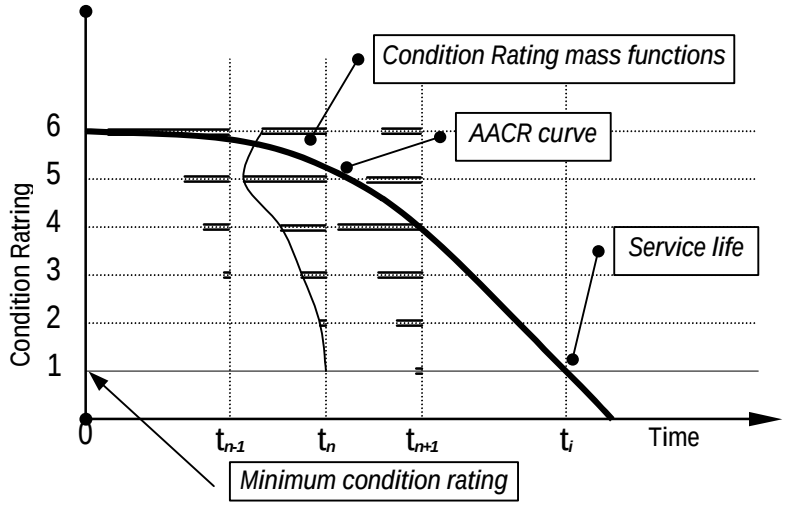

Figure 4. Condition state mass functions that define the aggregated component condition rating (AACR).

If a building maintenance manager is aware of the expected annual budget or has made the necessary provision for acquiring the requisite funds to conduct a proper maintenance program then in this case, the maintenance strategy is to maximize the overall component condition rating. Essentially, the manager has interest to maximise the gains afforded by a given annual maintenance budget allocation.

Another scenario is one where the building manger may know the overall component condition rating to attain, or maintain, but wishes to minimise the budgetary requirements. Whereas a more likely scenario, as in the third case, is one in which the manager may not as yet have defined budgetary requirements and as well, is not aware of the average aggregate condition state under which he should be operating the facility beyond minimum acceptable levels. Indeed, the building manager may require some insight into the most cost effective maintenance he can expect over a longer-term horizon and still operate the facility above a minimum acceptable condition state.

This is a case where a compromise is to be reached between two competing objectives: maintaining a minimum acceptable AACR in relation to the yearly maintenance budget. The intent is to determine the highest achievable AACR for any given yearly maintenance budget. As such, a multi-objective index (MOI) approach is used that is based on the: degree of criticality of amongst components; number of components being considered; condition state vector; relative importance brought to the budget in relation to the building condition state; and the AACR, and limiting values for ACCR (i.e. $ACCR_{min}$ and $ACCR_{max}$).

In respect to the limiting values for AACR, these values are selected by the building manager to better manage the maintenance process. For example, it is unlikely that a new window unit should require replacement in its initial years of use; likewise one would expect that a failed unit would be replaced. Hence, the manager can set limits on minimum and maximum values of ACCR for each façade component. For example, the building manager can determine that if the AACR of the components lies between “new condition” (e.g. state 6) and an “average” condition (e.g. state 4), then no action to consider replacing the unit should be taken. Whereas a repair could be requisitioned should the components be considered in the poor, urgent of critical states (e.g. condition states 3, 2, 1 resp.). The determination of such limits thus permits the building manager to establish a policy of when actions

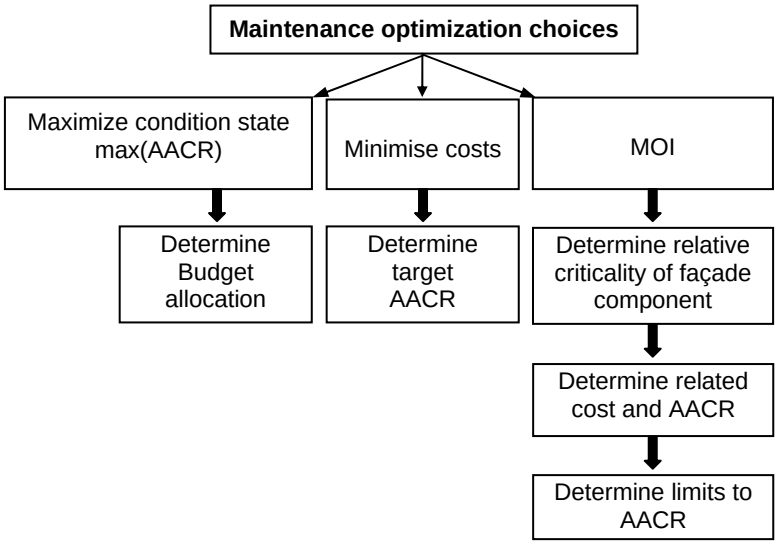

Figure 5. Maintenance optimisation choices: maximise condition rating; minimise maintenance budget; use of MOI – multi-objective index; AACR – average aggregate condition rating.

should be taken and indeed the system could be used to determine how such policies might affect overall maintenance costs. A summary of the three different maintenance scenarios is given in Figure 5. In essence, the façade BMM system provides yearly maintenance costs of individual components for a given wall system over a long-term horizon that spans the life of the façade system.

6 ~~CONCLUSION~~SUMMARY

A building façade maintenance management system is proposed that considers the effect of different maintenance options on the overall cost of maintenance over a yearly and longer time scale. Performance predictions in respect to component condition state are based on a one-step Markovian model. An optimization of different possible maintenance actions are considered in relation to the cost of specified actions to, or replacement of, components based on a multi-objective index. This index provides a means of relating competing maintenance objectives; that of controlling maintenance intervention costs and maintaining component condition ratings.

A Structural Condition Assessment;Environmental Agents versus Structural FailuresThe Case of Ataturk Culture Center AKM,Istanbul, Türkiye

Kemal Çayırlı [1]

T 72

ABSTRACT

A structural condition assessment is partially conducted in a specified method to reveal environmental agents that are causes of structural failures in the case of AKM. By suggesting a perceptually outlined assessment strategy, a structure of the case study is initiated to look closely structural partitions of the front foyer. Various site survey techniques, visual observation, measuring, interviewing and relate items are issued to collect rough data according to symptoms of the structural failures and these data are transformed into models of the symptoms. Furthermore, environmental agents, like wind, are identified that are stated as causes. Specific titles of the failures according to the symptoms, vibration of vertical member -louvers and canvas behavior of curtain wall -glass surface are named and related with corresponding environmental agents to conclude the case study that the front foyer of AKM partly has a sufficient service life.

1. INTRODUCTION

A building could be an object of cultural heritage in any country according to the certain way reading of its features no matter its construction date. Especially; when its features seem to be so identical, it becomes much more crucial to keep and improve its role not only in the position of the discipline but also in the atmosphere of the public realm by applying the concept of durability in overall building. Durability means to extent overall service life of a building, its components and materials. According to Feilden, [1982], "conservation" and "renovation" could be practically related with the concept of durability in the domain of historical buildings. This understanding fundamentally covers rejuvenating the building by preserving the image of the building in terms of its original systematic and main characteristics while applying current construction methods and materials for extending the service life of the building.

According to Modena, [2004], all conservations consist basically of actions taken to prevent decay, and within this objective it also includes management of change and presentation of the object so that intent of messages conveyed by the object are made comprehensible and without distortion. Furthermore, architectural conservation is more complex; first because a building must continue to stand up; secondly, economic factors usually dictate that it should remain in use; thirdly, it has to resist the effects of climate; and lastly, a whole team of 'professionals' have to collaborate.

When evaluating economic factors, the concepts of maintenance and renewal of the overall structure need to be challenged y considering all the pros and cons regarding maintenance issues. When the the concept of sustainability is considered in the case of AKM, then maintenance is a first priority, as in this instance sustainability of the AKM should be understood from a basis of cultural and social concern for this historical structure, given that the AKM is also central to its modern public image in Turkey.

Climatic effects are importance in this case study because of the geographical location of the building in Istanbul, which is located in proximity to Taksim Square. Taksim Square is a location subjected to considerable wind effects in particular on the west façade of the AKM. Although symptoms of failure are not clearly perceived at the first glance, the evidences of failure direct that vertical louver and glass curtain wall as partitions of the façade system should be issued as issues for the structural condition assessment. The partitions of the façade seem so critical not only in the concept of the facility management but also public appreciation of the building image.

The fourth notion of conservation actions as suggested by Modena [2004] relates to the requirement for collaboration among 'professionals'. This implies that for the process to be effective, it must obtain contributions from other disciplines needed to apply the proper procedures to bring about the necessary conservation measures. Specifically, when conducting this case study, precise information was needed regarding the wind speeds and direction and related behavior characteristics in the upper structure of the urban land in Istanbul.

The case study was conducted by applying a systematic process of structural condition assessment to distinguish critical symptoms on the structural system and its partitions that need to be revised to extent and improve the building service life and quality as much as possible in the example of the selected part, the front foyer and west façade of AKM. Beyond the process of the assessment, the concept of durability and sustainability could be extensively correlated as important partitions of design profession in nowadays as further applications of the study.

2. A CASE STUDY: The FRONT FOYER in AKM

In this section; specific data, information and a specific method of analysis about the front foyer of AKM are intend to provide a proper method and useful example for conducting a structural condition assessment methodology. Specifically detailed parts are determined to open up the topic in discussion

according to preliminary strategy of the case study such as site survey and available building specifications on the research issues; and static and dynamic loads.

The first part of this section provides an outline of the proposed assessment outline that reflects on an individual understanding and perception of the research process. The second part focuses on a physical definition and materialistic description of the front foyer of the AKM and gives a brief explanation of the space. Regarding symptoms of structural failure, basic graphics of visual observations obtained from an on-site survey are drafted and described. Building inspection data, in which the building movements have been monitored, form the basis for developing failure diagnosis evaluation models. Confronting possible environmental agents to symptoms of structural failure is a content of the report conclusion in that reason-result equations are established to clarify the environmental agents as causes.

2.1. A Proposed Condition Assessment Outline

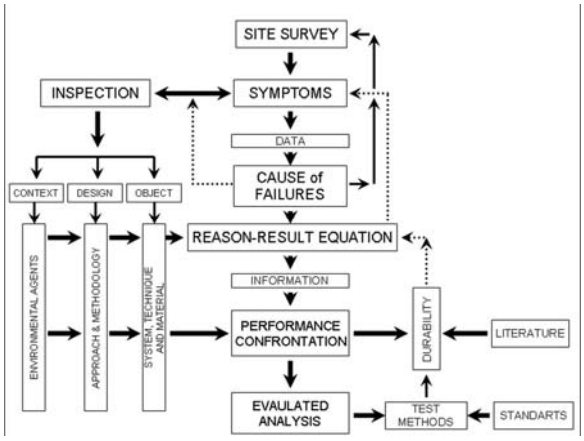

Fig. 1: A Chart of Proposed Assessment Outline

To propose a condition assessment outline is an individual outcome for understanding the process of the case study.

The proposed assessment outline becomes a priority for the researcher to limit the study to predefined expectations; it also serves as a useful guide. According to the outline, there is a hierarchal process suggestion in order to apply a directional approach while integrating supplementary components from test methods to concept of durability. Furthermore; "*Inspection*" that is divided into three interrelated partitions (context, design and object) directly supports the hierarchical process in two different steps.

By combining within the ready-made concrete knowledge as references –literature and test methods, it is expected to have a feedback process to reach a reliable end-result. In certain steps, there is a check point to help ensure a cross control of the process.

Although the assessment outline is a proposition to be a guide, it is not run effectively and accordingly as a result of lack of the local and referential resources. One of them is that even construction documents of AKM could not be institutionally revealed. For this reason, it becomes a conceptual statement that is not realized completely.

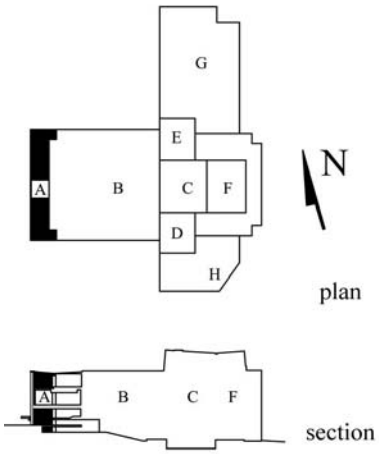

Fig 2: Schemes of AKM

2.2. Description of the Space

According to TMMOB, Branch of Istanbul publication about AKM, *As a Part of Cultural Life: Theatre and the Buildings,* and various site visits, the sections of **Description of the Space** and **Structural System & Material** are outlined. The Front Foyer of AKM, shown as **[A]** in the scheme is specifically chosen to apply structural condition assessment concept because of its fully exposed position to multi environmental agents and its visually accessible partitions. Because of that most of public access is on this side of the building and consequently, it becomes a hinge point. This possibly increases the effects of environmental agents on the components of this space.

Facing West, the front foyer outlines a dimensional space of 54.50x10.80x25.70 m dimensional space outline that covers whole façade, as an identical image of the building.

The vertical façade within a horizontally abstracted of a stage curtain defines the civic building image in the square of Taksim that is one of the most important public spaces of Istanbul.

The foyer also gives a unique baseline to the building circulation system. Major performance halls in the AKM are accessed from this foyer. Although, it gives a sense of a single volume from outside, it is divided into three non-uniform sub foyers in the building.

2.3. Structural System & Material

A close look to the front foyer reveals itself that multiple structural systems and materials are integrated into a unified space. It varies from reinforced concrete applications to structural metals; steel and aluminum. In addition to the specified and original structural detailing, nature of materialistic appearances are established in a way of realistic presentation.

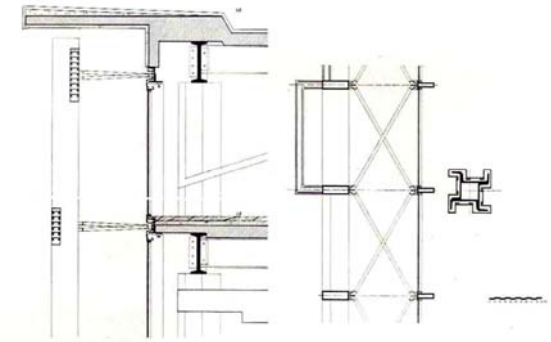

Fig 3: Section & Plan of West Façade System

In the general structural appearance, skeleton frame system is applied through out the building. Structural steel column-beam and reinforced concrete frame applications are unified into whole volume of the front foyer. Four (4) channels of structural steel are composed of being a single column of the façade and then it is connected to reinforced concrete portion of the building by I-beams. And, a reinforced concrete slab completes the main floors and roof enclosure. In the underground portion of the front foyer, structural steel columns are supported by single foot establishments and other reinforced columns transfer load by single foot and shear wall integration.

Two layers of the façade, louvers and a curtain wall, define an image of the West façade. While Grinatal Aluminum Louvers dominate the vertical portion of the west façade, a uniform glass curtain wall covers the inner side of the façade. A single louver, (8,2-20,3-2570cm), is made of a corrosion resistant grinatal which is an aluminum alloy (% 0,5-5 Si, % 0,7 Mg). With 7 segments and 3 pinpoint connections to the main floor slabs of the front foyer, it has a rigid connection to the ground. At the +22.20 level, there is a strip that connects all louvers to each other. The glass curtain wall is constructed by 4.5-10cm metal members without any vertical or horizontal differentiations. It is connected to structural steel column at three levels by edged connections and hinge type points.

2.4. Symptoms of Structural Failures

In the proposed condition assessment outline, the first stage of the assessment is site survey is pointed as process. In the content of 'Structural Condition Assessment', by Ratay R.T. [c2005], the site survey could be basically conducted by various steps: visual observation, measuring, photographing, interviewing, probing, record keeping, documentation, and report preparation, as a directional procedure. At this point, the visual observation step in the scope of the case study is initially directed to focus on main partitions of the space; floor, ceiling and walls. Among the various symptoms in the front foyer, the façade is specified to analyze deeply because of its vulnerability in terms of environmental agents and its openness characteristics to site survey. Two main symptoms were detected on the west façade of AKM. *Non-Axial Deformation of the Vertical Louver and Non Linearity of the Glass Curtain Wall.* Both these items were selected to carry out further stages of the proposed condition assessment outline.

2.4.1. Non-Axial Deformation of Vertical Louver

Because of its closely integrated vertical configuration within an image of gradually opened up stage curtain, it is pretty difficult to recognize with bare observation that every vertical louver segment of the façade has a defect. This defect is a non-axial deformation through its length of grinatal aluminum louver in various amounts and directions. Fifty six (56) vertical louvers within 7 segments at each louver have fragmental characteristics that are nature of the building elements.

Fig. 4.: Photographs of the Louvers

2.4.2. Non Linearity of Glass Curtain Wall

As a second layer of the façade, the glass curtain wall with almost 460 m^2 gross area is under risk of loosing its vertical linearity. The curtain wall that is composed of a uniform section of vertical and horizontal mullions and glass surfaces has rigid connections at the base and upper floor and it is attached to the main column of the foyer with a hinge type connection at three different levels. In particular, there is a limited hinge connection that looses its position at the + 0.65 level. When all these type of connections at the curtain wall are considered, at this level there is only a deformation on the hinge connections.

Fig 5: Photographs of the Curtain Wall

2.5. Evaluation Models of Object Inspections –The Building

As a result of visual observations from the site survey, simple models have been introduced to obtain basic data from the site. These models are based on measuring, photographing, record keeping, and documentation of physical substances that relate to with symptoms of structural failure in the foyer space. According to the symptoms' specifications, ground movement & settlement, vertical louver deformation and glass curtain wall deflection models are developed and presented.

2.5.1 Vertical Louver Deformation

It should be mentioned that there is a compact visual perception of the louver system at the west façade of AKM without perceiving any physical defect at the first glance. On the other hand, it should be an expectation that the louver system is under critical treat of various environmental agents; wind, temperature, and pollution, etc. since 1978.

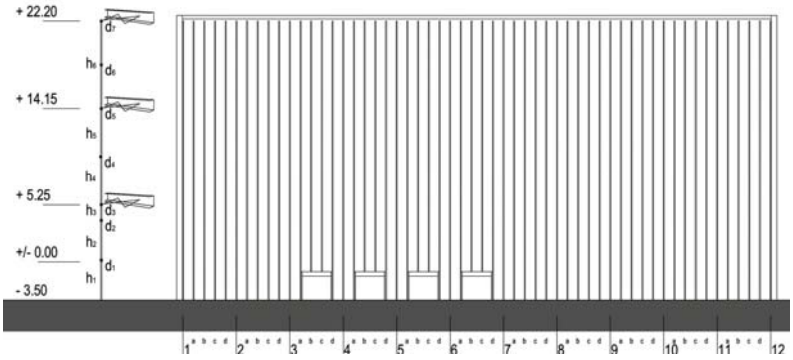

Fig. 6: The vertical louvers of West Façade

In Figure 6 one can identify whether the deformation is on or off of the vertical louver. For this reason, each louver is coded (i.e. 1a or 11d) and fragmented according to the number of portions (i.e. h1, h2) and joints (i.e. d1, d2) on the louver. Levels in elevation are pointed along the height of the louver to get numeric data of possible deformations.

In Figure 7, there is an end result drafting of the visual observation about the louvers' deformations. The main result in the visual observation is that most of the louvers have a defect of the deformation in various direction, position and degrees. Actually, there are two distinctive directions of the fragment movement, the north and south that are shown at the base of the figure (< >) within a colored line. And also, the deformation positions in terms of louvers' fragments and joints are presented in the format of the façade. This situation is more clearly understood by comparing with levels –fragments and joints– and connection type and the levels of the louver to the main building.

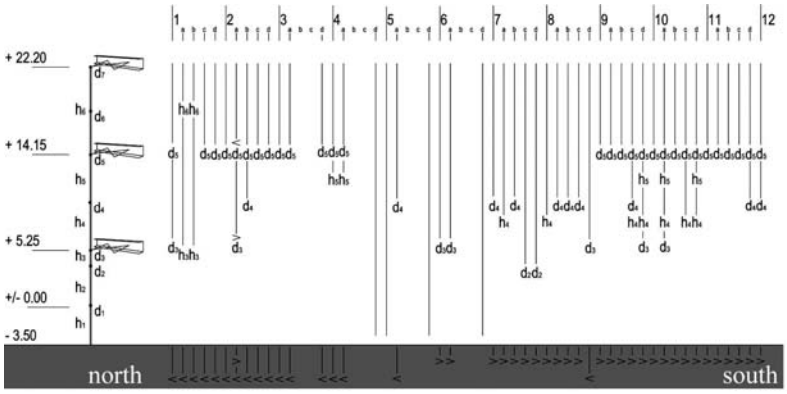

Fig. 7: Drafted Analysis of the Louver Deformation

Figure 8 contains measurement of the degree of deformation of the louvers. In this manner, there is only a degree that is stated in the direction of north to south. The data is only current for "*h1*" fragment of the louver. It is presented only a ratio of h1 deformation that is a result of a simple measuring. And it is expectation that a total deformation of h1 could be figured according to the full height of the h1 that is 3.65 m. That varies from 4,5 to 7,3cm.

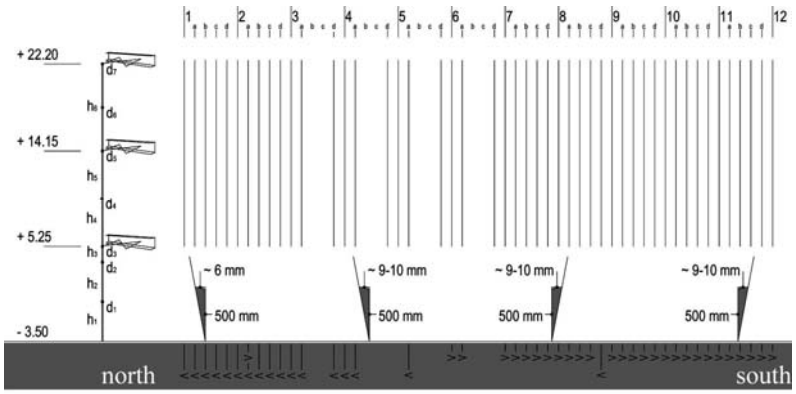

Fig. 8: Deformation Amounts in the partial level of the louvers

2.5.2 Glass Curtain Wall Deflection

In the model, the glass curtain wall system is defined by visual observation and measuring. It is stated that a uniform of the metal mullion with 4,5 / 10 cm rectangular section is applied along the every segment of the system without any differentiations in horizontal and vertical lines. On the other hand, it is noticed that horizontal segments of the lines have a continuum characteristic while vertical segments is fragmented according to the horizontal lines.

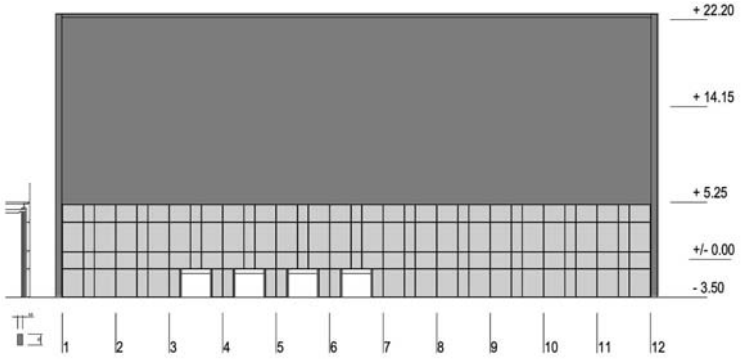

Fig. 9: Curtain Wall

The graphics explain the deflection's direction in the glass curtain wall and amount of the deformation in the system. Because of the movement at the middle hinge connection and the basics of measuring, the direction is observed towards to inside of the front foyer.

The measuring data reflects a ratio of the deformation in various points. The ratio should be evaluated and confirmed through whole façade.

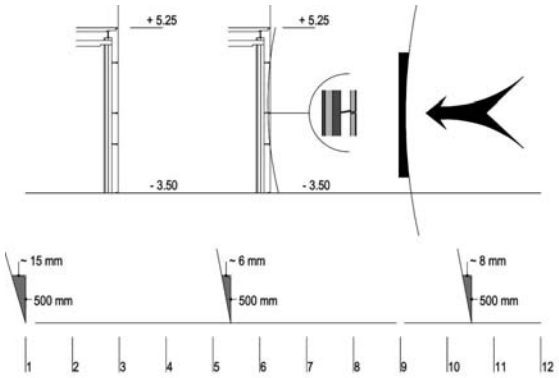

Fig. 10: Deflection Amounts in the Curtain Wall

2.6. Possible Environmental Agents to Symptoms of Structural Failure

In general understanding of performance requirement model, "safety" is defined as a social and psychological requirement of the building performance, and it has two fundamental environmental agents in its domain; static and dynamic loads. While static loads are classified by dead, live and impact load, dynamic loads are specified with earthquake and wind loads, thermal and moisture movements in the 'Structural Analysis of Historical Constructions' by Claudio Modena, P. B. [2004]. In this part of the study, a new perception towards structural loads is presented that is based on upper classified titles, named 'static' and 'dynamic'. This situation offer a transition point to relate the structural loads as environmental agents with the symptoms of structural failure in the front foyer of the AKM. Finally, this suggests a temporal reading of environmental agents that are specified in the example of the case study.

2.6.1. Static

- Eccentric Load

It is a type of a load imposed on a structural member at some point other than the center line of the section. In the case of an ideal column under an axial load, the column remains straight until the critical load is reached. However, the load is not always applied at the center line of the cross section, as is assumed in Euler buckling theory. In fact, misalignment of the structural member in the structural system could initiate and even multiple defects of the structural failure that are issued in the 'Design and Construction Failures' by Kaminetzky, D [c1991]. And also, dead load of the structural member becomes a reason of the eccentric load in itself. Within consideration of the symptom at the west façade of AKM, the eccentric load could be issued for the vertical louver. If certain construction

defects were in discussion like misalignment of linear elements, the eccentric load would be main causes of the defect; vertical louver deflections.

2.6.2. Dynamic

- Wind

Wind is the result of a number of factors such as atmospheric pressure differences, differential radiation of the sun, and the rotation, curvature & surface characteristics of the earth. Overall understanding and analyzing the wind are stated in the 'Wind Effects on Buildings', Lawson, T. V. [1980]. In the nature of wind characteristics, the behavior of the wind consists of two components: a steady flow; and a turbulent fluctuating system. The first has a mean of wind speed; the second, a fluctuating velocity due to turbulence or gusting. The dynamic component causes vibration & flutter of structures. In other words, wind load is a reason of turbulence at the side of the vertical object when it passes through by its vortex behavior. This consequence is a reason of vibration in the object. Vibrations are located at the perpendicular sides of the wind direction. When a flat surface reflects and redirects the wind, understanding the effects of the wind load on the vertical louver becomes more complicated analysis. In fact that a first effect of wind is to behave as a lateral load to turn over or relocate any structure in itself. But, if this is not possible by an existing sufficient structure, deformation effect is on scene in certain degrees. Especially, a flat surface becomes a dynamic object to see canvas behavior like a sail.

3. CONCLUSION

By comparing the symptoms as defects and agents as causes, three specific titles are listed as end result definitions of the specific structural condition assessment. *Vibration of Louvers and Canvas Behavior of Façade* are described with related defects and causes.

Vibration of Louvers

Wind is a natural event that occurs in any geographical location with variation in loads and intensities. As well, certain shapes common to nature naturally affect and shape, direct, deflect and perhaps increase the speed and effect of the wind on man-made structures. Besides the physical characteristics of a city, the layout of upper structure features within city could be important determinants of those effects. For example, a street could provide a channel to direct the wind in an intentional way or vice versa. In the same way, a building could be located in terms of getting positive wind effects or eliminating the negative circumstances of wind.

The AKM is located in one of the dominant hills in Istanbul. Although the dominant wind has not been monitored, it has been noticed that the center west façade could at times be under threat of prevailing winds, either from the direction of Gumussuyu and Macka Park to Tarlabası Avenue. Moreover, the openness characteristic of Taksim square could further raise the wind effects in an undetermined way.

A gradual graphic representation in Figure 11 is shown here to explore the expected outcome of wind effects on louvers. In the gradual sequences, the end point is seen as permanent deformation of a vertical object. However, the end point could also be a dynamic elastic deformation.

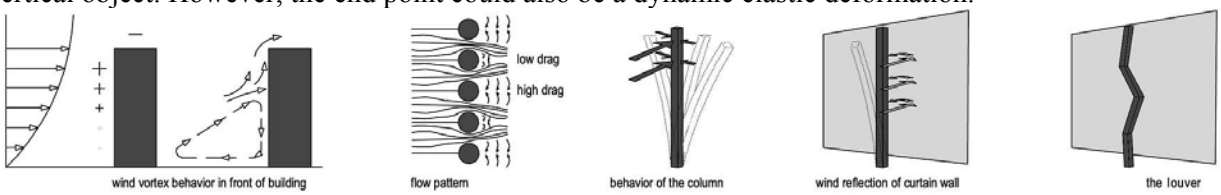

Fig. 11: Wind and its Circumstances

At the AKM, permanent deformation of the louvers and locations are presented according to a limited time based site survey. In the example of the louvers at the west façade of the AKM, extensive monitoring methodology that covers a long time based data should be applied to finalize determining the likelihood of deformations and their expected characteristics.

An eccentric load could be a main defect for a linear building element, if there is a failure to keep up the louvers' straightness during the construction phase. To investigate a misalignment of a louver is not possible in current database.

Canvas Behavior of Curtain Wall

Another negative effect of the wind could be mentioned on the curtain wall that could be called as a canvas behavior of the flat surface. In Figure 12, it is shown that this effect basically result from wind pressure in the direction of the wind. Uniformity and strength of the flat surface, while eliminating local failures, could become an initiative of the defect.

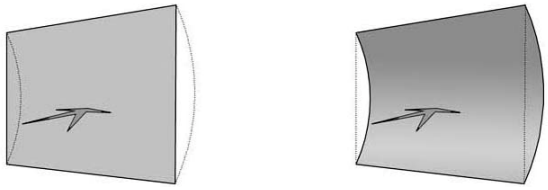

Fig. 12: Canvas Behavior of Curtain Wall

The west façade of the AKM is divided into three partial curtain walls having various dimensions. In this assessment, only the ground level curtain wall is considered in respect to deformation and this is estimated, based on interpolation, to range between 5 and 13cm. The interpolation method in various horizontal locations at the middle level of the curtain level, + 0,87 where it is already a deformed hinge connection line level. It could be possible to compare the amount of the deflection of the curtain wall with in relation to reference deflection data to state the amount that is in a critical level to determine whether total or partial collapse is in agenda.

As it is mentioned that the case study is to be a medium not only to offer further remediation outline but also to give a scientific perception to the public debate whether the AKM, in Istanbul, is well constructed and performed sufficiently without any fundamental renovation or it is necessary to design a new civic building. The outcomes given in the case study are accepted as an analytical data in the conclusion part to finalize the study. For this reason, there is a suggestive classification to outline as a next step after reviewing the failures. In the ISO 15686-1 [2002] standard relating to service life planning of buildings and constructed assets (i.e. Part 1) provides a method in which failure modes are classified into six levels according to safety and economic factors as shown in Table 1. In the table, three specific titles are perceptually ranked in terms of the classification strategy.

Table 1: Failure Modes versus Specific Titles

Failure Modes		Vibration of Louvers	Canvas Behavior of Curtain Wall
Danger to life	:		
Danger to health	:		
Costly repair	:	X	X
Frequent repair repeat	:	X	
Interruption of building use	:		X
No exceptional problems	:		

ACKNOWLEDGMENTS

The case study described in this paper that focused on the Atatürk Culture Center (AKM) in Istanbul, Turkey, formed part of a course taken in the fall session of 2007, entitled "Performance of Building Elements under Environmental Effects", conducted by Assoc. Prof. Hülya KUŞ in the Building Science Ph. D. program in the Faculty of Architecture, at ITU.
