Test has taken place following procedure proposed by EN 1062-3:1998 [«Paints and varnishes - Coating materials and coating systems for exterior masonry and concrete - Determination and classification of liquid-water transmission rate (permeability)»].

After a brief settlement period (not highlighted in diagrams), the results (Figs. 11 and 12) show that Metilsilossanico cycle (in its original version) has a transmission level of liquid water equal to 0.04 kg/m^2·h$^{0.5}$, while original Vinilversatico is certifiable to 0.16 kg/m^2·h$^{0.5}$. Numeric value determination comes from formula reported in Fig. 10.

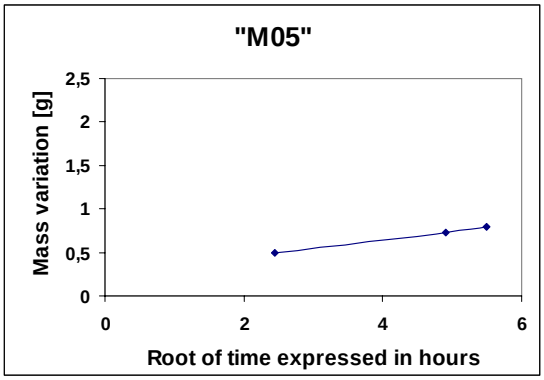

Figure 11. Liquid water transmission of Metilsilossanico cycle.

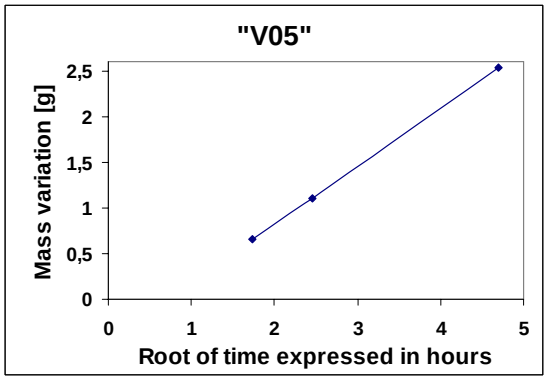

Figure 12. Liquid water transmission of Vinilversatico cycle.

4 RESULTS

4.1 Phenomena of Semi-Natural Obsolescence Pointed out in The Course of Time

It is evident, in Figs. 13 and 14 that the Metilsilossanico cycle has a bigger degradation than the other one. Vinilversatico treatment shows only the presence of some close-fitting particles on its surface and

no interruption of film continuity, whereas Metilsilossanico sample has displayed, in isolated portions, some film damages.

The real evaluation of superficial transformations is based on data collected on permeability features of film surface (water vapour and liquid water).

Change of water vapour permeability: as shown in Fig. 15, the level of Metilsilossanico cycle - after two years of exposition - has slightly decreased down to 11.15 g/m^2·d. Numeric value determination comes from formula reported in Fig. 9.

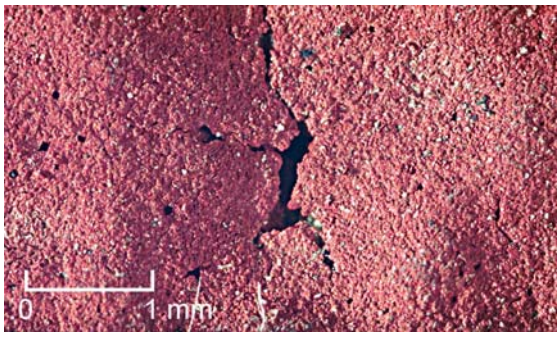

Figure 13. Close-up of Metilsilossanico cycle.

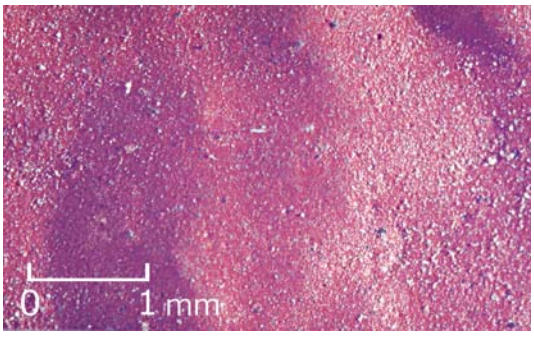

Figure 14. Close-up of Vinilversatico cycle.

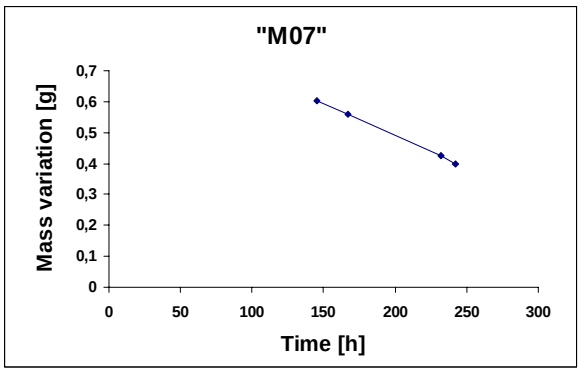

Figure 15. Water vapour transmission of Metilsilossanico cycle.

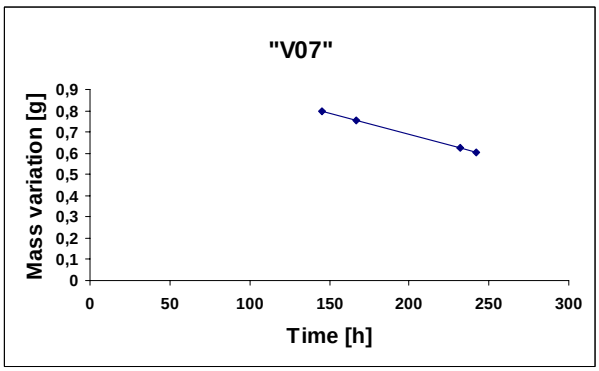

Figure 16. Water vapour transmission of Vinilversatico cycle.

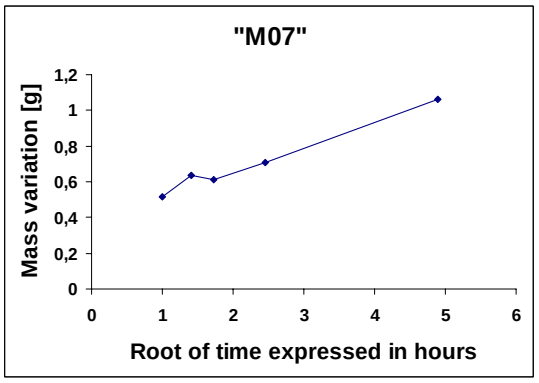

Figure 17. Liquid water transmission of Metilsilossanico cycle.

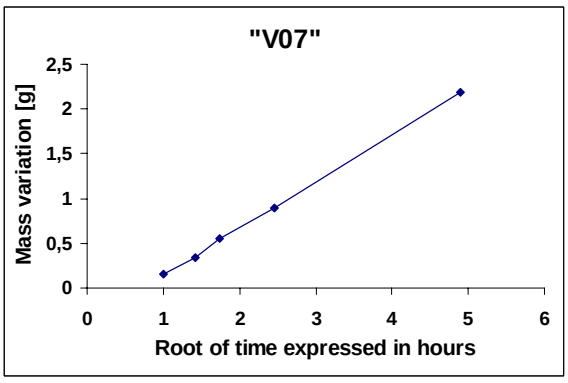

Figure 18. Liquid water transmission of Vinilversatico cycle.

Change of vapour permeability: as shown in Fig. 16, the level of Viniversatico cycle - after two years of exposition - has slightly reduced, achieving the value of 9.07 $g/m^2 \cdot d$. Surface tested has not shown visible phenomena of film break. Numeric value determination comes from Fig. 9 formula.

Regarding the transmission level of liquid water, Metilsilossanico aged cycle (two years) (Fig. 17) has a value of 0.023 $kg/m^2 \cdot h^{0.5}$, while Vinilversatico (Fig. 18) - after two years of outdoor exposition - shows a permeability value of 0.079 $kg/m^2 \cdot h^{0.5}$. For these two determinations has been applied formula reported in Fig. 10.

5 CONCLUSION

First laboratory results show that structure of resins permits to mantain a good water vapour permeability (with a 16 % value reduction), whereas greater impermeability to liquid water may lead to hardening of exposed surfaces. As visible in the diagrams, both solutions have shown a minor liquid water transmission level: about sixty percent for Metilsilossanico and fifty percent for Vinilversatico.

Moreover, it is also possible to point out a strong adherence of hydrocarbonous pollutants, made worse by 45° inclination of the specimen. Such inclination may determine significant casual lack of cleanness.
Obviously samples tested have excluded points of evident crack.

Outdoor exposition has been influent in the same way on Metilsilossanico and Vinilversatico samples, even if the Metilsilossanico film has a double average thickness compared with the Vinilversatico. To justify this reaction, it must be underlined that resin used to constitute the thickest film has a volumetric powder concentration equal to 60 %, while the value for Vinilversatico is limited to 45 %.

Durability Evaluation of Newly Developed Water-Based Paint Systems for Buildings

Kenji Motohashi [1]

T 16

ABSTRACT

According to the report, about 30% of total amount of organic carbons emitted into the atmosphere due to human activities have been considered to come from paint works. Different from coating work in manufacturing factories, it is difficult to collect organic solvents evaporated in the air because paint works in construction are carried out on construction site. The only method for decreasing organic solvent emission is to use coating materials including little organic volatile. In this context, various water-based emulsion paint products have been developed in Japan and applied to coating works for buildings.

This paper outlines the results of durability evaluation test for these new water-based paint systems. An accelerated ageing test and an outdoor exposure test for 10 years have been conducted for both newly developed water-based paint more than 10 years ago and existing organic solvent type paint.

High durability performance of some water-based paint systems has been demonstrated through the evaluation tests. It was confirmed that some of the newly developed water-based paint systems show competitive durability against existing organic solvent type of paint systems.

1 INTRODUCTION

According to Sakamaki [1986], about 30% of the total amount of volatile organic carbons (VOC) which were emitted into the atmosphere due to human activities has been considered to come from painting works. Ministry of Environment in Japan also reported VOC emission percentages from the fixed facility sources as shown in Fig. 1. Paint coating is the most important source of VOC emission to the environment. Moreover, in case of coating works on construction sites, it is difficult to control VOC evaporation into the atomosphere because they are carried out in outdoor conditions.

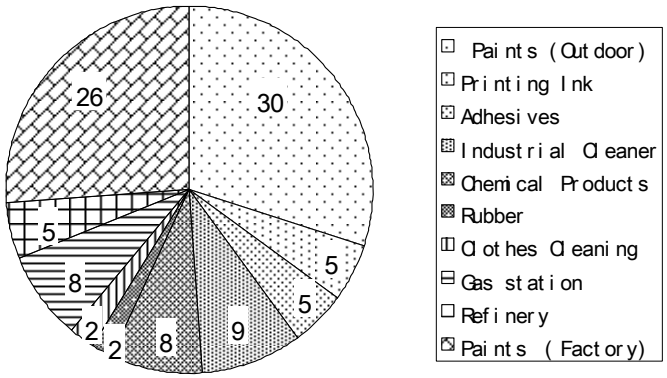

Figure 1. The percentages of VOC emission from the fixed facility sources in Japan.

For this reason, use of water-based paint has been recommended from the viewpoint of environment protection. This demand has become very strong recently. Paint manufacturers are intensively developing safer and more durable paint. Figure 2 shows fundamental methodologies for developing safer paint to the environment.

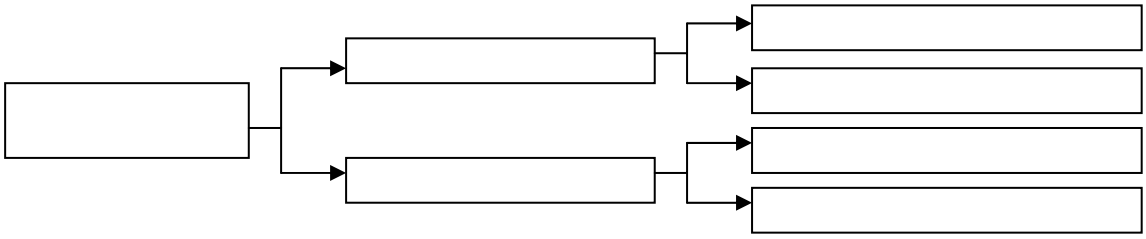

Figure 2. Basic methodology for developing environmentally safer paint.

Among the various types of paint shown in Fig. 2, poor solvent (mineral sprits, solvent with higher boiling point) type of paint, water-based paint and high solid type of paint have been on the market aiming at substituting for existing solvent type of paint used in construction works. Especially, water-based paint is considered to be most suitable from the viewpoint of environment protection. However, water-based paint is generally less durable than organic solvent type of paint. Therefore, it is not so easy to replace water-based emulsion paint for existing solvent type of paint especially where high durability is required.

Because of insufficient data on the durability of newly developed water-based paint, few types of durable water-based paints have been standardised in Japanese Industrial Standards (JIS) and other public material standards. In addition, few coating work specifications with durable water-based paint have been standardised in public construction works. The accumulation of durability data is a crucial point to promotion of water-based paint in construction works.

On this background, Building Research Institute has been conducting both outdoor exposure tests and accelerated ageing tests to obtain durability data for such durable water-based coating products which

are rather new on the market. The results of the 10 years outdoor exposure test and the acceleration test are reported in the paper.

2 EXPERIMENT

2.1 Outdoor Exposure Test

The coating products listed in Table 1 were evaluated in the outdoor exposure test. Water-based fluoropolymer emulsion paint [Motohashi et al. 1998] , acrylic silicon emulsion paint, and polyurethane emulsion paint were evaluated. A solvent type of fluoropolymer paint, acrylic silicon paint, and acrylic paint which had been already standardised in the material standards were also tested for comparison.

Table 1. Types and numbers of objected coating products in the outdoor exposure test.

Type of top coating paint	*Material standard*	*Number of tested brands*
Water-based fluoropolymer emulsion paint	Not standardised	17
Water-based acrylic silicon emulsion paint	Not standardised	17
Water-based polyurethane emulsion paint	Not standardised	10
Solvent type fluoropolymer paint	JIS K 5658:2002*	1
Solvent type acrylic silicone paint	JASS 18 M-404**	1
Solvent type polyurethane paint	JIS K 5656:2003*	1

* Japanese industrial standard, **Japanese architectural institute material standard

Each paint product listed in Table 1 was applied on the 70 mm x 150 mm x 6 mm (thickness) fibre reinforced cement sheet after application of a water-based emulsion primer. Paint (white opaque paint) listed in Table 1 was applied twice. Total coating amount of each paint product was about 150g/m^2.

The outdoor exposure test was carried out in the outdoor exposure site of Building Research Institute, Japan which is located some 50 km north of Tokyo and in rural district area. The painted specimens were mounted to the exposure rack facing the south at an angle of 30 degrees for 10 years.

2.2 Accelerated Ageing Test

The open-flame carbon-arc type of irradiation test was also conducted for most of the coating products which were evaluated in the outdoor exposure test in accordance with ISO 4892-4:1994 [ISO 1994]. The objected coating products are listed in Table 2.

Table 2. Types and numbers of objected coating products in the accelerated aging test.

Type of top coating paint	*Material standard*	*Number of tested brands*
Water-based fluoropolymer emulsion paint	Not standardised	9
Water-based acrylic silicon emulsion paint	Not standardised	13
Water-based polyurethane emulsion paint	Not standardised	8
Solvent type fluoropolymer paint	JIS K 5658:2002*	1
Solvent type acrylic silicone paint	JASS 18 M-404**	1
Solvent type polyurethane paint	JIS K 5656:2003*	1

* Japanese Industrial Standard, **Japanese Architectural Institute Material Standard

The acceleration test was carried out up to 5,000 hours. Water spraying was applied for 18 minutes in every 120 minutes. The painted test specimens were prepared by the same preparation method in the outdoor exposure test.

2.2 Optical Measurement

Gloss retention percentages were monitored periodically in both the outdoor exposure test and the acceleration test. Gloss reflection percentages were measured at angle of 60 degrees. In case of the outdoor exposure test, the gloss reflection values of the specimens were measured after washing with water and drying in order to eliminate dirt from the specimens.

3 RESULTS AND DISCUSSION

The changes in gloss retention of the fluoropolymer paint, acrylic silicon paint, and polyurethane paint in the outdoor exposure test are shown in Fig. 3, 4, and 5, respectively. Those in the acceleration test are also shown in Fig. 6, 7, and 8.

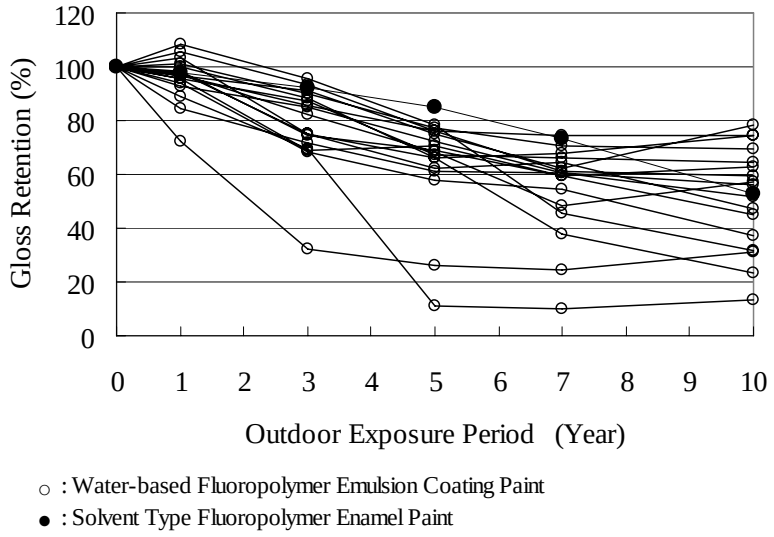

Figure 3. Gloss retention percentages of the fluoropolymer paint in the outdoor exposure test.

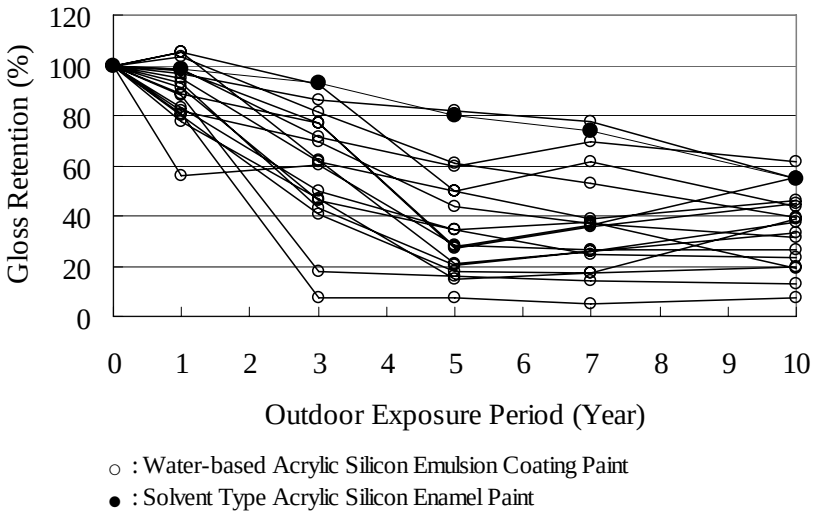

Figure 4. Gloss retention percentages of the acrylic silicon paint in the outdoor exposure test.

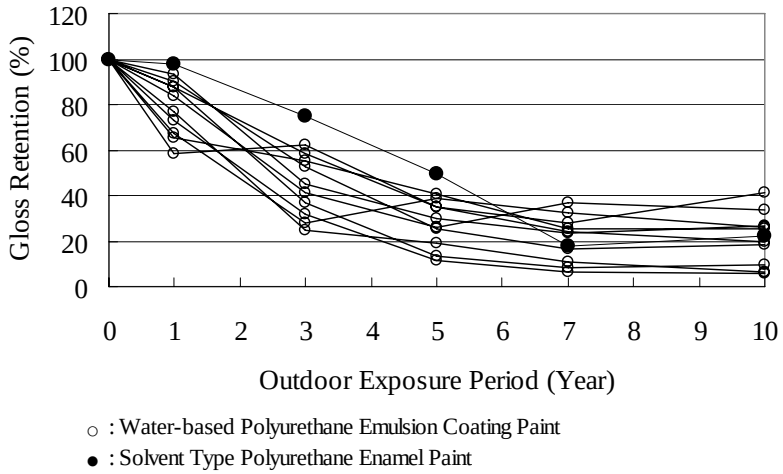

Figure 5. Gloss retention percentages of the polyurethane paint in the outdoor exposure test.

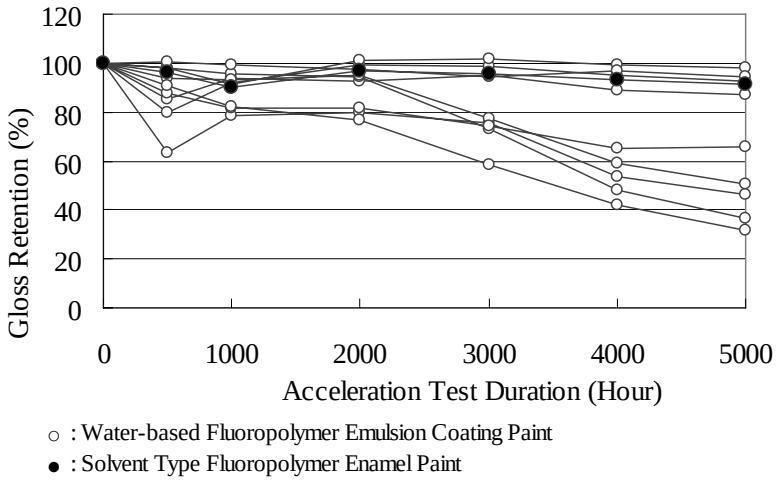

Figure 6. Gloss retention percentages of the fluoropolymer paint in the acceleration test.

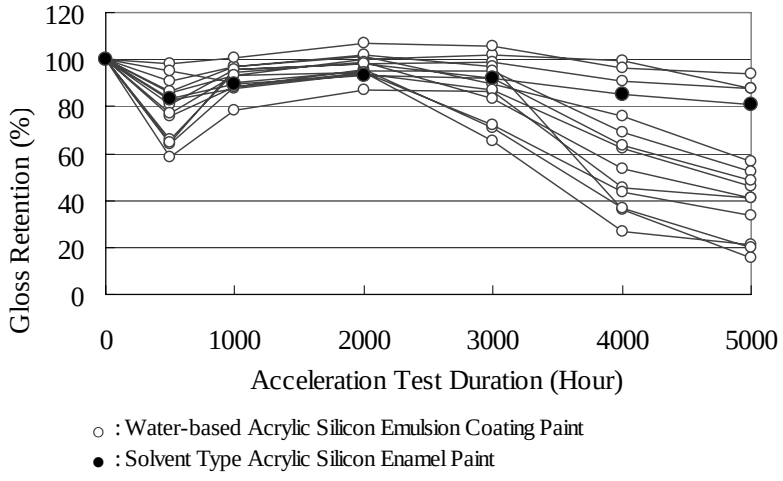

Figure 7. Gloss retention percentages of the acrylic silicon paint in the acceleration test.

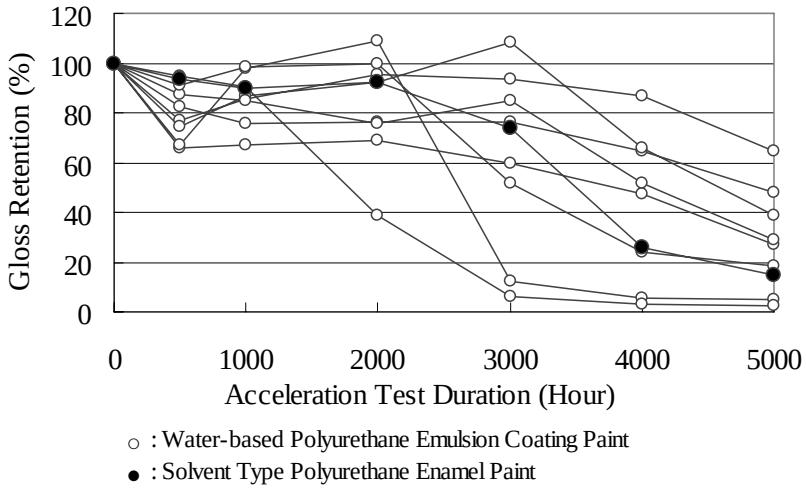

Figure 8. Gloss retention percentages of the polyurethane paint in the acceleration test.

First, when the three different types of polymers (fluoropolymer, acrylic silicon polymer, and polyurethane polymer) are compared one another by referring to the data obtained in the outdoor exposure test and the acceleration test, it can be said that fluoropolymer coating paint products are generally most durable among the three types of polymers and that the acrylic silicon coating paint products are generally more durable than the polyurethane coating paint products.

Second, in each type of polymer coating, it can be said that the standardised solvent type of paint is generally more durable than most of the water-based emulsion paint products made of the same type of polymer. However, on the other hand, it is possible to find a few water-based emulsion paint products whose durability is similar to that of the solvent type paint product among the evaluated water-based coating products. This fact could be confirmed in both the outdoor exposure test and the acceleration test.

Through Fig. 3 to 8, it is recognized that there was large variation in durability performance of the water-based emulsion products on the market. It means that the performance level of material standards for the durable water-based emulsion paint is very important. If we would like to select water-based emulsion paint which is as durable as solvent type of paint, the level of material standards for water-based emulsion paint products should be silmilar to that of the existing material standards of the organic solvent types of durable coating products. Through this experimental study, the durability data of the existing water-based paint products could be obtained and such data are very helpful for establishing rational material standards for durable water-based emulsion paint.

4 CONCLUSION

The 10 years outdoor exposure test and the accelerated ageing test were conducted for the durable water-based emulsion paint products on the market in order to investigate durability levels and their variation of fluoropolymer emulsion paint, acrylic silicon paint, and polyurethane emulsion paint which have been intensively developed in Japan. The organic solvent types of durable paint products were also evaluated in the same tests.

The results obtained can be summarised as follows:

1) When fluoropolymer emulsion paint products, acrylic silicon emulsion paint products, and polyurethane emulsion paint product are compared one another, the durability in the outdoor exposure

test and the acceleration test is generally superior in the order of fluoropolymer, acrylic silicon, and polyurethane.

2) Solvent type of paint is generally more durable than water-based emulsion paint which was synthesized by use of a similar type of base polymer. However, it is possible to find a few water-based emulsion products whose durability is comparable to that of solvent type of paint.

3) There is large variation in durability performance of the durable water-based emulsion paint products on the market. It is important to establish rational material standards for selection of proper products. Through this experimental study, the useful data could be obtained for establishing rational material standards of durable water-based paint products.

Effect of Anti-Graffiti Coatings on the Drying Behaviour of Building Materials

Barbara Lubelli [1]

Teun van de Weert [3]

T 16

ABSTRACT

Anti-graffiti coatings are used to protect façades against unwanted graffiti. Despite the fact that anti-graffiti are widely used, not much is known about their effect on the drying behaviour of treated materials. Existing recommendations generally only take into account the water vapour transport values, not considering that the drying behaviour of a material is largely affected by the liquid moisture transport.
This paper reports the results of a research on 6 types of anti-graffiti coatings (permanent and sacrificial, water repellent and not) applied on two substrate materials (fired-clay brick and calcium silicate brick). The effect of the treatment on the drying behaviour is evaluated by means of drying tests performed at different RH. The obtained results are explained in the light of the product composition and the properties of the substrate materials (porosity and pore size distribution). The possible consequences of the application of the tested anti-graffiti coatings on common damage processes, as e.g. frost, salt crystallization, are discussed.

1 INTRODUCTION

Anti-graffiti coatings are used to protect façades against unwanted graffiti. They have the aim of limiting or avoiding the penetration of the graffiti into the substrate, thus making graffiti removal easier.
Anti-graffiti coatings can be grouped into three distinct categories [Bunnink et al 2004]:

a) *Permanent coatings:* these coatings are generally based on epoxy or polyurethane. Graffiti can be removed (with solvents) without the loss of properties, performance or appearance of the coating itself. These coatings have a service life of about 10 years and can be re-applied only after an adequate pre-treatment consisting in sand blasting or laser cleaning of the wall to eliminate the residue of the old anti-graffiti coating.
b) *Sacrificial coatings:* are mostly based on acrylates, polymer waxes, biopolymers (polysaccharides) or combinations of these. After soiling with graffiti, the anti-graffiti layer and the graffiti are removed together. After the removal, the coating has to be re-applied. Most of these products can be easily removed with (warm) water. Their solubility in water limits their durability: the service life of a sacrificial coating is about 3 years, but in façades or objects exposed to rain the service life can be shorter. They have good transparency and do not alter the aesthetical aspect of the treated material.
c) *Semi-permanent coatings:* These systems can be of two types: (i) a combination of a permanent base layer and a sacrificial top-layer or (ii) a semi-permanent one layer coating. In the first case the properties of the two layers are the same described in a) and b). During removal of the graffiti (by a solvent) the oleophobic part is removed, while the hydrophobic part is maintained. After the removal of graffiti a new layer of coating should be applied. These systems do not usually alter the aesthetical aspect of the treated substrate and have a long service life (about 10 years).

Within each of the categories, a distinction can be made between anti-graffiti with water repellent properties (e.g. silane) and without water repellent properties (e.g. polysaccharides) and between film forming (e.g. polyurethane based products) and not film forming (e.g. polysaccharide based products) coatings.

Depending on its chemical composition, an anti-graffiti coating will have a minor or a relevant influence on the drying behaviour of the material on which it is applied.

In spite of the fact that drying is a combination of both liquid and vapour transport, recommendation related to anti-graffiti coatings generally consider only water vapour transport [WTA 2005]. It can be expected that anti-graffiti coatings having water repellent properties or forming a water-tight film on the surface may strongly reduce the moisture transport by hindering the liquid water transport. Drying will therefore take longer, even if the product does not have any effect on the water vapour transport. This may enhance some processes as e.g. salt decay, frost damage and biological growth; moisture and salt related damage processes are in particular important for ancient buildings and monuments.

In this research the relevance of the effect of anti-graffiti coatings on the drying behaviour of treated material has been investigated. A drying test has been performed on two common building materials (a fired-clay brick and a calcium silicate brick) treated with a selection of 6 types of anti-graffiti coatings. At the end of the drying test the specimens have been cut and their surface and cross section observed by means of optical microscopy.

2 MATERIALS AND METHODS

2.1 Anti-graffiti Products

Six anti-graffiti coatings have been selected, including sacrificial, semi-permanent and permanent systems. The most relevant properties of the products are summarized in Table 1.

Table 1. Properties of the selected anti-graffiti coatings.

Composition	*Type*	*No of layers*	*Solvent*	*Film forming*	*μd** [m]
Wax based	Sacrificial	2	no	no	0.050
Polysaccharides	Sacrificial	2	no	no	0.024
Acrylic	Sacrificial	2	no	yes	0.200
Acrylic (mixed with siloxane emulsion)	Semi-permanent	2	no	yes	0.200
Polyurethane (water based)	Permanent	3	water	yes	0.950
Acrylic + polyurethane	Permanent	2	no	yes	0.575

** relative water vapour diffusion resistance : it depends on the thickness of the anti-graffiti layer and expresses the thickness of the air layer having a water vapour diffusion equal to the one of the applied layer of anti-graffiti (determined on the anti-graffiti layer according to DIN 52615 – Bestimmung der Wasserdampfdurchlässigkeit von Bau- und Dämmstoffen, November 2007).*

The natural wax used in this experiment is a commonly used, sacrificial anti-graffiti treatment. It does not alter the aesthetical properties of the treated object and it is not harmful for the building or for the user. It confers to the substrate some water repellency. It has a limited service life.
The polysaccharide product is a commonly used, sacrificial anti-graffiti treatment. It swells if in contact with liquid water, thus it can be washed away by longer periods of rain. As a result its service life is limited.

Two acrylic products have been selected: one semi-permanent (mixed with a siloxane micro-emulsion), the other sacrificial. Both acrylics form a water-tight film on the surface of the treated material.

The one component polyurethane anti-graffiti used in this test is a water based coating, which forms a water-tight film on the surface of the treated material. It is a moisture curing product, thus a RH of at least 50% is necessary for the polymerization reaction to occur.

The acrylic and polyurethane combination constitutes a film-forming, permanent system.

2.2 Materials

Two building materials commonly used in the Netherlands have been selected: a fired-clay brick and a calcium silicate brick. These substrates have been chosen also because largely different in colour and smoothness of the surface (this is important for the aesthetical influence of the anti-graffiti coating) and in pore size distribution (this is the most relevant parameter determining the moisture transport behaviour). The total porosity and the pore size distribution have been measured by means of mercury Intrusion Porosimeter (Autopore IV/9500 by Micromeritics).

The fired-clay brick has a red colour, 5 sanded surfaces and a porosity of 29.25 % by volume with pore sizes mainly in the range between 2 and 10μm (Fig. 1). The calcium silicate brick is greyish, has smooth surfaces and a total porosity of 27.24 % by volume, distributed in very wide range of pore sizes (Fig 2).

During testing it has been found that the outer surface of this calcium silicate brick was treated at the production with a water repellent. The penetration depth of the water repellent has been measured by wetting a broken cross section of the calcium silicate brick and was found to be limited to the outer 2mm.

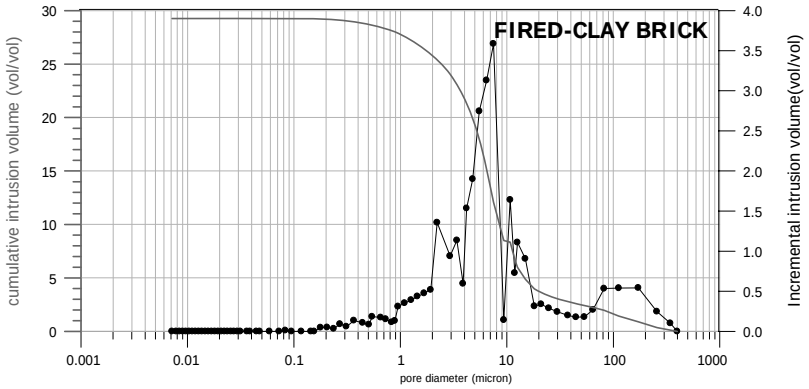

Figure 1. Pore size distribution of fired-clay brick.

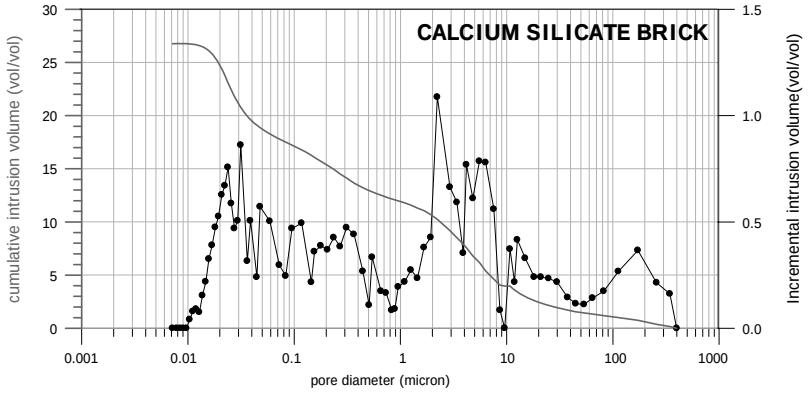

Figure 2. Pore size distribution of calcium silicate brick.

2.3 Procedure

The specimen consists in a half brick having the size of approximately 110 x 50 x 100 mm (b x l x h) in the case of the fired-clay brick and of 120 x 70 x 100 mm in the case of the calcium silicate brick.

Before the application of the anti-graffiti, the specimens were coated with epoxy resin on the 4 lateral sides, dried in the oven until they reached the constant mass and then conditioned at room temperature for one day.

The anti-graffiti coatings have been applied by roll, in 2 or three layers, on the upper surface of the specimen by an experienced person according to the prescriptions of the producer.

The treated substrates have been cured for 1 week at 20 °C 50% RH and then partially immersed in water until they reached the constant mass (mass change less then 0.1% per day). It was paid attention not to wet the upper surface of the specimens to avoid swelling and further dissolution of the polysaccharide. Then the bottom of the specimens was sealed with tape, so that drying could occur only through the treated surface. The specimens were stored in climatic rooms.

In the case of the fired-clay brick two drying conditions were used: 20°C 50% RH and 80% RH. In this way the effect of the anti-graffiti coating on the drying was studied not only at typical lab conditions (20 °C 50% RH) but also at more realistic environmental conditions (in the Netherlands the average RH is 82%). In the case of calcium-silicate brick only 20°C 50% RH conditions have been used, because of the very slow drying of this material. For each material/anti-graffiti/climatic condition combination 3 specimens have been used. Not treated specimens were used as reference.

At the end of the drying test the water repellency and the water tightness of the fired-clay brick treated with anti-graffiti have been tested by a drop test, i.e. by observing the shape of a water drop which was put on the surface and on a cross section of the material.

The cross sections were dried at 30°C before performing the test. This temperature was chosen to avoid re-emulgation of the wax and any possible shrinkage crack to the polysaccharide film. Both surface and cross section of the specimens have been observed by means of optical microscopy to study the thickness and adherence of the anti-graffiti layer.

3 RESULTS

3.1 Drying Behaviour

The drying behaviour at 50% RH of fired-clay and calcium-silicate bricks is reported in Fig. 3 and 4 respectively. The drying behaviour of the fired-clay brick at 80% RH is illustrated in Fig. 5.

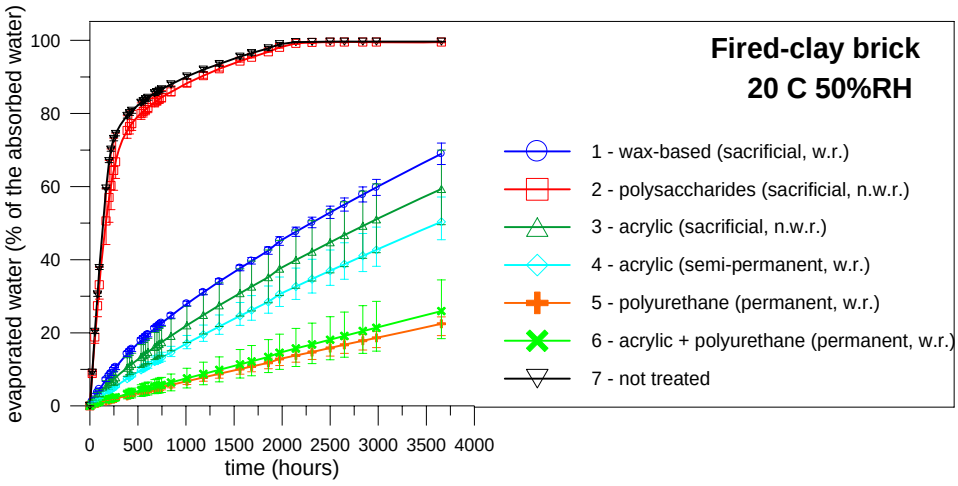

Figure 3. Drying behaviour at 20°C 50% RH of fired-clay brick treated with anti-graffiti coatings.

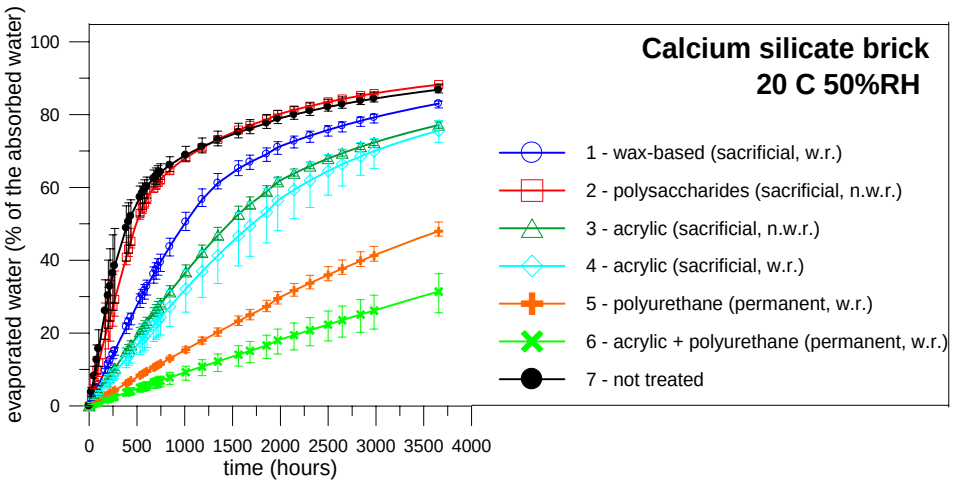

Figure 4. Drying behaviour at 20°C 50% RH of calcium silicate brick treated with anti-graffiti coatings.

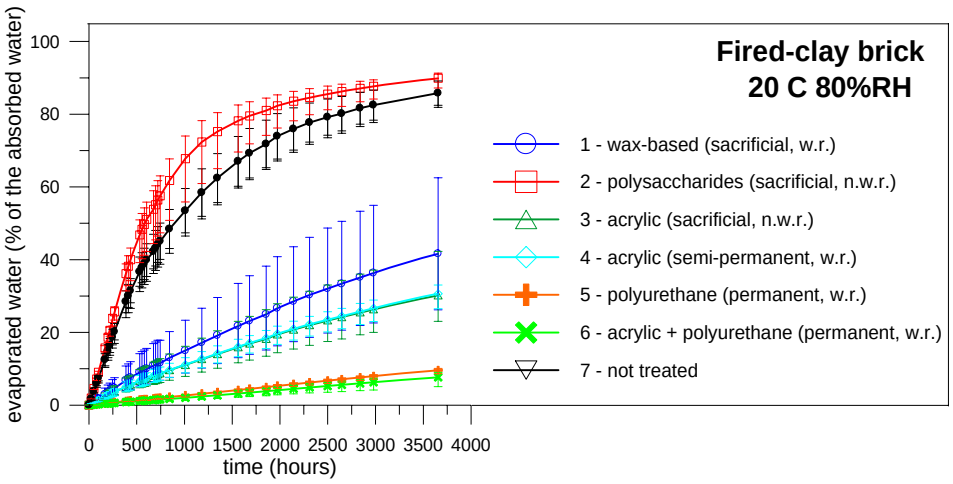

Figure 5. Drying behaviour at 20°C 80% RH of fired-clay brick treated with anti-graffiti coatings.

3.1.1 Reference Materials

The fired-clay brick dries faster than the calcium silicate brick. This is due to the presence of a water repellent layer on the calcium silicate brick and to the fact that the calcium silicate brick has finer pores than the fired-clay brick.

The drying behaviour of the reference fired-clay brick shows, as expected, two distinct drying phases: a first phase in which drying by liquid water transport prevails followed by a second phase during which drying occurs mainly through water vapour transport.

A porous material treated with a water repellent will not allow any liquid moisture transport and will therefore show no change in the slope of the drying curve, but a constant evaporation rate. This was expected for the calcium silicate brick the surface of which was treated during the production process with a water repellent. Figure 4 shows that this is not true in this case: two phases of drying are still distinguishable. This means that the water repellent layer is not completely effective and some liquid moisture transport remains possible.

3.1.2 Materials Treated with Anti-graffiti Coatings

The effect of the anti-graffiti coatings on drying of the fired-clay brick is clearly visible, both at 50% and at 80% RH. On the basis of the effect on the drying behaviour three “classes” of anti-graffiti can be distinguished:

- Anti-graffiti which do not significantly reduce the drying rate of the substrate: the polysaccharide belongs to this group. The drying behaviour of both fired-clay brick and calcium silicate brick treated with polysaccharide is about the same as the one of the reference materials.
- Anti-graffiti which reduce the drying rate: wax and acrylic products (sacrificial and permanent) belong to this category. These products significantly reduce but not completely stop liquid water transport: in fact a change in the slope is still visible in the drying curves.
- Anti-graffiti which strongly reduce the drying rate: polyurethanes coatings, alone or in combination with an acrylic primer, belong to this category. Due to the presence of a water-tight film on the surface of the treated material, liquid water transport is completely stopped and drying can occur only through water vapour diffusion, as shown by the constant drying rate. In the case of the calcium silicate brick the drying reduction due to the 3 layer polyurethane is less than for the combination acrylic primer and polyurethane. In the case of the fired-clay brick no relevant differences between the two anti-graffiti coatings are observed.

A correspondence exists in general between the water vapour diffusion data (see Table 1) and the drying behaviour measured on treated fired-clay brick and calcium silicate bricks: low water vapour diffusion resistance values correspond to a minor hindering effect on the drying. Nevertheless, the drying test gives more information about the simple water vapour diffusion resistance value, since it takes into account both phases of the drying and the effect of the material properties. In fact it has been observed that the properties of the material on which the anti-graffiti is applied play an important role. The hindering effect of anti-graffiti coatings on the drying is more pronounced for the fired-clay brick than for the calcium silicate brick. This can be explained by the fact that these products limit the liquid moisture transport, therefore they have a large impact on the first phase of the drying. As can be seen by the drying of the reference specimens, the first phase of the drying is more important for the fired-clay brick than for the calcium silicate brick (the fired-clay brick looses 60% of the initial moisture content in the first phase, while the calcium silicate brick only looses 30%), therefore the effect of these products on the drying will be more relevant for materials with a faster drying rate than for slow drying materials.

3.2 Water Drop Test

The water repellency and the water tightness of the fired-clay brick treated with anti-graffiti have been tested by performing the drop test (see section 2.3). As expected, the specimens treated with polysaccharide showed no water repellency: the water drop was immediately absorbed by the brick. On the surface of the specimens treated with acrylic products the drop remained spherical, while it was immediately absorbed on the cross section, indicating this anti-graffiti forms a water-tight film on the surface, and it has no penetration depth. The 3 layers polyurethane and the acrylic-polyurethane combination showed a reasonable (inferior to the acrylic) water tightness at the surface. The wax anti-graffiti show a good water repellency on the surface and some penetration depth (about 0.5mm).

3.3 Microscopy Observations

The microscopy observations of the surface and cross section of the specimens (Fig. 6) show that:

- The presence of the anti-graffiti is clearly distinguishable on the surface of the brick. Only in the case of the polysaccharide the amount of anti-graffiti left seems to be very limited.
- The surface is still opaque in the case of the brick treated by wax, the polysaccharide and acrylic anti-graffiti coatings, while it has assumed a glossy appearance in the case of the polyurethane and, in minor extent, of the acrylic and polyurethane combination.
- Wax and polysaccharide do not form a film on the surface of the brick. The other products form a more or less thick film. The thickness of this layer, observed in cross section, is not homogeneous.

4 DISCUSSION

The drying rate of a building material may influence its durability. Materials which retain water for a long time are generally more susceptible to decay.

The drying rate depends both on liquid and vapour transport; being the first much more effective than the second mechanism, hindering liquid water transport has a larger effect on the drying rate than reducing the water vapour transport. For this reason we believe that the effect of a surface treatment should be evaluated by measuring the drying behaviour of treated materials, instead of referring to water vapour transport values only, as usually done by the existing guidelines [WTA 2005].

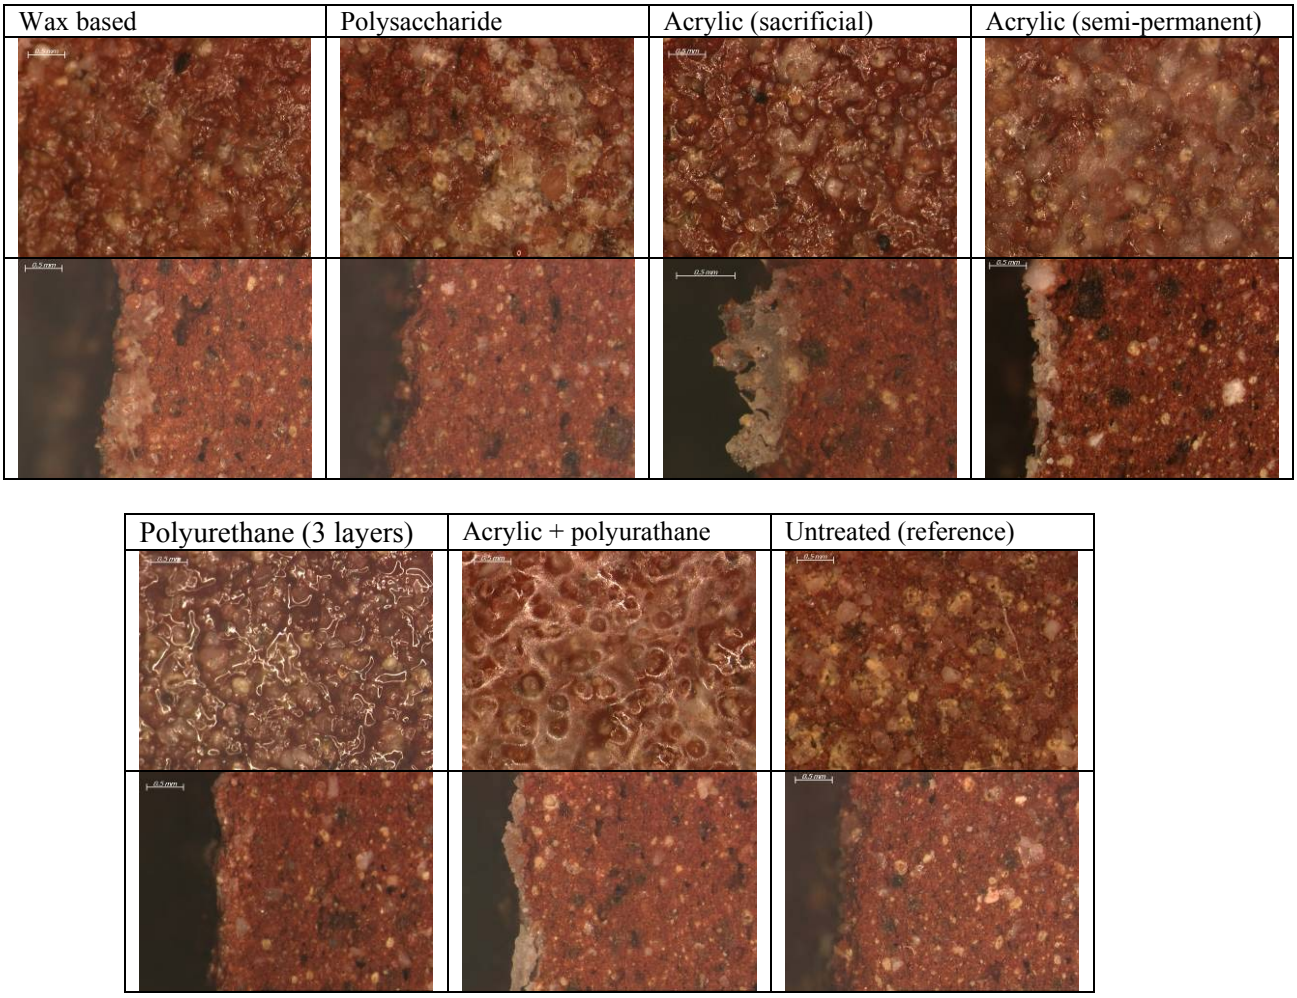

Figure 6. Pictures of the surface (above) and the cross section of fired-clay bricks treated with anti-graffiti.

This research has shown that some anti-graffiti coatings can strongly reduce the drying rate of a material. This may have negative effects not only on decay processes affecting high moisture loaded materials (like frost and biological growth) but also on salt crystallization damage. Similarly to what is observed in substrates impregnated with water repellents [van Hees & Brocken 2001], the salts, which can be transported only in liquid water and not in vapour, accumulate beneath the treated layer and may cause its detachment.

It is interesting to notice that the delaying effect of the anti-graffiti on the drying process is more evident in materials having larger pores and thus faster drying rate: the amount of water evaporated after one week from the fired-clay brick treated with a polyurethane is only 2.3% of the water evaporated from the untreated substrate, while in the case of the calcium silicate brick it is about 10%. The physical properties and in particular the pore size distribution of a material should therefore be taken into account when selecting the appropriate type of anti-graffiti coating.

5 CONCLUSIONS

This research has shown that some anti-graffiti coatings can strongly reduce the drying rate of a material. Polysaccharide has no or a very limited effect on the drying. Differently, wax, acrylic and, in larger extent, polyurethane based products partially or totally hinder liquid moisture transport, thereby

significantly reducing the drying rate of a treated material. This hindering effect may have negative consequences on the damage development in the case salts and/or moisture are present in the masonry.

Durability of Surface Protection Systems in Harsh Marine Climates

Claus K. Larsen [1]
Jan-Magnus Østvik [2]

T 16

ABSTRACT

The Norwegian Public Roads Administration owns and manages about 17.000 bridges, with several hundred concrete bridges in harsh marine environment along the long Norwegian coast-line. During the last 15-20 years a lot of work has been done on the effect of various surface protection systems for concrete in harsh marine environments. This paper summarises the work and the main conclusions drawn from some of the various field and laboratory investigations.

The objective for the various investigations has been at least two-folded: a) To investigate the effect of different types of surface protection systems in the field, both on the short and on the long term; b) to identify critical parameters with respect to technical performance of hydrophobic treatments and flexible cement-based coatings. Four large field investigations are reviewed; two large marine concrete bridges, one inland highway concrete bridge and one marine concrete quay.

Some of the results from the long-term investigations (up to 12 years) reveal systematically that impregnation of concrete with hydrophobic agents is very sensitive to the initial concrete moisture content. The penetration depth seems to be a critical parameter with respect to long-term chloride barrier effects. Coatings that are not flexible, or cracked after application, will fail due to cracking and subsequent loss of bond due to water accumulation and freeze/thaw actions. Surface protection systems might be very efficient over time when right products are chosen and applied properly.

1 INTRODUCTION

Concrete coastal bridges, ferry quays and wharf docks, especially those situated in harsh climatic conditions, suffer from various deteriorating mechanisms. The most severe is considered to be steel reinforcement corrosion due to chloride ingress from sea-water. Concrete bridges situated inland also suffer from steel reinforcement corrosion due to chloride ingress, but in this case from de-icing salt used on roads. The winter season requiring use of de-icing salt is normally 4-5 months in Norway, in some parts even longer. Especially for horizontal parts of a bridge, e.g. edge beams and concrete pavements, the chloride load can be rather high. Freeze/thaw actions in combination with salty water can lead to frost damages on the edge beams.

Maintenance of reinforced concrete structures is necessary to fulfil the designed or assumed service life [*fib* 2006]. The proper way of maintaining the concrete structure, i.e. the choice of repair/maintenance method, materials, application techniques and time of action is not always obvious. Wrong decisions can lead to increased problems, for instance if a coating starts to crack and fall off shortly after application. The chloride ingress is not necessarily affected by this, but the costs of repairing the surface protection system might be high. In many cases there is a need for repair of damaged areas (corroded steel and delaminated concrete) prior to surface treatment. Such repair is complex since the concrete has to be removed to a depth where the chloride content is lower than a certain critical level, a level that in many cases is difficult to identify as an unique value. Another uncertainty during maintenance and repair work is, of course, the weather conditions on site. Doing maintenance and repair work in a harsh and rough climate (strong winds, low temperatures and rough sea) is very challenging and demanding.

2 BACKGROUND AND EXPERIMENTAL

2.1 "OFU Gimsøystraumen Bridge Repair Project"

This EUR 4 million project ended in 1997, and was concluded in the international conference *Repair of Concrete Structures. From Theory to Practice*, held in Svolvær, Norway, May 1997. Main results up to 2005 from the on-going follow-up project that started in 1997, are summarised and discussed in [Larsen & Østvik 2005]. In addition to full-scale maintenance and repair work on the bridge, a research program was undertaken on the effect of various surface treatments on small-scale concrete slabs with two different initial moisture contents and two different surface preparations. Results from up to 10 years exposure will be reported and discussed in this paper.

Gimsøystraumen Bridge is a cantilever bridge finished in 1981 and situated in Northern Norway with a harsh marine environment. The bridge is 840 meters long with 5 long spans (126-148 m) and 4 short spans (25-65 m). The post tensioned box girder has a height that varies from 2.2 to 7.4 m. The highest and lowest point of the bridge deck is 36.5 m and 6.3 m above the sea level, respectively.

Small concrete slabs, 500mm by 500mm with thickness 50 mm, were cast with an OPC concrete with w/b-ratio 0.40 and 5% silica fume (by cement mass). A total of 87 slabs were cast, and they were all wrapped in plastic after de-moulding, and cured for 10 weeks in sealed conditions (no moisture exchange), i.e. the concrete was self-desiccated after curing. The degree of capillary saturation was measured to 79%. After 10 weeks, half the number of slabs was taken directly from the sealed condition, i.e. the concrete was still self-desiccated at the time of application, while the other half was immersed in water for five days to bring the concrete close to water saturation prior to application of the various surface protection systems. Immediately before application, half the number of slabs in each of the two moisture conditions was sand-blasted, i.e. there were four different concrete surface conditions available for application:

A.	Semi-dry; sand-blasted surface	B.	Wet; sand-blasted surface
C.	Semi-dry; virgin surface	D.	Wet; virgin surface

For each surface condition, nine different surface protection systems were applied on two parallel slabs and two parallel slabs served as untreated reference slabs – a total of 80 slabs. The slabs were placed on the North and West side, respectively, of one of the pillars of the bridge in August 1995. Many of the applied products were part of a development plan and are not commercially available today; therefore only four products will be reported. The products are (numbers refer to the original research plan and are therefore not in sequence):

1. Hydrophobic impregnation; a mixture of silane and siloxane in White Spirit (20% active substance).
4. Hydrophobic impregnation; pure silane (100% active substance).
6. Hydrophobic impregnation (same as #4) with a silane-acrylic based top-coat.
7. Flexible cement-latex-based coating
10. Untreated reference

The idea behind the topcoat for system #6 is to prevent degradation of the silane impregnation by UV-radiation. It is accepted that UV-radiation is the major reason for braking down a silane hydrophobic treatment [Basheer *et al*. 1992].

In 1998, five extra slabs that were cast, but not treated in 1995, were subjected to a new research plan. The slabs had been stored wrapped in plastic inside the box-girder of the bridge for three years. The slabs were treated with three different hydrophobic impregnations without any moisture conditioning or sand-blasting, i.e. the surfaces were comparable with condition C (but even drier). Two slabs served as untreated references. One of the products was in the development stage at the time of application, and is therefore not included in the results.

I. Reference N
II. Reference S
III. Pure silane (same as product #4)
IV. Silane gel (pure silane made slightly thixotropic with clay minerals)

2.2 “Skarnsundet Bridge”

Skarnsundet Bridge, once the longest cable stayed bridge in the world and still the world’s longest cable stayed bridge with a super structure in concrete, was finished in 1991 and is situated in marine environment close to Trondheim in the middle part of Norway. In 1993 it was decided to investigate various surface protection systems and their long term effect as chloride barriers on this bridge. The lowest part of the two pillars that form one of the towers of the bridge was divided in 28 sections, each 1m wide and 5m high, such that ten different surface protection systems could be applied on two opposite sides of the pillars, in addition to eight untreated reference areas (one section on each side of the two pillars). The different products are divided in two hydrophobic impregnations (silane diluted in White Spirit with 13% and 40% active substances, respectively), two impregnations (thin-film paints) and six cement based coatings (two flexible and four non-flexible). Results from up to 12 years exposure will be reported in this paper.

The concrete substrate is a typical Norwegian concrete used for bridges, with w/b-ratio 0.40, 5% silica fume and high strength OPC. Prior to application, the chloride content in the reference areas was determined by profile grinding, and each section was carefully investigated with respect to cracking and other surface failures that could influence the effect of the surface treatments. One idea behind the project was to let the suppliers find their best chloride barrier, suggest the proper pre-treatment of the concrete surface and apply the products themselves. This would lead to the very best application any

supplier could get for such a research project. Each application was carefully monitored with measurement of the amount of agents applied.

2.3 "Lundevann Bridge"

Lundevann Bridge is a 12-span beam bridge on the E18 highway in the southern part of Norway. It is situated in inland-climate and suffers from intensive use of de-icing salts 4 to 5 months per year. During repair work on the edge beams in 1998, due to heavy reinforcement corrosion after nearly 30 years in service, a field investigation on the effect of surface protection systems was started. The new parts of the edge beams and test specimens (small concrete slabs, 300 mm x 500 mm x 50 mm placed on top of the edge beams), were cast with a OPC concrete with w/b-ratio 0.40 and 5 % silica fume (by cement mass). Both the edge beams and the slabs were treated with four different products, two hydrophobic impregnations and two flexible cement based coatings. Results from up to 9 years exposure will be reported and discussed in this paper.

2.4 "Sjursøya Quay"

The Sjursøya Quay is part of the Oslo Harbour, and serves as an important quay for the oil industry in the Oslo region. The quay was repaired in 1999, due to heavy chloride induced corrosion of the steel reinforcement and subsequent loss of load bearing capacity. The quay is a traditional concrete beam-slab structure, about 300 meters long divided in 48 beam-slab sections. The chloride contaminated concrete in the bottom part of the slabs and the beams was removed by water-jetting, and replaced by shotcrete for the slabs and ordinary concrete for the beams, both OPC concretes with w/b-ratios 0.40 and 5% silica fume. A few weeks after concreting eight of the sections (a section includes one beam and the corresponding slab underside) were treated with different surface protection systems; five hydrophobic impregnations and three cement-based coatings. Some results from up to five years exposure will be reported and discussed in this paper.

2.5 Chloride Ingress

The chloride ingress was measured on specimens either cut from the various slabs or on cores taken from the various structures. Concrete powder was carefully grinded in thin layers parallel to the exposure face of the specimens, and the acid-soluble chloride content measured with potentiometric titration.

2.6 Penetration Depth of Hydrophobic Impregnation

The penetration depth of the hydrophobic impregnations was measured on freshly split concrete surfaces that immediately after splitting were submerged for a few seconds in water. The concrete that is hydrophobic will not turn dark grey due to wetting, and the depth of impregnation is therefore easily measured. The reported impregnation depths are the average value of ten single measurements along the split surface (typically about 100mm long).

3 RESULTS AND DISCUSSION

3.1 Chloride Ingress

Figure 1 shows the chloride ingress for the 1995 Gimsøystraumen slabs after 10 years exposure.

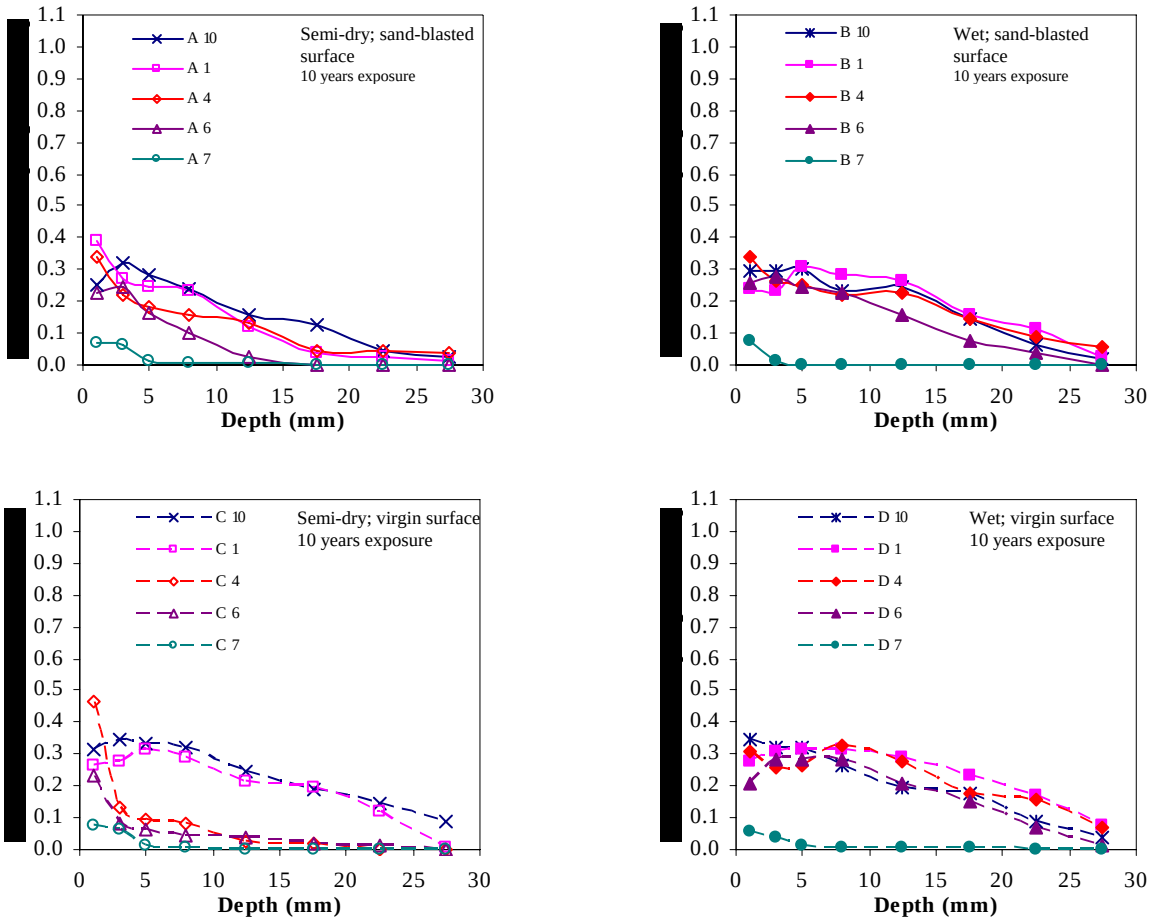

Figure 1. Chloride ingress after 10 years exposure, 1995 Gimsøystraumen slabs.

It can clearly be seen that the long-term effect of the surface protection systems to decrease chloride ingress is affected by the pre-treatment of the concrete substrate. The concrete moisture content plays an important role as all the hydrophobic treatments (#1, #4 and #6) on initially wet concrete have very little effect after 10 years in service, whereas the same products applied on semi-dry virgin concrete, except product #1 (20% silane/siloxane), still are fairly good chloride barriers. This can be visualized by plotting the chloride barrier effect (the filtration degree, i.e. the ratio of the total amount of penetrated chlorides in a treated sample versus the untreated reference), as seen in Fig. 2.

From the right part of Fig. 2 it is obvious that the effect of the hydrophobic treatments have been reduced gradually over the years, as one would expect for a UV-exposed silane-treated surface. A UV-filter on top of a hydrophobic treatment seems to prevent some of the degradation process, as product #6 has a better long term barrier effect than product #4.

The most important factor for preventing degradation of the impregnated surface is perhaps the penetration depth of the hydrophobic treatment. If the silane agents can penetrate deep into the concrete surface, the idea is that no UV-radiation can reach and destroy the impregnation. It was reported after application that penetration depths were hardly measurable and always less than 0.5mm for the wet concrete slabs, whereas the penetration depths for the semi-dry slabs were measured to 2-4mm.

This difference in penetration depth might explain the difference between the wet and the semi-dry substrate as seen in Fig.2.

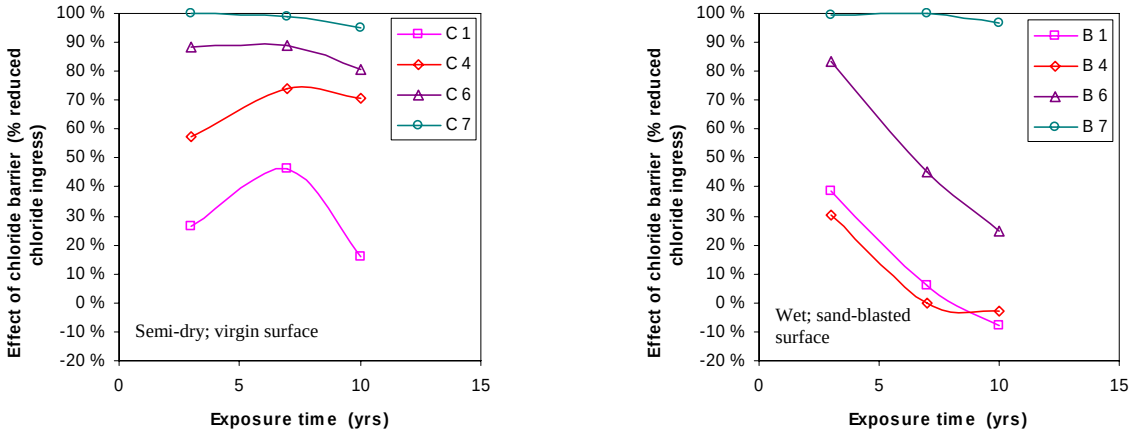

Figure 2. Chloride barrier effect for Gimsøystraumen slabs (1995).

Another marked effect from Figs 1 and 2, is the very good chloride barrier effect over time for the flexible cement-latex based coating (#7). This system has a chloride barrier effect above 98% even after 10 years in harsh marine environment and it still is flexible and adheres very well to the concrete as visually observed on-site during condition assessment.

To follow up the promising long-term effect of a large penetration depth, some of the 1998 Gimsøystraumen slabs were treated with a silane-gel that in the laboratory had proven to penetrate this type of concrete to very large depths (product #IV). The average penetration depths for the silane-gel and the pure (liquid) silane are 22 mm and 2 mm, respectively. The same trend was found on the Lundevann-slabs, where the same two products (silane-gel and liquid silane) were applied on self-desiccated concrete. In that project the ratio between silane-gel and liquid silane was on average 7.1. The penetration depth for the silane-gel is therefore on average about one order of magnitude larger than for the liquid silane.

The chloride ingress over time for the 1998-Gimsøystraumen slabs is shown in Fig. 3.

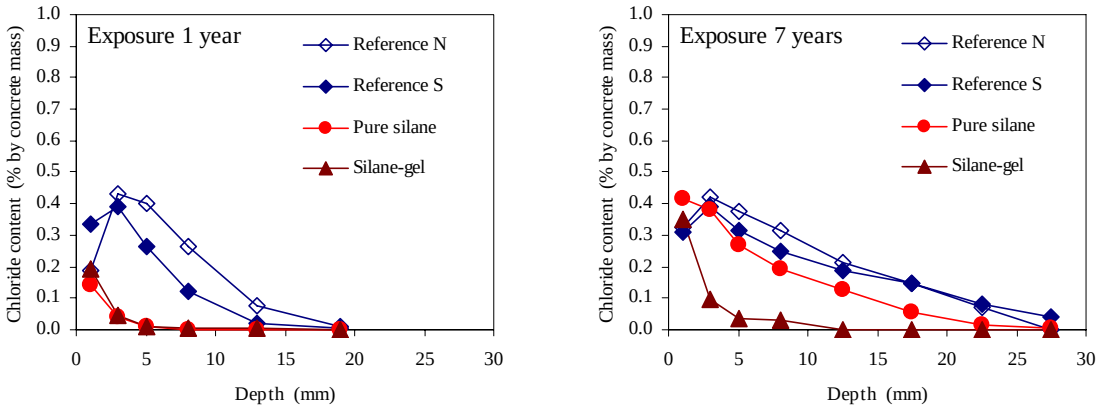

Figure 3. Chloride ingress for the 1998-Gimsøystraumen slabs.

It is clear that the pure silane (liquid) has lost most of its chloride barrier effect (decreased from 87% to 28%) from one to seven years exposure, whereas the silane-gel has more or less kept its barrier effect (decreased slightly from 83% to 80%) in the same period of time.

Figure 4 shows the chloride ingress in the sprayed concrete slab (underside) of the Sjursøya Quay after 5 years exposure. It is clear that all the surface protection systems, even the hydrophobic treatments, have a very good chloride barrier effect.

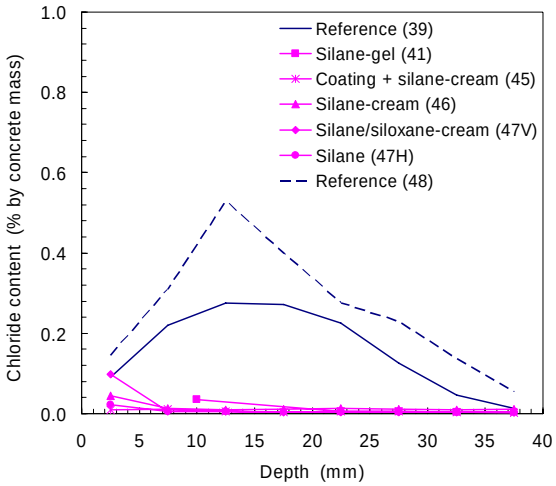

Figure 4. Chloride ingress in the sprayed concrete slab (underside) of the Sjursøya Quay, 5 years exposure.

On the Sjursøya Quay the measured penetration depths for the various hydrophobic impregnations were: silane-gel (41), 17.5 mm; silane-cream (46), 15 mm; silane/siloxane-cream (47V), 7 mm; and silane (liquid) (47H), 4.5 mm. The large penetration depths probably explain the high chloride barrier effect over time for all the impregnations. The reason for the high penetration depths might be the rather high porosity of the shotcrete used for repair of the slab underside. Measurements indicate a capillary porosity of about 22 % for the shotcrete, which is very high compared to the ordinary concrete used for the beam-repair, at about 13 %. A higher porosity will of course lead to an improved penetration of the impregnation agents, and not to forget increased chloride ingress into the untreated concrete. Both these factors would lead to a bigger difference between treated and untreated concrete. Another reason for the good long-term effect might be the fact that the underside of the quay-slab is protected against direct sun-shine, as the slab extends several meters towards open sea from where the samples have been extracted. However, there are signs of a degradation of the impregnations, as a thin outer layer of the surface no longer is hydrophobic after five years exposure. This can be seen in Fig. 5.

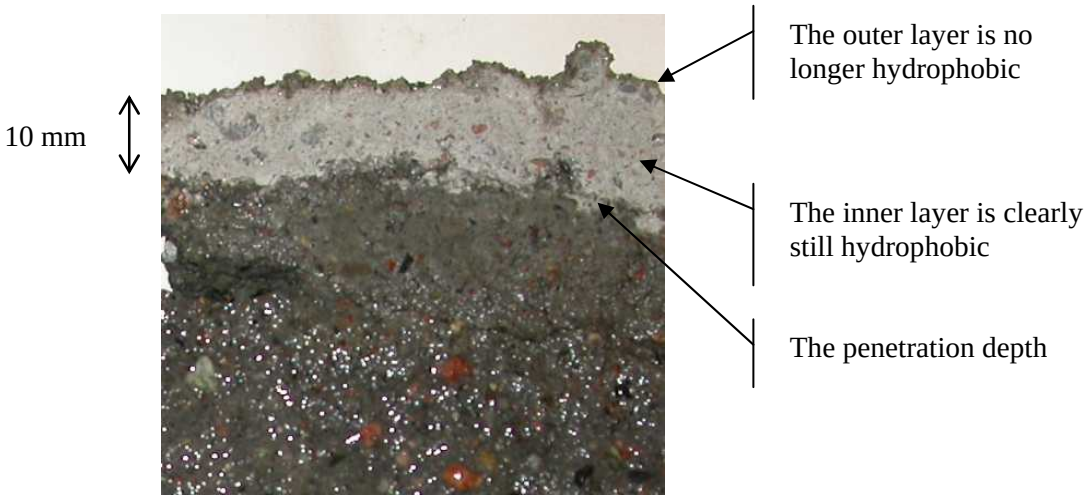

Figure 5. Degradation of a hydrophobic treatment, the Sjursøya Quay, 5 years exposure.

Figure 6 shows the chloride ingress on the surface facing south of the north and south pillar on Skarnsundet Bridge after 12 years exposure.

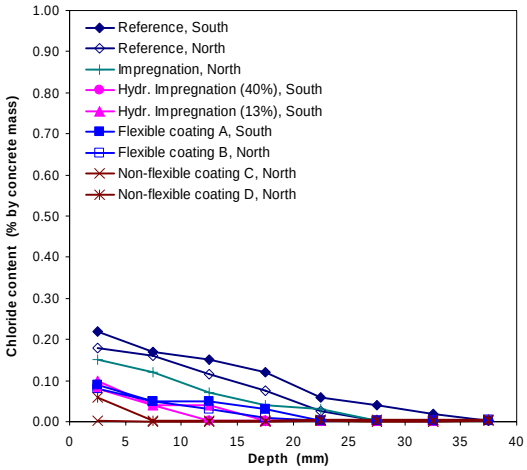

Figure 6. Chloride ingress on the south face of the north and south pillar on Skarnsundet Bridge, 12 years exposure.

In the Skarnsundet project it is clear that most of the surface protection systems have a rather good chloride barrier effect after 12 years in service. The hydrophobic impregnations, both being diluted solutions, have more or less the same chloride barrier effect as coatings, which is very unusual especially when considering the fact that it was not possible to measure any penetration depth (zero penetration, i.e. no measurable hydrophobic layer) for these two products. The product with the poorest chloride barrier effect is the impregnation, or more precisely a thin-film coating on the northern pillar. This product showed already after one year in service signs of degradation, as the thin-film coating cracked and started to change colour. After four years in service the product was no longer visible on the surface, it was simply worn off due to the harsh marine climate (rough winds combined with heavy rain).

3.2 Cracking of Coatings

The chloride barrier effect for flexible cement-based coatings is excellent, as have been shown in this paper. However, there is one major concern for these coatings – the risk of cracking. The Lundevann Bridge project demonstrated clearly the destructive effect of cracks when the structure is exposed to harsh climates, with heavy use of de-icing salts and long winters with a lot of freeze-thaw action. Half the height of the edge beams of the bridge was removed by water-jetting, the corroded reinforcement was replaced with new rebars and concrete was thereafter cast to fully repair the edge beams.

The surface protection systems (two flexible cement-latex based coatings and two hydrophobic impregnations) were applied about two weeks after demoulding, in such a way that the edge beams were fully covered.

The problem occurred after a few weeks when the concrete started to crack, probably due to shrinkage. The cracks penetrated the coatings, even though both were flexible. However, this is not strange if one considers that when cracking occurres after application of the coating, the coating suffers from an infinite strain at the cracking point. Only the most extreme products will withstand this.

Figure 7 shows three pictures from three different stages of the crack-failure. The first stage (Fig.7 a) is the cracking of the coating it selves with subsequent water penetration/accumulation and a microscopic freeze-thaw damage in the crack. After a few years the freeze-thaw damage expands from the crack and outwards (Fig.7 b) until the entire coated area is affected (Fig.7 c).

(a) (b) (c)

Figure 7. Crack-failure for the flexible coatings on Lundevann Bridge; (a) initial stage with cracked coating; (b) advanced stage with loss of bond adjacent to the crack; (c) final stage with a massive loss of bond originating from the crack.

After the first winter it was obvious that there was only a matter of time before the coatings would fail and fall off. For one of the coatings this was the case after two years in service, whereas the other coating lasted for another three to four years before large areas started to loose bond and fall off. There was little doubt that freeze-thaw damage was the main cause of loss of bond, as there was a thin layer of concrete still adhering to the scaled off coating indicating a surface freeze-thaw action. This suggests that application of coatings must be done after any initial cracking of the concrete.

4 SUMMARY AND CONCLUSIONS

Concrete surface protection systems can, if properly applied and the right product is used, be very efficient chloride barriers on the long-term even in harsh exposure climates. The most important results reported in this paper, indicates that:

- the long term effect of hydrophobic impregnation is influenced by the penetration depth, possibly due to the improved UV-protection at larger penetration depths
- the wetter the concrete substrate is before application, the smaller is the penetration depth
- silane-gel and silane-cream show a much larger penetration depth than pure liquid silane
- flexible cement-based coatings perform excellent as chloride barriers if the coating remains un-cracked
- cracks in coatings can have a devastating effect on the service-life of a treatment in harsh climates with freeze-thaw actions

Long-term Performance of Extruded Polystyrene Thermal Insulation Products

Holger Merkel [1]

T 17

ABSTRACT

One of the essential requirements of the European Construction Products Directive (CPD) is the durability of products. This is closely linked to the sustainability of buildings and their energy consumption. Hence thermal insulation products have to provide evidence that they are durable over their service life.

The paper presents ways how to adress this complex issue using the example of factory made extruded polystyrene foam XPS according to the harmonized European standard EN 13164.
XPS insulation is applied in numerous constructions which are subjected to different combined loadings, such as combined mechanical, moisture and heat impact.

In particular the hygrothermal and mechanical durability of XPS products were investigated. Both laboratory results and practical results will be presented in order to show the correlation between short-time durability tests and practical performance of products.

The application of insulation products under sustained load is another topic which will be adressed in the paper. The durability of insulation products against mechanical degradation when subjected to long-term loading is characterized by its creep performance (EN 13164 Annex ZA). The method according EN 1606 and the results of creep performance measurements for XPS products will be presented and discussed.

1 INTRODUCTION

One of the essential requirements of the European Construction Products Directive (CPD) is the durability of products. Durability is defined as *the ability of a product to maintain its required performance over a given or long time, under the influence of foreseeable actions, subject to normal maintenance* [EC 2004].

To attest its conformity with the CPD, a product put on the market must carry CE marking. CE marking attests that the product complies with the applicable technical specification (hENs, ETAs). In addition, it is compulsory for the manufacturer to declare the performance of the product for the mandated characteristics which are required by the technical specifications[CEPMC 2005].

The concept of durability related to CE marking means the permanence of the mandated characteristics of a product**,** linked to one or more of the 6 essential requirements. This permanence is dependent on the evolution in time, or ageing, of one or several performances of the characteristics and implies resistance to deterioration during exposure to normally foreseeable external or specific agents[EC 2004].

Table 1. Illustrative assumed working life (design working life) of works and construction products [EOTA 1999].

Assumed working life of works (years)		Working life of construction products to be assumed in ETAG's, ETAs, hENs (years)		
Category	Years	Category		
		Repairable or easily replaceable	Repairable or replaceable with some more efforts	Lifelong [2)]
Short	10	10 [1)]	10	10
Medium	25	10 [1)]	25	25
Normal	50	10 [1)]	25	50
long	100	10 [1)]	25	100

[1)] in exceptional and justified cases ; e.g. for certain repair products a working life of 3 to 6 years may be envisaged (when agreed by EOTA TB or CEN respectively)
[2)] When not repairable or replaceable "easily" or "with some more efforts"

Thermal insulating products are repairable or replaceable "with some more efforts" in many cases. There are exceptional applications, e.g. foundation insulation where the product must be assumed at least in category "Normal" which means 50 years of working life according to Table 1.

2 ASSESSMENT OF DURABILITY OF INSULATING PRODUCTS

The assessment of durability of thermal insulating products is possible by:

- Laboratory short-term test methods
- Laboratory ageing test methods
- Testing products in application under natural climatic conditions.

2.1 Laboratory Test Methods

In the following two mandated characteristics which are specified in the European product standards will be addressed:

- durability of thermal resistance against wheatering, degredation and freeze-thaw

- durability of compressive strength against ageing and degradation.

2.1.1 Durability of Thermal Resistance against Wheathering, Degradation and Freeze-Thaw

One of the most important tests for extruded polystyrene is the freeze-thaw test. It comprises two separate tests. The test for water absorption by diffusion [EN 12088] and the test for water absorption after freezing and thawing cycles [EN12091].

The test is mandatory for applications like Inverted Roofs and any insulation below ground level; e.g. perimeter insulation and insulation of road- and railways [EN 14934].

The Figures 1 and 2 show schematically the test build-up and the boundary conditions of the diffusion and freeze-thaw test.

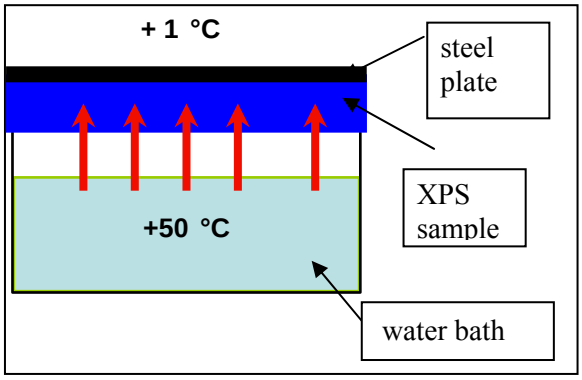

Figure 1. Diffusion test (schematically), 28 days.

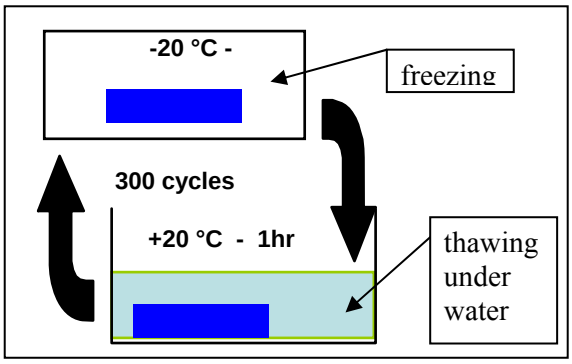

Figure 2. Freeze-thaw test (schematically), 28 days.

After a 28 days diffusion test the samples are used for the freeze-thaw test. The boundary conditions are more severe than climatic conditions in most of the European countries. But the results are in good agreement with practical long-term results. Thus the test conditions are simulating short-term the performance of the product under climatic conditions.

The requirements for both water absorption by diffusion and after freeze-thaw cycling are listed in Tables 2 and 3.

Table 2. Levels of water absorption by diffusion in relation to nominal thickness d_N according to EN 13164 [EN13164] for extruded polystyrene.

level	Requirement [m³/m³ (Vol-%)]		
	d_N = 50mm	d_N = 100mm	d_N = 200mm
WD(V)5	≤ 5	≤ 3	≤ 1,5
WD(V)3	≤ 3	≤ 1,5	≤ 0,5

The actual values from test results of various notified bodies in Europe are shown in Figure 3.

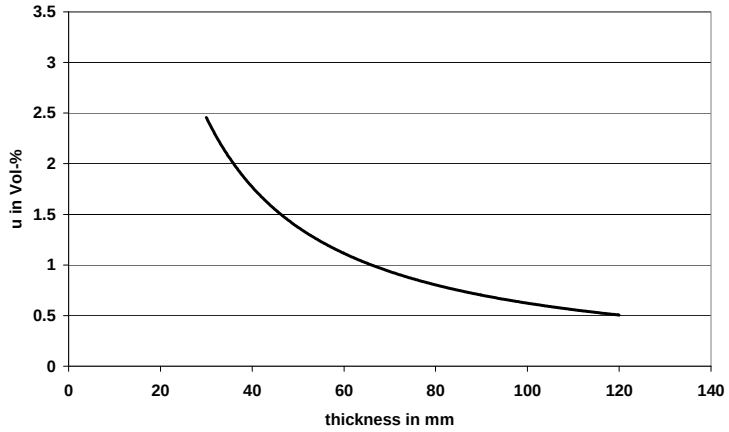

Figure 3. Water absorption by diffusion, typical values for XPS products (Roofmate).

The values in Figure 3 lead to a declaration WD(V)3 according to EN 13164. It can be assumed that such a product is durable against water impact.

Table 3. Levels of resistance against freez-thaw cycling, water absorption after freeze-thaw cycling for extruded polystyrene according to EN 13164.

level	Requirement [m³/m³ (Vol-%)]
FT 1	≤ 2
FT 2	≤ 1

After freeze-thaw cycling the reduction of compressive strength shall not exceed 10% of the initial value before the freeze-thaw test. This requirement ensures that the material structure of the foam has not been deteriorated during the freezing and thawing processes.

Actual values from tests performed by European notified bodies, show nearly no reduction of compressive strength for XPS products such as Styrofoam.

2.1.2 Durability of Compressive Strength

There are applications where it is not possible or not affordable to repair or replace insulating products. In particular when products are applied under foundations or within other structural parts of a building. In such a case the products must comply with the category “NORMAL” specified in Table 1. Normal means a lifetime of at least 50 years.

Extruded Polystyrene Foam has been successfully used for many years under road-and railway constructions as well as under load-bearing concrete slabs, such as foundations or industrial floors. It is necessary to know the stress-strain behavior (compressive creep) of XPS under sustained load. The assessment of thermal insulating products shall follow the European test standard EN 1606 [EN1606].

The standard comprises the measurement method and a calculation method to predict the long-term creep according to the FINDLEY approach [Merkel 2004].

This method describes the viscoelastic behavior of cellular plastic foam.

$$X_t = X_0 + m \cdot t^b \quad (1)$$

where:
X_0 : initial deformation 60s after the load has been applied
m,b : material parameters (FINDLEY parameters)

The equation (1) is known as Findley equation. The second term describes the visco-elastic part of the deformation. The material parameter m and b are stress dependent.
Equation (1) can also be expressed in a linear form by introducing logarithmic terms:

$$\log (Xt - X0) = \log m + b \cdot \log t \quad (2)$$

The parameters m and n can be obtained from a linear regression curve, which is calculated using the measured values starting 168 hours after initial measurement. From equation (2) it follows the parameter b as the slope of the curve and log m the intercept of the ordinate.

Figure 4 shows a typical linear regression curve for XPS from which m and b can be determined. The details of this procedure are described in EN 1606. An extrapolation 30 times the testing time is permitted when $R^2 \geq 0.9$.

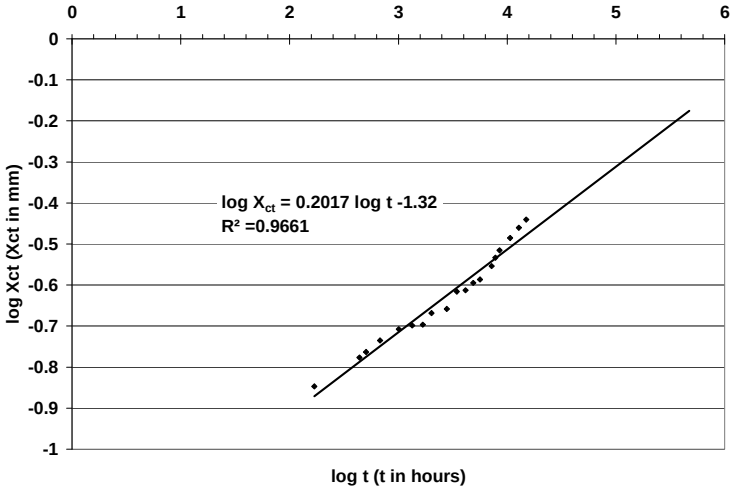

Figure 4. Typical regression curve for XPS to determine the FINDLEY parameter m and b (Dow Building Solutions).

Taking the given example, the FINDLEY parameters are determined to be: b = 0.2017 and m = 0.048. For building applications such as thermal insulation of foundations a total reduction of ≤ 2% of the initial thickness and an extrapolation time of 50 years are generally required.

Conclusively, thermal insulating products have to be tested for 608 days at a stress level which will finally result in deformations less than 2%.

Figure 5 shows a creep curve for an XPS product according EN 1606.

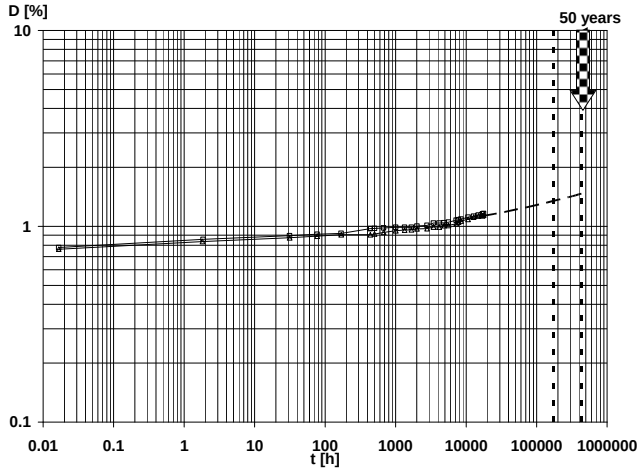

Figure 5. Creep deformation of an XPS product under constant load of 270 kPa (Graph: Dow Building Solutions).

It is obvious that after a short period of initial response to the load applied the remaining creep part of the deformation is pretty small. The dashed perpendicular lines on the right side of the figure are at 20 years and 50 years. Between 20 years and 50 years of service the creep deformation is practically negligible.

The foam remains structural stable during the entire test-period. This means extruded polystyrene foam is highly durable against sustained mechanical loads.

2.2 Long-term Performance Under end-use Conditions - Examples

2.2.1 Civil Engineering Application

The performance of XPS frost insulation layers in roadway application in Siberia were studied over a time period of 20 years [Polukhina et. al. 2003].

The insulation layer was located about 50cm to 65cm below ground level. The climatic conditions were characterized by typical continental climatic conditions with temperature variations of about 90K between summer and winter. The results which characterize the durability of XPS products applied in this project are listed in Table 4.

Table 4. Results of long-term performance of XPS in roadway application [Polukhina et. al. 2003].

property	1983	1995	2003
Compressive strength [N/mm²]	0,40	0,48	0,52
Thermal conductivity at 20°C, dry sample [W/(mK)]	0,028	0,0286	0,0295
Thermal conductivity at 20°C, wet sample [W/(mK)]	-	0,0301	0,0309

The XPS product investigated showed no deterioration under very severe climatic and complex soil and hydrological conditions over 20 years of service. The increase in thermal conductivity due to moisture impact is less than 5%. The time dependent change in thermal conductivity due to cell gas exchange is about 5 %. This is well below the increase predicted at 10% according to previous German standards.

2.2.2 Building Application

The application of XPS outside of the water-proofing layer requires high mechanical and moisture resistance. In such applications the insulation product is exposed to a combined impact of heat, moisture and mechanical loads. Hence, the long-term performance of XPS is of topical interest.

XPS products have been tested after 5 to 22 years of service in different roofing applications and in perimeter insulation below groundwater level.

Figure 6. Sampling of XPS boards from a green roof (Photo: Dow Building Solutions).

The results are summarized in Table 5.

Table 5. Results of long-term performance of XPS in Inverted Roof (IR) and Perimeter application (Dow Building Solutions).

construction	**service-life [years]**	**thickness [mm]**	**compr.strength [kPa]**	**$\lambda_{10\ measured}$ [W/(mK)] 1)**	**λ_{design} [W/(mK)] 2)**
gravel ballasted IR	8	140	not measured	0,036	0,038
gravel ballasted IR	22	80	359	0,029	0,033
Roof garden IR	22	60	459	0,029	0,033
Perimeter below ground-water level	5	60	357	0,031	0,035

1) unconditioned sample as taken from the building
2) design values according National regulations in Austria, Germany and Switzerland

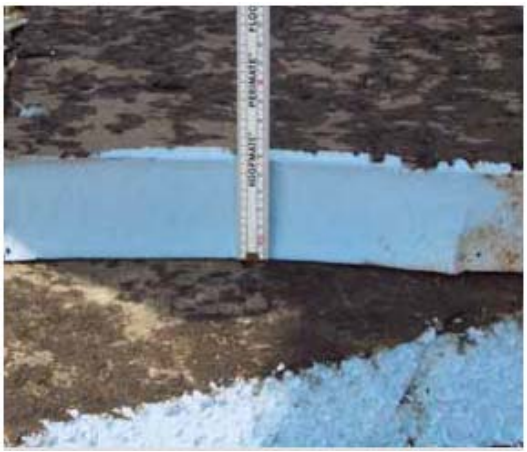

Figure7. Cross section of XPS insulation board after more than 20 years of service in an Inverted Roof outside of the water-proofing layer (Photo: Dow Building Solutions).

The sample shown in Figure 7 was taken from the roof and cut in half to investigate whether the foam structure has been deteriorated over the life-time. No change in cell structure could be detected. This explains why the properties of the foam are practically unchanged.

Durability of Roof Underlays Exposed to Natural Climate

Birgitte Dela Stang [1]
Erik Brandt [2]
Morten Hjorslev Hansen [3]

T 17

ABSTRACT

Durability of roof underlays is of large importance as they serve as the ultimate barrier against water ingress in roof constructions. This is especially true in Denmark because of the frequent use of clay tiles on buildings with low pitched roofs where wind-driven rain has fairly easy access to the roof underlay. Also, some tiles allow a high amount of solar radiation to pass through the corner joints.

A large part of roof underlays used in Denmark are based on flexible polymer sheets that are not supported by a rigid underlay. A popular trend in contemporary Danish architecture is low pitch roofs with ceilings parallel to the roof surface leaving no or very poor accessibility for inspection of the roof underlay.

The paper presents results from testing of watertightness and tensile strength on 5 different types of flexible sheet roof underlays, a woodfibre board, and a bituminous roof underlay supported by plywood. The 7 roof underlays were exposed to natural climate on a south-facing roof with a pitch of 20° and without roof covering. Tests were carried out at various exposure times between 3 months and 32 months. Also, supplementary samples of the 7 roof underlays were exposed to accelerated ageing according to EN 13859-1. Reference data were obtained from unexposed material.

1 INTRODUCTION

For quite some years Danish common practice has been use of roof underlays (also designated sarking felt or underlayments) for sloping roofs with roof coverings of tiles or slates. Roof underlays are also used for metal roof coverings to catch drips from condensation on the backside of the roof covering.

The main purpose of the roof underlay is to act as a barrier against water penetrating the roof covering itself. In Denmark some types of roof coverings – especially clay pantiles with small overlapping joints and fibre cement slates – are fairly open to water, especially in the form of wind-driven rain. When it comes to drifting snow, all tile or slate roof coverings will allow snow to pass unless special solutions e.g. mechanically tightened joints are used.

In addition, the roof underlay must not jeopardize the natural moisture transportation by diffusion through the roof construction. Traditionally this has been achieved by using roof constructions with a vented cavity between the insulation and the roof underlay. In such cases vapour tight materials perform very well as long as the cavity has sufficiently large openings to the surroundings. During recent years a new type of materials has been introduced to the market. These materials which are very open to water vapour diffusion are used in a different way than previously as they are placed directly on the insulation i.e. such roofs do not have the possibility of removing moisture by ventilation. Moisture penetrating from the interior of the building must consequently be removed by diffusion instead of ventilation. These materials must be water vapour permeable to such extend that moisture is not accumulated inside the construction.

Further, some clay pantiles allow a relatively high amount of solar radiation to pass through the corner joints. Hence, the roof underlay must be resistant to UV-radiation.

A relatively large part of roof underlays used in Denmark are based on flexible polymer sheets that are not supported by a rigid underlay. A popular trend in contemporary Danish architecture is low pitched roofs with ceilings parallel to the roof surface leaving no or very poor accessibility for inspection of the roof underlay.

In a previous study [Brandt & Hansen, 1998] the most important properties for roof underlays were found to be:

Tightness against precipitation - this property is especially required during the construction period until the primary roof has been laid.

Tightness against water - this property covers standing water as well as water running on the surface. When well constructed no ponding should occur on the roof underlay.

No tent effect - tent effect refers to the well-known fact that touching of the inside of a tent during rain may cause penetratiom of water. For underlayments laid directly on wood and insulation, no tent effect should occur, as it would impair the watertightness.

Water vapour permeability - for unventilated constructions it is evident that moisture from the interior of the building can only escape through the underlayment by diffusion. Consequently the material shall be very permeable to diffusion of water vapour.

Moisture accumulating properties - are a supplementary asset if all other requirements to the roof are fulfilled. It allows the take-up and accumulation of moisture during periods with high exposure. The moisture is allowed to be removed during other periods.

Dimensional stability against changes in RH - is an important property but is not a problem with current materials.

2 THEORY AND TEST SET-UP

Degradation of polymer based materials is mainly caused by UV-light, heat and moisture. Most roof underlays are used as interim roof in the construction period – which often lasts several weeks – where it is exposed to UV-light (together with ambient temperature, precipitation and wind). Further, it has been shown that for some clay pantiles with small overlapping joints as much as 5 % of the UV-light in the environment may reach the roof underlay [Holck & Rosenfeld, 2005]. In an earlier study, [Brandt & Hansen, 1998], it was found that the temperature of the roof underlay is normally below 45° C in the finished roof. It is anticipated that temperatures in the construction period is at the same level.

When used as a provisional roof the roof underlay is exposed to precipitation and consequently is moist a fair part of the time dependent on the weather conditions. In the finished roof the roof underlay will only be exposed to water occasionally but it will more regularly be exposed to high relative humidity from the environment due to diurnal and seasonal changes in temperature etc.

Based on the conditions described above and problems seen in practice it is assessed that the main degradation factor for roof underlays is UV-light [Brandt *et al.*, 2007].

One purpose of the study was to compare results from natural ageing with results from accelerated ageing according to EN 13859-1. In Denmark it is common to test roof tile underlays for so called tent effect after accelerated ageing to a somewhat harsher UV-exposure than used in EN 13859-1, cf. [Nordtest Method 488]. Testing of the same specimens used for this study is currently being performed.

2.1 Test set-up

The paper presents results from testing of watertightness and tensile strength for roof underlays after exposure to natural climate and after accelerated ageing testing according to EN 13859-1.

The study encompasses 5 different types of flexible sheet, 1 wood fibre board, and 1 bituminous roof underlay supported by plywood. The test specimens of the 7 roof underlays were exposed to natural climate on a south-facing roof with a pitch of 20° and without roof covering.

Figure 1. Test set-up for exposure to natural climate. The 7 roof underlays where placed on a south-facing roof with a pitch of 20°.

2.1.1 Test Material

Table 1. Materials used for the testing were 5 different types of flexible sheets, 1wood fibre board, and 1 bituminous membrane.

Material name	*Type of roof underlay*	*Material type*	*Area mass [kg/m^2]*
A	Permeable	Laminate of HD-PE & PP	125
B	Permeable	Laminate of polypropylene	135
C	Non-Permeable	Laminate of polyester mesh and bitumen	450
D	Non-permeable	PE-foil with reinforcement mesh (12x12 mm)	530
E	Non-permeable	Bitumen impregnated polyester mesh	1500
F	Permeable	Wood fibre board*	3000
G	Non-permeable	Bitumen impregnated polyester mesh**	2200

*: Not a flexible sheet
**: Supported by plywood

3 TEST RESULTS

Natural ageing was carried out at various exposure times between 3 months and 32 months (2,75 years). Accelerated ageing was performed according to EN 13859-1. After exposure, tensile strength, deformation at maximum load and watertightness were tested. Reference data were obtained from testing of unexposed material.

3.1 Results of Tensile Testing

Tensile testing was performed using rectangular specimens with a length of 300 mm. Materials A-E had a width of 100 mm. The sides (25 mm) were folded to the centre resulting in a 50 mm 2-folded specimen. Test results for materials A-E were divided by 2 representing the strength of a 50 mm wide specimen. Materials F and G were tested according to EN 12311-1. Specimens had a width of 50 mm. The crosshead speed was the same in all tests: 100 mm/min. Simultaneous measurements of load and crosshead movements were logged.

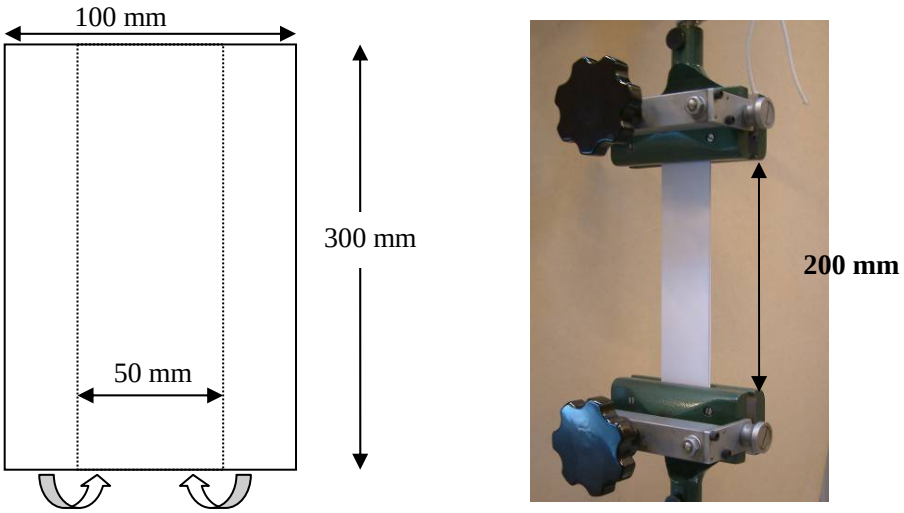

Figure 2. Test set-up tensile tests. Tests of materials A-E were performed according to EN 13859-1. Specimens were folded according to the sketch.
Tests of materials F and G were performed according to EN 12311-1.

Subfigure 8 (bottom right): Strength for the 7 tested materials at different duration of exposure normalized to the unexposed testing materials.

3.2 Results of Watertightness Testing

Tests of watertightness were performed in a plexiglass cylinder with a 200 mm head of water. A filter paper was placed under the testing materials to simulate tent-effect. Watertightness between test material and container is obtained by silicone grease. The container is bolted to the lower plate in the 4 corners. Water is poured along the cylinder until a water level of 200 mm above the test material. The

weight of the filter paper was determined before and after 60 minutes of testing (materials D-F were tested for at least 15 hours). The tests were considered failed if the water uptake exceeded 0.5 g.

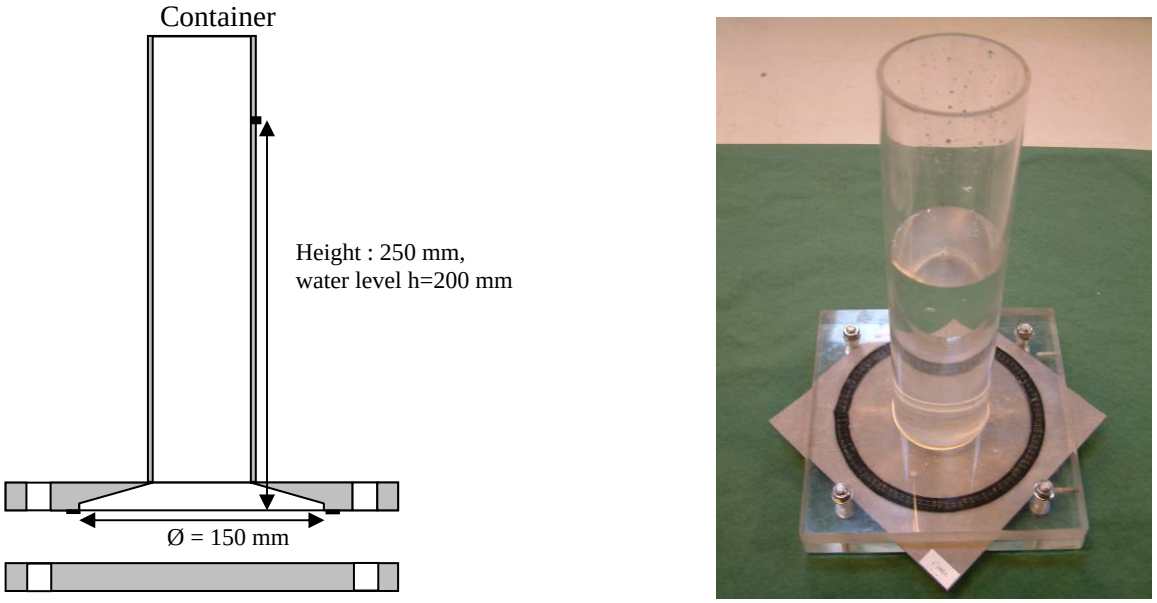

Figure 5. Test set-up for watertighness. A filter paper and the test material are placed on the lower plexiglass plate. The container is bolted to the lower plate in the 4 corners. Water is poured along the cylinder until a water level of 200 mm above the test material.

Table 5. Watertightness. Ratio between number of failed and tested specimens at different levels of exposure.

Test material	*EN 13859-1*	*Exposed to natural climate*		
		3 months	5 months	32 months
	Fail/test	Fail/test	Fail/test	Fail/test
A	1/3	0/3	0/3	3/3
B	0/3	0/3	0/3	3/3
C	0/3	0/3	1/3	3/3
D	-	-	-	0/3
E	-	-	-	0/3
F	-	-	-	0/2
G	-	-	-	0/1

4 DISCUSSION AND CONCLUSION

4.1 Tensile Testing

As generally expected, it can be seen from figure 3 that results from naturally aged materials are ranked according to the exposure period, i.e. the longer exposure the bigger changes are seen.

In contrast to this, results from natural ageing differ from results for materials aged according to EN 13859-1. For example it appears that for material B ageing according to EN 13859-1 corresponds to

less than 3 months natural ageing whereas for material G it corresponds to more than 32 months of natural ageing.

From figure 2, subfigure 8, it can be seen that the change in tensile strength not only differs considerably from material to material but also that it is extremely difficult to predict long term changes from short term testing.

There is no obvious correlation between results from short term natural ageing and long term natural ageing. Therefore, long term natural ageing appears to be necessary. Neither, any correlation can be observed between natural ageing and accelerated ageing according to EN 13859-1. The reason for this is believed to be too weak UV-radiation in the test (UV radiation ought to be at least partly UV-B radiation). EN 13859-1 appears to be unsuitable for accelerated ageing of roof underlays as it is not able to rank materials in accordance with natural ageing.

Materials A, B, C and F continue to loose strength after 5-32 months whereas materials D, E and G only show minor changes throughout the period of natural exposure.

4.2 Testing of Watertightness

Tests of watertightness show that after 32 months of natural exposure the lightweight materials A, B and C failed the watertightness test. The tests showed that the filter paper under the test materials was soaked after only 5 minutes of water exposure. However, only one test failed after 5 months of natural exposure. Unfortunately, no test results are available for materials exposed between 5 months and 32 months making it difficult to estimate a time of failure. The heavier materials D-G proved to be watertight after 32 months of exposure. These materials were tested for a longer period of water exposure (15 hours).

Polymer-based Building Materials: Effects of Quality on Durability

Esin Kasapoğlu [1]

T 17

ABSTRACT

Polymer is the main substance of plastic. Monomers are the 'building blocks', polymer is the completed plastic and the reaction is called polymerization. During production processes, as well as oil-based chemicals, chlorine, hydrochloric acid, fluorine, nitrogen, oxygen and sulphur are the substances used. Nearly all plastics include additives like plasticizers, pigments, stabilizers against solar radiation, preservatives and perfumes. Plastic is a substance that contains natural or synthetic high molecular organic material which can be liquefied and thereby cast in specific moulds.

Quality can be defined as the appropriateness level of a product to the desires of the consumer. The quality of a product or a complete building or other construction is the totality of its attributes. Quality enables to perform a stated task or to fulfil a given need satisfactorily for an acceptance period of time. If the material has low level of quality, durability of the material will be shortened. Plastic building materials are used in floors, roofs and walls. It is difficult and expensive to repair or replace them. Plastics should have a functional life-span at least 50 years equivalent to other materials in the building. It is unlikely that any of today's plastics can satisfy such conditions.

In this paper, the meaning of quality will be defined again through the view of polymer based (plastics) building materials. Quality properties which will enable the durability of polymer based materials with a more functional life span will be discussed. The last developments in plastics industry and their effects on durability will also be reported.

1 INTRODUCTION

Throughout the 1990s, polymer based building materials, especially plastics, have been used widely in construction industry. Superior strength in weight performance, corrosion resistance, environmental stability, insulation properties, lower cost are the main properties of polymer based building materials.

Although, polymer based building materials have some important superior properties compared to traditional materials, they have some disadvantages, like their flammability and smoke toxity. However employing additives or combining with other materials, helps plastics gaining superior properties. Quality level of polymer based building materials can be evaluated through the new results. Durability of the material will be affected also by the quality level of the material.

2 POLYMER BASED BUILDING MATERIALS

Polymers are organic compounds which are the main substance of plastic. Monomers are the 'building blocks', polymer is the completed plastic and the reaction is called polymerization. During production processes, as well as oil-based chemicals, chlorine, hydrochloric acid, fluorine, nitrogen, oxygen and sulphur are the other substances used. Nearly all plastics include additives like plasticizers, pigments, stabilizers against solar radiation, preservatives and perfumes. Plastic is a substance that contains natural or synthetic high molecular organic material which can be liquefied and thereby cast in specific moulds [Berge 2001].

Plastics were first used as ornament, superficial finish, or as secondary parts for enclousure systems, in building and construction. Although, plastics are in construction industry as a wider scope of uses such as interior finishes, glazing, plumbing fixtures and even structural components today, only recently they began to gain respect and appreciation as a viable primary material. Having a lower fire-rating and limited usage in applications of requiring fire resistance are the weakness of plastics compared to other construction materials. However, there are some advantages plastics can offer like they are lightweight, lower in cost, resistant to corrosion and moisture, can be relatively strong and are readily shaped. One of the other disadvanges of plastics was their being short-lived fad that is brittle and prone to discolor, but has recently been revised due to enormous advances in the plastics industry, which has manufactured unprecendented variety of new products with improved physical properties. Since the material is intrinsically man-made, there is no limit for the charasteristics and expanding will continue [Bell 2006].

Plastics can be divided into two basic categories: thermo plastics and thermosetting plastics. Thermosetting plastics and thermoplastics are both used in building. Thermosetting plastics are generally harder and stronger than thermoplastics. Adhesives, laminates, rigid foam insulation, waterproofing membrances and window frames are typical applications of thermosetting plastics. Polyvinyl chloride (PVC), polycarbonate and acrylic are the three types of thermoplastics which are most often used in building construction. PVC is the most commonly used plastic in building construction. Resistance to water, and some chemicals, low cost and resistance to tearing are the main charasteristics of PVC. [Bell 2006] When produced as a foam, many plastics have high thermal insulation properties and good water- and vapour-proofing properties. Paint, sheeting, paper, sealing strips and mastics are the guises plastic can take as a sealant. Polyisobutyl, polyehylene and PVC are the three plastics used for sheeting. Sheetings can be used as damp-proofing for foundations, vapour barrier or moisture-proofing. A mastic has to fulfill the conditions of constant elasticity and durability. Polysulphide, silicone, polyurethane and various acrylic substances are used as mastic. The composition is usually based on at least five chemical substances with at least eight different additives. Sealing strips are the materials used mainly between the sheets of glass in window and door reveals. Polyurethane, polyamide, PVC, ethylene-propylene rubber, chloroprene rubber and silicone rubber are the important plastics used in sealing strips. The products include different additives also. Polystyrene, polyurethane and urea formaldehyde are the plastics used to produce different insulation materials [Berge 2001].

Plastics is rarely used as a structural material in building. In the western world, a large amount of unspecified plastic waste exists now which can be possible raw material for simple structural elements. If supporting substances are added in proportions of 10-15 percent, polystrene waste can be cast into solid beams and columns. The components are suitable for sawing and nailing and the structural properties are approximately the same as timber. [Berge 2001] For structural applications, pultruded glass-fiber-reinforced polymer (GFRP) profiles have a great potential; the higher strength to weight ratio, the lower weight, the electromagnetic transparency, the ease of installation, the lower maintenance requirements, and the improved durability in aggressive environments are the advantages over traditional materials. Although (GFRP) profiles have been used mainly in nonstructural or secondary structural elements up to now, such as ladders, handrails and pavement grids, according to the results of researches, they offer a very good mechanical performance and lightness, as well as good durability charasteristics, compared with those of traditional structural materials [Correia *et al*. 2006].

Crack repair systems have been used for many years and polymer based building materials are one of the most common crack repair materials. Epoxy resins generally have very good bonding and durability characters that commonly used repair materials. According to Calder and Thompson the overall structural performance of reinforced concrete slabs repaired using epoxy resin injection performed best compared to other materials such as polyester and methl methacrylate resins. The use of carbon fiber reinforced polymers (CFRP) is a new development in the repair and the rehabilitation of reinforced concrete. In recent years, the applications of these materials to structural repair and retrofit have grown significantly. Carbon fiber reinforced polymers fabrics offer supperior performance such as resistance to corrosion, and a high stiffness-to-weight ratio. [Ekenel & Myers 2007] As the results of researches with advanced composites had shown that plastic composites were more durable than steel and conrete and also they are lightweighted, energy-absorbent, less corrosive and low cost new methods to strenthen bridges, buildings and other forms of civil infrastructure with plastic composites are being developed. According the results plastic ‘wraps’, which are only a few millimetres thick and consist of a fibreglass-graphitecomposite, around concrete structures can increase their strength [Jones 2007].

3 QUALITY OF POLYMER BASED BUILDING MATERIALS

Construction quality is a measure of the level of meeting a particular work the requirements demanded by the building project. [Mora 2007] The quality of a product or a complete building or other construction is the totality of its attributes. Quality enables to perform a stated task or to fulfil a given need satisfactorily for an accepted period of time. If the material has low level of quality, durability of the material will be affected negatively. During the construction process by ensuring to use materials of the same durability, the use of raw materials is reduced, by producing more durable products. Therefore it is possible not sacrificing better quality components in a building when there is decay elsewhere. When there are any materials with less quality, it is important to be easily replaced while the more durable materials can be dismantled for re-use or recycling in the case of demolition. There is a clear advantage in using robust materials and allowing buildings lasting as long as possible. [Berge 2001] Energy required to produce the material, CO2 emissions resulting from the manufacture of the material, toxity of the material are some of the factors determined by the quality of the materials. Like quarry pit, wood taken from forest, oil spills from an oil well, the impact on the local environment resulting from the extraction of the material is the other factor of quality of the materials. Degree of pollution resulting from the material at the end of itsuseful life, lifetime of the material and its potential for reuse if the building is demolished are the other factors that can be taken into consideration while determining quality of a material. [Roaf *et al.* 2003].

Plastic composite building materials obtain much of their versatility because they can be engineered to provide specific performance charasteristics including durability, light weight, corrosion resistance, high strength, and low maintenance requirements. In cooler climates, fiber-reinforced polymers (FRP)

could increase the use of concrete in architectural cast fences. As the thread of freeze-thaw and corrosion require substantial concrete coverage forrebar protection, concrete is not a suitable material for thin wall structures. FRP composites could present a solution, when a structural element, such as a wall or beam can benefit from additional support. A combination of wood fibers and plastics is wood-plastic composites (WPCs). Their durability and weather-resistance can be appropriate for outdoor environments. Wood-plastic composites (WPCs) are commonly used, where durability is an important performance attribute. In order to improve processing and performance, small amounts of other materials can be added to wood-plastic composites (WPCs) as with inorganic-fiber composites. WPC lumber rarely rots, cracks, warps, or splinters, when properly manufactured and installed. WPC are typicaly stain resistant, waterproof, ultraviolet (UV) light-resistance and impervious to insects and can be made strong enough for applications such as load-bearing deck boards. A good dimensional stability and a lower coefficient of expansion than solid plastics are the other properties WPCs tend to have [Krebs 2006].

Plastics will burn, like all organic materials. As such, increasing the temparature necessary before ignition and/or lower the rate of burning, plastics used in construction contain fire-retarding. The various building codes typically have regulations require specific fire performance characteristics that deal with plastics. These characteristics are for fire/flame retardation and safety. Today's plastic construction materials, when used in the proper application and correctly installed, can meet or exceed the fire performance charasteristics required by most codes and standarts, can help provide a nice living environment by performing their intended function. Different performance requirements are specified, when foam plastic materials are installed on the exterior of buildings. As the foam plastic insulation material contribute to upward flame spread over the surface or within the exterior wall, additional specialized tests are also specified to prevent. [Parker & Beitel 2006]

Including acrylic, some interesting products have left their mark in recent years. Acrylic plastic products are known with the virtue of material lying in its clarity and ultraviolet (UV)- resistant attributes. When the material is extruded, thin UV-resistant coatings can be applied to polycarbonate, offering enhanced protection for performance and aesthetics. Besides, light-diffusing charasteristic of the celular structure can leave any strach or dirt almost undetectable. A simple hosing or pressure-washing usually suffices, when cleaning is desired. [Bonenfant 2006] Vinyl can be easily kept clean and disinfected, since it can be washed or scrubbed. This is an important consideration for healthcare projects the spreading of germs and bacteria must be minimised. Vinyl can be versatile and durable. Strong and scratch-resistant vinyl products are continually becoming easier to apply, partly due to bette pastes. Especially for high-traffic areas, vinyl coverings are ideally suited. Vinyl becomes a wide variety of price and design options. [Jacop 2006] In window applications, although other plastics are also employed, PVC is often used as the thermoplastic matric. 80- to 200- mesh wood fiber which is a wood-filled PVC product is usually employed in windows and doors, offers thermal stability, moisture resistance, and stiffness. Wood flour have been combined with both vinyl and polyolefin to form exterior trim in new exterior applications that resists rot and weathering. A wide range of design can be shaped by the resulting material that typically do not require painting or the use of special cleaning agents [Krebs 2006].

Polycarbonate, among the first window glazing materials certified, can resist the impact of a 2.4m. (8-ft) long 2x4 fired from an air cannon at 55 km/h (34 mph). A polycarbonate barrel-vault skylight was impact load and high-pressure winds. Polycarbonate can offer opportunuties for day lighting, in addition to impact resistance. Daylighting is not only a matter of bringing in the sun's light but also efficient systems must insulate well [Bonenfant 2006].

4 DURABILTY OF POLYMER BASED BUILDING MATERIALS

Durability is an ability of a building or a material to maintain its performance over time and use. It can be measured in terms of the time until some loss of function occurs that renders the service provided

unacceptible. It depends on the degrading effects of the service and the environment to which it is exposed, it is not a fundamental property of a material. Refering to service, life, is more appropriate, as this properly implies the effects of the particular conditions of service. Being long lasting, can reduce maintenance and repair costs, and often cost-effective from a life-cycle perspective are advantages of durable materials and building systems. Minimized disruption of building operations and environmental benefits resulting from the reduced disposal and replacement of materials.

Durability is not only a quantifiable technical property, but has also an aesthetic and fashionable aspect. Designing a product that can outlast the swings of fashion is also quite a challenge. Rather than a maximum durability, it is also important to consider an optimal durability, especially with technical equipment. The lifespan of a material depends on mainly four factors which are the material itself, its physical structure and chemical composition; construction and its execution, where and how the material is fitted into the building; the local environment, the climatic and other chemical or physical conditions; maintenance and management. [Berge 2001] Durable materials will not need to be replaced or repaired as frequently, so the raw materials, energy, and environmental impacts invested in them can be spread out over more time. Durable materials provides a long period of time to amortize the environmental and economic costs that were incurred in building it. Durability is an issue of water management to a significant extent. The ratio of durability problems in buildings are fully 80 percent about moisture. By causing materials to expand and contract, thermal stress can reduce durability. This can affect, for example, long-term window performance. Making windows leaking over time, including vinyl and aluminum certain frame materials expand and contract at a higher rate than glass. Roofing materials are also affected by high roof temparatures. Ultraviolet light (UV) degrades most plastics. Along with heat, degradition of roofing materials is a major problem. Including vinyl siding, although in some cases UV stabilizers themselves carry environmental burdens, plastics that are used outdoors are typically treated with these stabilizers. Ozone and acid rain, various atmospheric pollutants, can damage building materials. Ozone and other air pollutants damage materials, including rubber, nylon, dyes polyster, and certain paints, many synthetic materials.[Wilson 2007] Heat, cold, wind, snow, hail, ice, mechanical stress, acids, animals, plants, water and other liquids and micro-organisms are some of the external factors which can break down plastics. The type and the position of the plastic and the local climate determines the life-span of a plastic [Berge 2001].

It is difficult to anticipate the lifespan of most new materials like plastics. Although it is possible to create accelarated deterioration in laboratories, these are not the results of actual situation which is more complex. [Berge 2001] Causing embrittlement and a change in surface appearance short-wave solar radiation affects plastics negatively. In coastal and rural areas the risk is greatest. Using some additives incorparated into the plastic the effects can be reduced or increased. Adding fire retardants reduces resistance to degradition. Although, moisture in general has little effect but can reduce bond strength between glass fibre and polyester resin. Depending on the control exercised in manufacture greatly, the extend of any weakening of bond strength can be controled also. In general, contact with other building materials do not harm plastics, though the use of oil base jointing compounds cause cracking of polyethylene cold-water cisterns [Ransom, 1987].

PVC and polycarbonates have high thermal expansion and varieties of polyethylene have even greater thermal movement. Down pipes can cause joint failure and leakage, when the movement of PVC gutters, unless properly allowed for. Under continued, loads plastics creep when stresses are high, as in filled cold-water cisterns, special precautions are needed. [Ransom, 1987] It is also difficult to make a picture, as the plastics are often full of additives. Although PVC is known as a plastic with a very good durability, it has been known to undergo very rapid breakdown. Sometimes addiditives can be harmful, just the opposite of the expectations. One of the examples is crumbling of 10-year-old plastic skirtings made of PVC, because of an added acrylonitrile butane styrene (ABS)-plastic which should have increased the strength and durability. All plastics oxidize easily. Another plastic polyethylene sheeting, had an effective lifespan of ten years and used as a moisture barrier until 1975. As the sheeting is usually in accessible within the fabric of a building and often supposed to prevent

condensation within the walls, this is extremely low. Some additives included polyethylene to make it more stable [Berge 2001].

When the material has to be replaced or the use that material had is brought to an end, durability ends. A durable material is useful for longer. Durability is an indicator which informs if a material maintains its original requirements over time. The material durability will increase, when the time and resources required to maintain it decrease. [Mora 2007] Sometimes 1 year is enough losing functionality. Ethylene proppylene rubber (EPDM) is used as sealing strips between the elements in prefabricated building of timber and concrete. According to researches certain makes have lost elasticity after only one year and causing the joints open and the material does not function. As many of the plastic products currently on the market have been around for less than 15 years, there is very little feedback on their life span. Altough some of the products have been on the market, for a longer period, todays' components are very different from those that were used in products of 20 years ago, as it is well known by the polymer technicians. It is difficult to find examples giving a picture of the lifespan of the plastics products made today, as the design of products has changed so much recently [Berge 2001].

5 CONCLUSION

In construction industry, polymer based building materials have a rapid development and have been used widely throughout 1990s. Especially having different kinds and offering different types of design enabled them gaining popularity among architects. Polymer based building materials, especially plastics, are man-made, therefore there is no limit for the charasteristics and development will continue. New products with improved properties can be manufactured. This continuous development is the main difference between polymer based building materials and traditional materials. Additives help improving charasteristics against resistance to fire, UV ray and other disadvantages. Especially as an element of composite material specific performance charasteristics can be improved. The combination of distinctly different components of composites can make new high-strength, lightweight materials with corrosion resistance, long-term durability, low maintenance requirements, design flexibility, good vibrational damping and resistance to both fatigue and temperature extremes. The performance capabilities of the composites can be developed and high-performance composites can be manufactured. This means, quality of polymer based building materials can be developed also. Every material have some specific characters but a general definition of quality for polymer based building materials can be written as:
"A polymer based building material should be resistant to fire, UV ray, water and some chemicals, corrosion, moisture, thermal and mechanical stress, ozone and other air pollutants; should have good water and vapour proofing, high thermal insulation properties, and high strength and should be load bearing, lightweighted, appropriate for outdoor environment and lower in cost."

The characteristic of a building material being durable affects the level of quality or on the other hand improving the level of quality of a building material can affect the material being more durable. As quality enables to perform a stated task or to fulfill a given need satisfactorily for an accepted period of time, quality is improving the characteristics of a building material. Improving characteristics can also affect the material being more durable. Being a wall covering more durable it is needed to have an average compressive strength, a negligible level of moisture content, resistant to thermal stress, ultraviolet light and high wind pressure and it is also preferred to be sustainable. Improving a material having more compressive strength or decreasing the level of moisture, affects its quality level positively also. As the level of quality is increasing, the material can be more durable also. Polyvinyl chloride (PVC) or vinyl is perhaps the most versatile of all plastics. In construction vinyl is used as flooring, siding, piping and single-ply membrane roofing. Vinyl is generally self-extinguishing and resists weathering, oils, greases, acids, fungus and moisture and and abrasion-resistant depending on the type. One of the vinyl types used in building commonly is siding. There is little that challenges vinyl's versatility, durability and possible textures, colors and shapes. Vinyl siding requires little

maintenance, remaining attractive for years. These are the characteristics of vinyl siding and they can be listed as the quality criteria, also. Being recycling can be added as a quality criterion that nearly all waste of vinyl is recycled. [Knowles 2003] As a durable material lasts a long time and provides a long period of time to amortize the environmental and economic costs that were incurred in building it, durable materials and materials will not need to be replaced or repaired as frequently. So, the raw materials, energy and environmental impacts invested in them can be spread out over time. The longer-lasting building's higher economic and environmental costs can usually be justified by its durability.

Another building material is spray polyurethane foam (SPF) which is one of the fastest growing polymers in construction and can be used for specific purposes including roofing insulation, wall insulation, air barrier systems, and below-grade foundation insulation and below slap-on-grade. According to performance studies and research suggest SPF roofing systems can last 30 or more years. They require low maintenance, resist high wind blow-off, add structural strength and minimize moisture damage within the building envelope which are among the quality criteria. [Knowles 2003] Characteristics of the material can be developed also by using closed-cell formulations or open-cell formulations which is also enables developing the charasteristics of the material. Developing charasteristics of a material affects quality level positively, also, which will affect durability positively. Closed-cell formulations typically range in density from 27 kg/m3 to 51 kg/m3, while compressive strength ranges from 103 kPa to 345 kPa. The density and composition of closed-cell foams help the building gaining more structural integrity. When closed-cell MD-SPF is sprayed in place, makes the applied place seamless and 100-percent fully adhered. This means, SPF roofing limits moisture intrusion because of its 90-percent closed-cell properties. Damage to the system typically does not cause leaks into the building and moisture intrusion is isolated to the areas of damaged foam cells. SPF roofing system has exceptional wind uplift resistance. According to the researches SPF roofs applied over a built-up roof and metal increased the wind uplift resistance of roof coverings. The tests showed similar results for concrete, metal and wood. It requires no fasteners or adhesives, and may not shrink or sag over time, making it ideal for use in vertical wall and below-grade exterior applications. [Harris 2004] [Knowles 2003] Having needed characteristics of a building envelope also refers to the building material having needed quality level which means also affecting durability positively. According to the researches existing performance attributes of SPF has an average compressive strength and core density, offers a very high wind uplift resistance rating and average moisture content was negligible. SPF air barriers offer long-term durability greater than or equal to the building's life span which means the developed charasteristic of the material that affected quality positively, also.

As the type and the place where the material is used changes, needed quality criteria differs. The quality of a building material is the totality of its attributes. When there are any materials with less quality, it is important to be easily replaced with the more durable materials. A different quality definition is needed for every product which can be defined again through the view of durability. For instance the definition of quality for PVC can be written as: "A PVC building material should be resistant to water, some chemicals, tearing, thermal stability and moisture, should have high strength and low cost." When produced as a foam, PVC should have high thermal insulation properties and good water, moisture and vapour proofing properties. The more efficient use of building materials mainly tendencies like the improvement of the quality of the materials, affects improvement of durability, also. Having needed characteristics of a building envelope also refers to the building material having needed quality criteria. It means; if there is a stable interaction between heat, air and moisture transports, the building material will have needed characteristics which also show the level of quality. It affects also the durability. The durability of a material in a building envelope not only depends on the quality level of the building material but also the outdoor and indoor climate, type of construction and conditions of service, also.

Service Life of Light Weight Bathrooms

Erik Brandt [1]

T 17

ABSTRACT

Traditionally bathrooms in Denmark have been made from heavy inorganic materials like masonry and concrete clad with ceramic tiles. To make it simpler, easier and cheaper to make bathrooms – including installation of bathrooms in old houses where no bath was available earlier – there has been a wish to make light weight bathrooms i.e. mainly made from wood based products or building boards, e.g. gypsum boards.

In Denmark the use of light weight bathrooms has been allowed since the 1970'es. The use has not been without problems as a lot of the early constructions proved not to be watertight – at least not over time. The experience was such that some organisations tried to make it illegal to use light weight bathrooms due to the large number of errors and the very large sums used for repair work.

The paper describes the problems experienced over the years including identification of the most important properties for light weight bathrooms and the prerequisites for the use. In addition the changes in requirements over time are discussed. The changes are generally more rigorous requirements first of all to secure the watertightness of the construction. In order to use light weight bathroom constructions documentation must be available for example from testing and subsequent approval. The test procedures used is currently - in a slightly modified form - being treated by EOTA in connection with a Technical Guideline for "Watertight covering kits for wet room floors and walls". The test methods which to a certain extent takes durability into consideration is shortly described.

It is discussed how long a service life might be anticipated for a light weight bathroom in comparison with a traditional solution. Finally the importance of regular survey and maintenance is discussed.

KEYWORDS

Bathrooms, Watertightness, Service life.

[1] Danish Building Research Institute, Aalborg University, DK-2970 Hoersholm, Denmark, Phone +45 4574 2370, ebr@sbi.dk

1 INTRODUCTION

In Denmark bathrooms have traditionally been made from heavy inorganic materials e.g. floors of concrete with iron beams and walls made from masonry or concrete. These constructions were considered to be watertight provided that they had a water repellent surface, e.g. ceramic tiles.

Different solutions have been invented to install bathrooms in older houses which originally did not have bathrooms. Typically old houses have floor constructions with wooden beams and walls containing wood in some form. The old wooden beams have e.g. been used to support a concrete slab used as floor in the new bathroom. Also lighter construction materials have been used, e.g. wooden studs, plywood or gypsum boards.

The advantage is that they are cheap, easy to install and without excess water. The drawback is damages resulting in reduced service life and excessive repair costs.

The use of lightweight constructions was introduced in Denmark some 35 years ago. The use has always been restricted to constructions and/or materials either with a national approval for a specific material or construction or approved via directions issued by the Danish Building Research Institute.

Experience gathered in the 1990'es, e.g. by the so called “building defects funds”, showed quite a few problems with light weight bathrooms due to insufficient watertightness of the solutions in practice. The problems were almost entirely connected to bad workmanship or use of unsuited materials e.g. watertight membrane was missing or there were failures around details especially floor gullies.

As a consequence of the findings a series of changes were made to the requirements for obtaining an approval as well as to the constructions described in the directions from the Building Research Institute with the purpose to improve the service life of the light weight constructions.

2 PERFORMANCE ANALYSIS AND PROPERTIES

Before light weight bathroom constructions were allowed in Denmark an analysis was made in order to identify all the functions of bathroom walls and floors and all the agents acting on them. Based on the performance analysis it was possible to set up a list of performance properties for bathroom walls and floors. The five most important properties related to service life are found to be:

2.1 Watertightness

Watertightness which is especially required in areas exposed to water. In Denmark the use of bathtubs or shower units is not common and consequently the floor and the walls are directly exposed to water.

2.2 Water Vapour Permeability

In bathrooms a high relative humidity can be expected. This causes a high vapour pressure in the bathroom and consequently diffusion of moisture through floor, ceiling and walls. Especially for constructions that are part of the building envelope it is necessary to take precautions to avoid condensation of moisture inside the structure – this is normally done by the use of a vapour barrier.

2.3 Resistance against Mechanical Loads

The floor and wall constructions in bathrooms shall be able to resist ordinary loads from persons and furniture. This is also the case for vulnerable details like floor gullies and pipe penetrations.

2.4 Dimensional Stability against Changes in RH or Temperature

The constructions must not be damaged by dimensional changes in the materials e.g. due to unavoidable changes in RH due to seasonal variations. For materials where dimensional variations are unavoidable, e.g. wood, precautions must be taken to accommodate the dimensional changes envisaged.

2.5 Compatibility

The materials used shall be compatible including materials used for cleaning and maintenance. Besides the above mentioned the bathroom shall ensure that the functions foreseen can take place, for example must the floor be safe to walk on and the surfaces shall be easy to clean.

3 MATERIALS AND CONSTRUCTIONS USED

To ensure a satisfying service life the requirements to materials and constructions for bathrooms are generally higher than for ordinary rooms due to the exposure to water: Besides the consequences of failures are most often very severe. For constructions the requirements are expressed as stricter rules regarding strength and stability in order to ensure they are strong and stiff enough to prevent damages to the watertight membrane. Further the materials in the construction should either have small dimensional changes when exposed to variations in relative humidity (unavoidable due to seasonal changes) or measures should be taken to accommodate them. In Denmark it was in the first years required that wood based materials were pressure impregnated in order to make them resistant to water. This requirement was given up after a few years due to a philosophy stating that water shall not be present in the interior of the construction. Surfaces in wet rooms are required to be water repellent or even watertight in order to ensure that water runs of and to avoid ingress of water to any vulnerable materials in the construction. The following is a brief description of materials and constructions used in floor, wall and surface constructions respectively.

3.1 Floor Constructions

Light weight floors in bathrooms are normally made from board materials supported by wooden beams. The board material may either act directly as sub-floor or as underlay for a levelling compound.

To increase the stiffness of the floor compared to ordinary rooms a reduced distance is used between beams/joists. The distance is dependent on the material used and the intended surface material. Boards for floors are most often plywood or chipboard. The latter is nowadays only allowed for resilient floor coverings due to insufficient dimensional stability. Other materials used are polystyrene (PS) boards with a facing or wood based boards with a coating to make them inherently watertight. For inherently watertight boards it is in addition to the watertightness of the board itself required that the joints are watertight. PS boards and gypsum boards are only allowed with a national approval and they both have special requirements to the underlay to ensure a sufficient strength and stability.

Service life for light weight floors is good as regards resistance against mechanical loads and dimensional stability. There are only few examples on insufficient stiffness and this has especially been in connection with a change from PVC floor covering to ceramic tiles where the requirements are higher. Problems with floors are usually connected with watertightness.

3.2 Wall Constructions

For walls there have earlier been problems with insufficient stability. This has resulted in increased requirements to stiffness which may be fulfilled by a combination of 1) reduced distance between studs, 2) greater dimensions of studs (the standard is now a 70 mm stud - i.e. a 70 mm cavity in the

wall), 3) thicker boards or 4) two layers of boards. Studs may either be wood or steel. Boards come in several materials of which gypsum board are most popular probably due to the price and the fact that they are dimensionally very stable. Due to earlier problems gypsum boards in Denmark now comes as special "wet room boards" with a higher density than normally and with silicone impregnated gypsum. The carton is not impregnated as this would jeopardize later application of watertight membranes etc. Gypsum boards are also available as fibre reinforced boards without carton. Other materials include calcium silicate boards (water resistant) with or without a watertight facing, plywood, chip board and plastic laminate. Finally are used - as for floors - polystyrene (PS) boards with a facing and wood based boards with a coating to make them inherently watertight.

The experience with performance and service life for the current constructions are good as regards resistance against mechanical loads and dimensional stability. There have only been a few cases of insufficient stability, e.g. where studs have been cut to make room for pipe penetrations or where walls are not provided with 2 layers of boards. Problems with water tightness are mainly due to lack of watertight membrane or bad detailing. A special problem is seen for walls supplied both with a vapour barrier behind the boards AND a watertight membrane on the face of the board, see below.

3.3 Watertight Layer

For lightweight constructions it is of utmost importance that vulnerable materials are protected from water and moisture. To ensure watertightness not only the materials but the entire construction including joints, penetrations etc. must be watertight if a long service life shall be achieved.

For stud walls protection against moisture is normally achived with a vapour barrier. In bathrooms the watertight layer shall replace the ordinary vapour barrier which consequently shall be left out. If not, water may under unfortunate conditions – e.g. due to an even minor leak – penetrate into the board where it is trapped between the two impermeable layers without possibility to escape. This might lead to accumulation of moisture and severe damages.

To day watertightness of a light weight construction is achieved in one of the following ways:

- application of a watertight membrane (in fluid form) on the underlay. The membrane is normally protected by a wearing surface most often tiles. In Denmark it is to day a requirement that the membrane shall be at least 1 mm thick.
- application of a pre-fabricated membrane. Prefabricated membranes include PVC floor and wall coverings (with welded joints to achieve watertightness). For membranes placed inside the construction all materials over the membrane shall be able to withstand exposure to water.
- application of a watertight paint system with a glass fibre cloth as reinforcement. The watertightness is normally achieved by the use of a special adhesive for application of the glass fibre cloth.
- inherently watertight boards with watertight joints.

Earlier other watertight layers have been used. For example systems based on polyurethane or acrylic materials were used as a combined watertight layer and wearing surface. These systems were used in accordance with national approvals but were given up may be due to problems with crack propagating from the substrate, i.e. insufficient crack bridging ability of the material. Glass fibre reinforced polyester was used to a limited extent but was given up due to safety problems for the workers. For many years all suppliers in Denmark had systems where the watertightness was based on a combination of a primer and a tile adhesive. In principle it is still possible to use such systems provided that watertightness can be documented. However, they are not on the market anymore. Some 12 years ago the building defects funds preferred pre-fabricated membranes because they had seen a lot of problems with fluid applied membranes. This led to a requirement of a minimum 1 mm thickness of the fluid applied membranes. This requirement has resulted in a change so to day the fluid applied membranes are the preferred. Both systems have their advantages and drawbacks. A prefabricated membrane has a well defined thickness but may cause problems with the joints

especially in the corners. A fluid applied membrane has no problems with joints but may cause problems if the thickness is to low.

4 COMMON FAILURES IN BATHROOMS

Failures in bathrooms are generally related to ingress of water or condensation of moisture in the construction. Failures will normally lead to reduced service life and quite often renovation is comprehensive and associated with excessive costs. Failures are seen in all bathrooms including the traditional ones made from concrete, masonry etc. However, the traditional constructions are often more "tolerant" against small failures i.e. the consequences are less severe and renovation not as comprehensive as for light weight constructions.

For light weight constructions the most common problems are:

- watertight layer/membrane missing or not thick enough resulting in ingress of water in the construction, see figure 1.
- lack of detailing for floor gully, pipe penetrations and joints resulting in ingress of water around details, see figure 2.
- insufficient stiffness resulting in cracks in tiles – and in some cases damages to the membrane, see figure 3.
- insufficient welding of joints in PVC floor and wall coverings resulting in ingress of water through the joints, see figure 4.
- illegal changes to floor gully – normally made in connection with renovation of floor where the existing floor gully is extended to a new floor surface. Many problems are seen due to ingress of water through the extensions, see figure 5 and 6.
- the bathroom is not designed to resist moisture transport, e.g. vapour barrier is used in connection with watertight membrane or less permeable layers are used inside the construction resulting in accumulation of moisture and deterioration of materials.

Besides other problems are seen, e.g. insufficient slope and inaccessible floor gully, which do not have direct influence on the service life.

Figure 1. Example of a bathroom wall made from wood based material without a watertight membrane. The lack of watertightness resulted in a total renovation of the bathroom due to fungus and dry-rot in the constructions.

Figure 2. Example of pipe penetrations in a floor construction. The tubes (for the pipe in tube system) are finished just over the floor allowing water to run into the construction.

Figure 3. Example of cracks in a floor with underlay of plywood but with insufficient stiffness.

Figure 4. Example of insuffiient welding – worst example ever seen – with repair of the joint with tape. Probably a do-it-yourself work.

Figure 5. Example of new floor covering on top of the old. The floor gully has been extended with a plastic frame but unfortunately it is not watertight, see figure 6.

Figure 6. The result of lacking watertightness of the extended floor gully is seen as a drop on the water lock (inside the marking) in the flat underneath after floding the floor above under 10 mm water for about 10 minutes.

5 APPROVAL AND TESTING

In Denmark the use of new light weight constructions for bathrooms is only allowed with an approval. So far approvals have been national and issued by ETA-Denmark (national approvals are in Denmark designated MK-approval i.e. approval of materials (M) and constructions (K)). Shortly it will also be possible to get European approvals (ETA's).

All approvals are for systems, e.g. a bathroom partition with specified studs, specified boards and specified screws assembled in a specified way. Approvals are issued on basis of a testing. Approval can be obtained for constructions, i.e. floor constructions, or for watertightening systems.

Testing of constructions is done in order to ensure that the strength and stiffness is sufficient for use in a bathroom. For example walls are tested according to ETAG 003 (European Technical Guideline for testing of partitions in general and partitions in bathrooms in particular), [EOTA, 2003], with hard and soft body impacts.

Testing of watertightening systems has until recently mainly been performed according to Nordtest methods, [Nordtest, 1994], [Nordtest, 1991], [Nordtest, 1987]. These methods were developed as a sort of accelerated test methods with exposure to mechanical loads, humidity changes and cycles of hot and cold water. The exposure was chosen to simulate exposure under use conditions but with

tougher extremes. The test specimens include all types of details to be expected in bathrooms, e.g. in- and outgoing corners, floor gullies and pipe penetrations. The details are included to ensure that not only can they be made in the intended way but they shall also be able to resist in-use conditions under a long period of use. Actually problems most often occur at the details. It can not be said how much the testing accelerates the real life exposure as this very much depend on the actual use.

New products appear regularly and even though standard procedures exist for some products these can not always be followed. New products may have properties different from what have been seen earlier and consequently may call for a different test. In such cases it might be necessary to develop new or modified test procedures with the aim of ensuring a sufficient performance and service life.

During the past five years an EOTA (European Organisation for Technical Approval) working group has been working on a European Technical Guideline (ETAG 022) for waterproofing of wet rooms. The first part dealing with watertight membranes applied in fluid form is now finished and the remaining two parts (dealing with watertight systems applied as pre-fabricated sheets and inherently watertight boards respectively) are currently under finalisation [EOTA, 2007].

The properties dealt with in the ETAG guideline 022 comprise performance properties as well as properties used for characterisation and production control. The performance properties include, e.g. watertightness, tensile strength (initial and after different exposure conditions), crack bridging ability and water vapour permeability. A number of the test methods in the EOTA work are full scale tests very similar to the NORDTEST methods used in Denmark, Norway and partly in Sweden and Finland until now, i.e. with testing of all relevant details like floor gully and corners.

Some of the above mentioned properties are compulsory, whereas others are dependent on national requirements and consequently only need to be documented in the relevant country. For example there are requirements in the Nordic countries (dependent on country) as regards water vapour permeabilty and thickness of membrane.

6 FACTORS AFFECTING THE SERVICE LIFE

The service life of light weight bathrooms is dependent on several factors. Besides the factors already mentioned the following should be taken into account:

The workmanship is crucial for a good result. Even a good product/system is worth nothing if not installed properly. In Denmark the most common problem is probably that too little watertight membrane is applied. The reasons are believed to be that the membrane is expensive and the application time consuming. This calls for a quality control of the work best performed by the contractor himself and followed up by an independent body. In Denmark a voluntary control scheme has so far only been used for works with PVC floor and wall coverings used as watertight membrane. For PVC works the contractor – actually the individual craftsman – controls his own work and this is followed up by independent surveys of randomly chosen bathrooms. The control scheme has led to a significant improvement of the quality of the work.

Maintenance is important and is best performed on basis of regular inspections. Any sign of leakage or potential risk of leakage should be reported and repaired as soon as possible in order to avoid damages. In Denmark light weight bathroom shall be designed so any leakage shows immediately, e.g. by water from a leak dripping out a conspicuous place. Thereby it is possible to make necessary repair works before a damage spread out and gives serious and expensive problems in the entire construction.

7 DISCUSSION

Light weight bathrooms have now been used in Denmark for more than 30 years. A number of light weight bathrooms have been in use since the use was allowed in the beginning of the 1970'es and still perform well.

The increased requirements introduced over the past 12 years have proved to have a good effect as the number of problems has been reduced significantly. Contributing to the reduced number of problems is also that a huge effort to teach consultants and contractors about the importance of good design and workmanship has been fruitful. Today most architects, engineers and craftsmen are very much aware that bathrooms constructions are complicated and require special attention.

It is believed that good performing bathrooms with long service lives can be achieved if the earlier mentioned factors affecting the performance and service life are taken into account when designing and executing a light weight bathroom, i.e.:

- the bathroom shall be designed taking into account not only the constructions but also the installations and any complications that may arise due to the severe exposure to water and high relative humidity,
- floor and wall constructions shall be stable enough to avoid deflections that may damage the watertight layer and the surface covering,
- vulnerable materials shall be efficiently protected by a watertight layer, e.g. a membrane. The watertight layer shall be approved for the intended use or sufficient documentation for performance and service life shall be provided by the supplier,
- vulnerable materials shall be protected from condensation of humidity, e.g. by a membrane (normally the watertight membrane),
- all details shall be well described and tested for watertightness,
- design as well as execution shall be under quality control,
- the contractor shall be made aware of the importance of good workmanship,
- the bathroom shall be maintained regularly preferably on basis of regular inspections.

Based on the experience gained after the implementation of the stricter requirements it is assessed that light weight bathrooms are able to function properly. On condition that the above mentioned requirements are met it is assessed that light weight bathroom have service lives of 30 years or more.

T 18

ABSTRACT

The ever-increasing volume of discarded tyres poses a serious problem from the point of view of solid-waste disposal as well as its derogatory environmental impact. Research is being carried out to solve this problem by reusing or recycling material from such tyres. One such study was undertaken to determine the effects of incorporating shredded rubber tyres into Portland cement concrete mixes. Tests were carried out on experimental blocks prepared with concrete mixes in which predetermined portions of coarse aggregates were replaced by two lengths of rubber fibres from shredded tyres, separately, to the order of 10, 15, 30 and 45%. A total of 9 mixes, including the control mix, were prepared and 17 samples of each were tested for their unit weight, slump, flow, air content, density, water absorption, porosity, water permeability, durability after freeze-thaw cycles, compressive and flexural strengths. This paper presents the findings of experiments related to the physical and mechanical properties of concrete with varying ratios of the rubber fibres from waste tyres.

KEYWORDS

Rubberized concrete, Waste tyres, Shredded tyres.

1 INTRODUCTION

The production of tyres has increased proportionally to the production of automobiles, in Turkey. In the year 2000, total sales of tyres was around 126,000 tons of which 86,000 tons were sold directly to vehicle owners; hence, the assumption that approximately 90,000 tons of rubber tyres are replaced annually. In addition to locally manufactured tyres, imported tyres are also sold in the domestic market. Thus, based on these figures, it is estimated that the total volume of waste tyres needing disposal is approximately 120,000 tons annually [DPT Report 2000a].

Most of the discarded tyres in Turkey are recycled in some ways; for instance, 11% of the waste tyres are used in the production of rubber soles for shoes [DPT Report 2000b]. Hence, the number of discarded tyres to be disposed of as solid waste is small compared to Western countries. On the other hand, the ever increasing production of vehicles may lead to a higher rate of tyres being discarded than can be recycled. Consequently, even Turkey can face a dilemma similar to that of the EU, Japan or USA where the number of tyres discarded per annum is in the region of 240, 100 and 285 millions, respectively.

Up until the eighties, the only way to dispose off waste tyres was to burn them; but the oil and soot thus produced caused tremendous environmental pollution, which was not only a health hazard but also in contradiction to the environmental policies and legislation in place. In order to use up this waste in an environmentally acceptable manner, the first attempt to recycle rubber from discarded tyres was in the form of rubber crumbs, which was used as light aggregate in hot asphalt for paving roads [Lougheed and Papagiannakis 1996].

Recycling or reusing any kind of discarded material is always a better option than dumping it as waste, from the point of view of environmental impacts as well as the country's economy. Of the many ways being investigated to accomplish this objective, using rubber from waste tyres as coarse aggregate in concrete mixes is an option that is being tested in many parts of the world. Rubber is chopped up into granules of predetermined sizes; however, for this research project, rubber was shredded into fibres of lengths 1cm and 4 cm with diameters of 0.1cm and 0.4cm, respectively [Dogan 2005]. A literature survey regarding experiments with recycled rubber concrete has shown that with the addition of rubber granules into the concrete mix the properties of concrete change. Compressive and flexural strength of such concrete are lower than conventional concrete, while this decrease is directly proportional to the amount of crumb rubber present in the mix, and its size. On the other hand, presence of some rubber helps improve crack resistance and the ability to absorb shocks from impacts; hence, it is more tough and durable. The decreased brittleness prevents concrete from disintegrating under compressive or flexural loads. Since the unit weight is reduced and the surface is not as hard, Recycled Rubber Fiber Concrete (RRFC) provides better acoustics control and heat insulation [Rad 1967, Fang *et al*. 1992, Sukontasukkul & Chaikaew 2006].

2 EXPERIMENTAL PROCEDURE

Predefined ratios of coarse aggregate in the concrete mix were replaced separately with two sizes of fibres from shredded rubber tyres, while ratios of other material were kept constant. Samples were then prepared with these mixes and tested for various physical and mechanical properties, keeping in mind the following three objectives:

- To test the performance of concrete when coarse aggregate (crushed stone) is partially replaced with rubber fibre and to compare it with the control mix.
- To investigate the effect of the size of the rubber fibres replacing crushed stone aggregate, on the properties of concrete.
- To investigate the effects of increasing the ratio of rubber fibre in the concrete mix.

2.1 Materials

The following materials were used to prepare the various concrete mixes:

- Portland cement: complying with EN 197-1 and having a 28-day strength of 42.5N/mm².
- Sand: complying with EN 12620 and having granule size of less than 4 mm, unit weight of 1740 kg/m^3, specific gravity of 2640 kg/m^3, water absorption ratio of 0.99%, and fineness module of 2.44.
- Crushed stone: aggregate complying with with EN 12620 and having sizes of 1-12 mm and 1-24 mm with unit weights of 1520 kg/m^3 and 1490 kg/m^3, specific gravities of 2720 kg/m^3 and 2720 kg/m^3,water absorption ratio of 0.50% and 0.25%, and fineness modules of 5.31 and 6.58.
- Water: complying with EN 206-1 standards, suitable for use in concrete mixes.
- Recycled rubber fibres (RRF): produced by shredding discarded tyres into two sizes of fibres, which had a specific gravity of 650 kg/m^3, modulus of elasticity E= 5-15 N/mm^2, and heat conductivity of 21 Kcal/m^{2}h^{0}C. The shorter fibbers (RRF1), of length 1cm and a diameter of 0.1cm, had a unit weight of 405 kg/m^3 and a modulus of fineness of 2.2; while the longer fibres (RRF4) of length 4cm and diameter 0.4cm had a unit weight of 370 kg/m^3 and a modulus of fineness of 4.9 (Figure 1). Since the rubber was shredded into fibres instead of granules, sieve sizes used were 4-31.5 mm and 1-16 mm for the long and short fibres, respectively. The granulometric charts are shown in Figs 2 a and b below.

Figure 1. Short and long rubber fibres (RRF1 and RRF4) obtained by shredding discarded tyres.

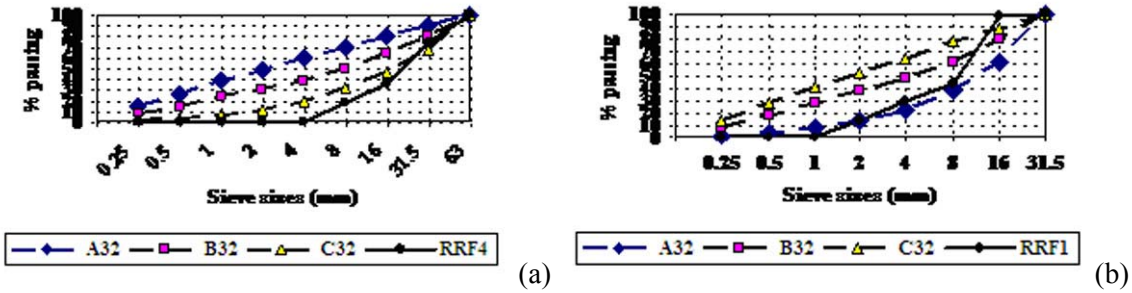

Figure 2. Granulometric chart for: (a)long rubber fibres (RRF4) and (b) short rubber fibres (RRF1)

2.2 Mix Design

Apart from the control mix, 8 varieties of recycled rubber fibre concrete (RRFC) mixes were prepared by replacing 10%, 15%, 30%, and 45% of the coarse aggregate (crushed stone) with the short and long rubber fibres. Of these, 4 mixes were prepared with the short and the other 4 with long recycled rubber fibres (RRF1 and RRF4) separately. Thus, a total of 153 specimen were cast for testing, of which 17 were prepared with the control mix (without any rubber fibre) and 17 each with 10%, 15%, 30%, and 45% of coarse aggregate replaced with RRF1 and then with RRF4.

Table 1 below lists the proportions of Portland cement, water, sand, fine aggregate and coarse aggregate in the mixes for the control specimen, along with the four mixes prepared by replacing 10%, 15%, 30%, and 45% of the coarse aggregate with the long recycled rubber fibre RRF4 (denoted by 4RRFC10, 4RRFC15, 4RRFC30, 4RRFC45) and the four mixes prepared by replacing 10%, 15%,

30%, and 45% of the coarse aggregate with the shorter recycled rubber fibre RRF1 (denoted by 1RRFC10, 1RRFC15, 1RRFC30, 1RRFC45).

2.3 Preparation of Test Samples

All the dry ingredients were first mixed for two minutes in the Pan Mixer, with a capacity of 20 dm^3, before adding the water and mixing again for another two minutes, after which the concrete was poured into the moulds. Two types of plastic moulds were used to prepare the samples; cubic ones of dimensions 15cmx15cmx15cm and cylindrical ones with 15cm diameter and a height of 30cm. The mixes were filled and compacted in the cubic and cylindrical lubricated moulds placed on the vibration table, in accordance with the EN12390-1 and 2 procedures. After leaving them in the laboratory for 24 hours at room temperature, the moulds were removed and the samples were left in the curing room at a uniform temperature of 20 °C.

Some samples were taken out after 7 days and others after 28 days of curing and were then left to dry at room temperature for another 24 hours, before performing the tests.

Figure 3. Mixing the concrete in the pan-mixer and Preparing test-samples by compacting concrete mix into moulds placed on the vibration table.

2.4 Experimental Tests

Various tests were carried out to determine the physical and mechanical properties of the 9 mixes. These tests were carried out according to Turkish standards complying with European norms; the relevant standard notations are given next to the tests applied as listed below:

1. Unit weight of fresh concrete (TS EN 12350–6)
2. Unit weight of hardened concrete (TS EN 12390–7), which was determined for 7 and 28 day old samples
3. Slump test (TS EN 12350–2)
4. Flow table test (TS EN 12350–5)
5. Air content – pressurized testing (TS EN 12350–7)
6. Density, water absorption, and porosity tests (TS 3624)
7. Water permeability test (TS 4045): 27 cubic specimens were tested. (3 each for the 9 mixes)
8. Compressive strength (TS EN 12390–3): a constant loading speed of 0.2 MPa/sec to 1.0 MPa /sec was applied to the samples until they failed.
9. Flexural strength (TS EN 12390–5): a constant loading speed of 0.04 MPa/sec to 0.06 MPa /sec was applied to the samples until they failed.
10. Durability; after freeze-thaw cycles (ASTMC290,C291,C292, and C310): the 28-day samples were frozen for 12 hours at a temperature of -25 ^{o}C and the left to thaw for another 12 hours at 25 ^{o}C. This freeze-thaw cycle was repeated for 25 days and then the samples were tested for their unit weights and compressive strengths.

4 DISCUSSION OF RESULTS

As a result of the experiments carried out on RRFC samples prepared with 8 types of concrete mixes by incorporating different ratios of two lengths of rubber fibres from shredded recycled tires, the following physical and mechanical properties were determined:

- The unit weight of fresh concrete is reduced from 2.384g/cm³ to 2.008g/cm³ by replacing 45% of the coarse aggregate with RRF1, and to 2.155g/cm³ by replacing the same amount with RRF4; i.e. an increase in the percentage of rubber fibre decreases the unit weight of concrete. This decrease is less for RRF1 than for RR4 replacements.
- The unit weight of 28 days old concrete samples is reduced from 2.337g/cm³ to 1.960g/cm³ by replacing 45% of the coarse aggregate with RRF1, and to 2.153g/cm³ by replacing the same amount with RRF4; i.e. an increase in the percentage of rubber fibre decreases the unit weight of concrete. This decrease is less for RRF1 than for RR4 replacements.
- As the percentage of rubber fibres increased, segregation and settlement of aggregates decreased. In other words, the high frictional resistance of the rubber aggregate decreases the workability of the cement.
- As the amount of rubber fibres increased, fluidity of the concrete also increased. It was observed that when shaken repetitively, the rubber fibres in the cement lost their frictional force and the fluidity increased.
- As the amount of rubber fibres increased, air content in the concrete also increased. When fresh concrete with RRF is subjected to pressure, the rubber fibres contract in size and when the pressure is released they spring back, causing an increase in porosity within the concrete.
- The water absorption capacity of RRFC is more for RRF4 than for the shorter fibre, RRF1. Due to the porosity of the rubber fibres themselves, the higher the percentage of RRF in the concrete, the higher is its water absorption capacity and volume of air pockets within.

- As the amount of rubber fibres increases, capillary action in the concrete also increases.

Tests related to compressive strength, flexural strength, and durability, applied on the recycled rubber fibre concrete samples gave the following results:

- Compressive strengths of cubic RRFC samples (15x15x15cm³), which had been cured for 28 days dropped from 38.57 MPa to 16.2 MPa for 45% RRF1 replacements and to 15.33 MPa for 45% RRF4 replacements. Replacing coarse aggregate in concrete mixes with 10%, 15%, 30%, and 45% RRF1 caused a decrease in the compressive strength by 23, 31 , 52 , and 58 percent respectively; while replacements with RRF4s caused a decrease of 18, 23, 45, 60 percent, respectively.
- Compressive strengths of cylindrical RRFC samples (15x30 cm³), which had been cured for 28 days, dropped from 32.31 MPa to 14.08 MPa for 45% RRF1 replacements and to 13.32 MPa for 45% RRF4 replacements. Replacing coarse aggregate in concrete mixes by 10%, 15%, 30%, and 45% RRF1s caused a decrease in the compressive strength by 23, 29, 50, and 56 percent respectively; while replacements by RRF4s caused a decrease of 22, 25, 45, and 59 percent, respectively..
- Flexural strengths of cubic RRFC samples, which had been cured for 28 days dropped from 6.89 MPa to 3.85 MPa for 30% RRF1 replacements and to 4.01 MPa for 30% RRF4 replacements. It was observed that an increase in the amount of RRFs caused a reciprocal decrease in the flexural (tensile) strength of the concrete. Samples made with the control mix or with 10% RRFs exhibited brittleness and broke under tensile strain; however, when the amount of RRFs was increased to 30% the concrete samples cracked but did not break under the same loads.
- The Unit weights of RRFC samples that had undergone 25 freeze-thaw cycles increased slightly after this treatment; this behaviour is in contrast to normal concrete where unit weights drop after the freeze-thaw cycles. The unit weights of the control mix, 1RRFC15, 1RRFC45, 4RRFC15 and 4RRFC45 increased from 2.37, 2.24, 1.96, 2.31, and 2.15 g/cm^3 to 2.36, 2.28, 2.11, 2.33 and 2.18 g/cm^3, respectively.
- The compressive strengths of RRFC samples that had undergone 25 freeze-thaw cycles decreased slightly after this treatment; this behaviour is in contrast to normal concrete where compressive strengths increase after the freeze-thaw cycles. The decrease is more for the longer fibres as compared to the shorter ones. The compressive strengths of the control mix, 1RRFC15, 1RRFC45, 4RRFC15 and 4RRFC45 dropped from 38.57, 26.73, 16.20, 29.67, and 15.33 MPa by 0%, 3%, 7%, 7.5%, and 8.8%, respectively, to 38.90, 25.97, 15.13, 27.43, and 13.96 MPa.

5 CONCLUSION

The experiments conducted by incorporating two lengths of rubber fibres into the concrete mixes have demonstrated that the compressive and flexural strengths of RRFC decrease with the addition of rubber fibre from shredded waste tyre. The reduction in mechanical properties is directly proportional to the amount of fibre and also the size of the fibre that replaces the coarse aggregate in the concrete mix. However, with the increase in compressive or flexural loads, the RRFC did not disintegrate like conventional concrete, but held together in spite of surface cracks. Furthermore, when the applied load was removed, the samples were seen to have undergone plastic deformations. On the other hand, the presence of RRFs led to a reduction in the unit weight of concrete, which was proportional to the amount of fibre present in the mix; therefore, it is lighter than conventional concrete. Despite the reduction in compressive and flexural strengths, RRFC was observed to be more durable as it is more impact resistant and has higher plasticity. Also, RRFC is able to absorb more energy; hence, it has better sound absorption and heat retention properties.

T 18

ABSTRACT

A low strength cementitious matrix composite that is reinforced with oriented wheat straw cables was investigated in the study. The composite can offer an inexpensive, locally available, renewable and environmentally friendly construction material that can be used in regions where these criteria are critical for housing needs. They can offer a solution for the housing problems throughout the world as their assembly will also be quick and effortless considering their light weight. The composites can be used for housing applications in low income areas of developed and developing countries or in emergency situations where housing needs emerge due to force majeure events or places such as refugee camps.

A series of experiments were performed on the composites to obtain their mechanical properties. The load carrying capacity average for small scale composite columns tested in compression was 12,663 N (2,847 lbf). A life cycle assessment (LCA) study was also performed to identify the environmental burdens associated with the composite as a building material. The critical processes in the life cycle of a wall system of the composite were identified using Simapro.

1 INTRODUCTION

Natural fibers are grown throughout the world and are mostly byproducts of agriculture. The use of natural fibers in building components is an important research area since a large portion of natural fibers are being burned or disposed of with serious environmental consequences. Composites based on natural fibers offer a wide variety of advantages in the building sector. They can be expected to be renewable, at least partially biodegradable, and not highly energy-intensive. Potential uses for such composites can be either as non-load bearing elements such as wall and insulation panels, or they can be used as load bearing elements for simple building frames.

Natural fibers are great alternatives for housing applications where very high strengths are not required [Satyanarayana et al. 1984]. Natural fiber reinforcement have been used both in cement and in polymer composites [Burgueno et al. 2004]. The main advantages in cement composites of natural fibers were listed as increased flexural capacity, post crack load bearing capacity, increased impact toughness and improved compressive strength [Sera et al. 1990]. The performance of discontinuous and randomly distributed natural fiber was investigated in cement board applications, wall panels, and suggested as a substitute for asbestos cement [Ghavami et al. 1999]. Natural fibers such as bamboo and date palm fronds were used as continuous reinforcement because such fibers are quite strong even as individual fibers.

Wheat straws as an abundantly available agricultural fiber have only been investigated as discrete fibers in a composite. A wheat-straw based particleboard was found to meet industrial standards [Boquillon et al. 2004]. In addition to the environmental and economical advantages, natural fibers are good insulators; low density straw panels have been suggested in thermal insulation applications [Strivasta and Grupta 1990].

This paper presents information on basic mechanical properties and the environmental impacts of a novel composite building material - oriented straw cable composite (OSCC). Wheat straws were oriented in parallel and assembled into cables which were then embedded in a low strength cementitious matrix. No literature on this particular subject has been found by the authors.

Reinforcing matrix materials with organic fibers can be expected to increase the compressive and flexural strength compared to non-reinforced matrix material. The tensile strength of the fibers constitutes an ideal flexural reinforcement. Wheat straw, like most agricultural residue, does not behave elastically under loads. The behavior has been defined as viscoelastic or even as a combination of plastic, viscous and elastic behavior [Moustafa et al. 1968]. As a first approximation however, the calculations in this preliminary study are based on a linear analysis.

The environmental impact of the OSCC material was another aspect of this study. Natural fiber composites are claimed to offer various environmental advantages over conventional composites such as reduced dependence on non-renewable energy sources, lower pollutant and green house gas emissions, and end-of-life biodegrability [Joshi et al. 2004]. Environmental burdens of the OSCC manufacturing processes were quantified to identify critical processes. The Life Cycle Assessment (LCA) methodology was used for the environmental burden analysis. There is no specific LCA study for wheat reinforced composites; therefore, in this study the scope and boundaries were set according to similar studies found in the literature [Corbiere-Nicollier et al. 2001].

2. MATERIALS AND PRODUCTION

Specimens to be tested were manufactured by Ashland Prototypes (Ashland, Oregon, USA). An extrusion machine was used in production of the OSCC, mounted on a combine chassis and used to harvest a portion of the remaining wheat plant after harvest. Wheat straw, clay, clay bearing subsoil,

recycled newspaper, cement, polyethylene string, were the materials used for the production of the OSCC. The length of the straw was dependent on the type or setting of the combine.
The OSCC prototypes studied here were small scale columns and beams. The OSCC columns consisted of four 50.8 mm (2.28 in.) diameter straw cables and the matrix covering the cables, the nominal cross section being a 101.6 × 101.6 mm (4 in. × 4 in.) square 'Fig 1'. Seven different column specimens with average length of 457 mm (18 in.) were tested. Two OSCC beams were also tested, with an average length of 1626 mm (64 in.) and rectangular cross sections of approximately 102 × 203 mm (4 × 8 in.). A total of eight continuous straw cables were running through the whole beam length. The specimens were stored and tested in normal room conditions (22 ± 2 °C).

Figure 1. A small scale OSCC (oriented straw cable composite) column.

3. MECHANICAL TESTING

3.1 Experimental Method

The overall objective of this part of the study was to investigate the loading behavior of OSCC. The composite specimens were tested in compression and bending. Testing was carried out in the Materials Testing Laboratory of the Civil and Environmental Engineering Department at Tulane University (New Orleans, Louisiana, USA). Compression tests were conducted at a rate of 0.025 mm/sec (0.00098 in./sec), and for the bending tests the rate was 0.017 mm/sec (0.00066 in./sec).

Wheat straw is an anisotropic and heterogeneous material with a loading response of combined elastic, inelastic, and viscous behaviors. It is highly complicated to evaluate its response to any type of loading [Liu et al. 2004]. Considering the limited scope of this research, a number of assumptions were made to simplify the evaluation of the wheat straw behavior. The strain calculations were based on the engineering strain definition. Stress calculations were based on the bulk area of the specimens. The modulus of elasticity calculations were based on the linear portions of the stress-strain graphs.

Testing for small scale OSCC columns was conducted on an MTS 311.31 load frame, with a 244.51 hydraulic actuator (the motor that converts hydraulic energy to mechanical work) and a Flex Test III CTM controller. The MTS Basic TestWare software was used to carry out the experiments and to acquire data. The bending tests on small scale OSCC beams were performed in a MTS fixture with the 355.86 kN (80 kips) hydraulic MTS actuator. The beams did not show sudden deflections or failure, but they underwent large deflections with small increments of applied load. Deflections were measured to analyze the behavior of the beams. Extensometers and string pots were used at multiple positions of the test set-up to monitor displacements. The test fixture for the bending tests was shown in 'Figure 2'.

Figure 2. The bending test set up for a small scale OSCC beam.

3.2 Mechanical Testing Results

The average load carrying capacity value for OSCC columns was 12,663 N (2,847 lbs). A typical load displacement graph for the OSCC columns is shown in 'Figure 3'. The average stiffness value for the wheat straw reinforced composite group was 257.98 MPa (35,407 psi). The composite beams had ultimate flexural stresses of 331 and 462 kPa (48 and 67 psi) for the elastic portion of their load behavior. The load versus mid-span deflection graph was shown in 'Figure 4' for one of the beams.

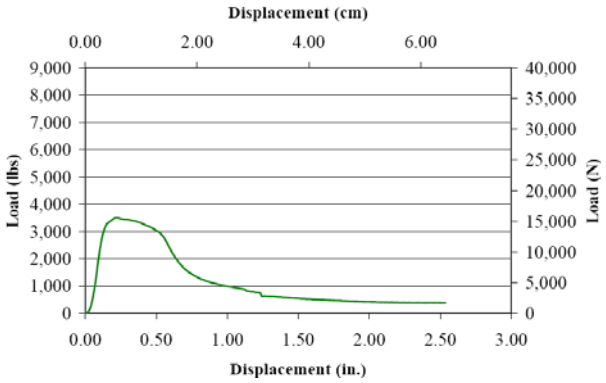

Figure 3. Load-displacement graph for an OSCC tested in compression.

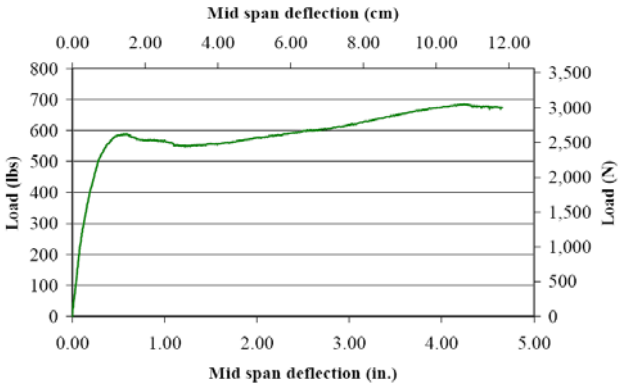

Figure 4. Load-mid span displacement graph for 4-point bending test on an OSCC beam.

4 ENVIRONMENTAL IMPACTS OF OSCC PRODUCTION

The life cycle assessment (LCA) method was used to quantify the environmental impacts associated with the production of an OSCC beam. The use of renewable sources such as OSCC can also increase material efficiency corresponding to the goals of sustainable development. The life cycle assessment is expected to extend the knowledge base on the environmental impact of bio-based building materials. The target audiences are sustainable materials researchers and LCI practitioners.

The function of the beams as building materials was defined as the structural support, thermal and sound insulation, and protection against water and air intrusion. The functional unit for the comparison study was selected as an OSCC beam with a 20.3 × 20.3 cm (8 × 8 in.) square cross section and a length of 3.05 m (10 ft).

4.1 Method, Data Quality and Sources

The composition of the OSCC was obtained from the strawjet manufacturer (Smith, 2004). Life cycle inventory and life cycle impact assessment results were obtained using the Simapro v.7 software (Pre-Consultants bv. Amersforth, NL). As a first step, an LCI was compiled for the materials used in the beams and burdens associated with these materials. Life cycle inventory contributions to different environmental impact categories were assessed using the impact assessment method TRACI (Tool for the Reduction and Assessment of Chemical and other environmental Impacts) (Bare 2002) which was part of the Simapro software.

Since the material is new and unique, the primary data - the data about the OSCC production process itself - are prospective data estimated by the designer of the composite production process. The geographic scope was the US region, time coverage was from 1995 to 2005, and the technology is the only technology currently available for OSCC production. The secondary data – the data on pre-production and disposal processes – were obtained from various databases as listed below. The geographical coverage for all secondary data was the US and Canada, except the Ecoinvent database which is mainly based on European data. The time coverage, technological coverage, representativeness, precision, completeness, consistency, and reproducibility of the secondary LCI data varies with the source database used.

Databases used for the study include the Franklin US LCI Database, the Ecoinvent database, and the US Input/Output database. These databases were included with the commercial LCA software used in the study. The inventory for the wall systems also includes data from other sources, the US LCI Database, the ATHENA Environmental Impact Estimator software database ,and the 2002 commodity flow survey (CFS) [Franklin 2003 & NREL 2001]. The data were reviewed for consistency with the system boundaries set for the project. The environmental impact categories included in the impact assessment method were: global warming, acidification, human health (HH) cancer, HH non-cancer, HH criteria air pollutants -point source, HH criteria air pollutants -mobile source, eutrophication, ozone depletion, ecotoxicity, smog.

4.2 System Boundaries and Description

The system includes “cradle-to-gate” processes; that is, the use phase and disposal of the beams were not considered. All the processes related to raw materials extraction, and production were taken into account in the study. Capital goods such as the infrastructural facilities needed for the manufacture of products were not included in beam system definition with the exception of the strawjet machine and the processes taken from two databases that routinely consider capital goods contributions - the Ecoinvent database and the US input/output library. These two databases were only used when data from other sources were not available. Ancillary materials such as engine oil for the OSCC production machinery, as well as human labor were not considered.

The allocation considerations in this study simply followed those by the databases used for the processes. Transportation distances were considered in two parts for each beam component purchased off-farm. The products were transported from the manufacturing plant to a retailer, then from the retailer to the on-farm construction site. The distances for the first part of the transportation varied by material and US average distances were obtained from the US Bureau of Transportation Statistics 2002 Commodity Flow Survey (CFS). The second part of the transportation - from a retailer to the OSCC production site - was represented for all materials purchased off-site by the same ad-hoc estimate. A wide triangular probability distribution was assumed to reflect the large uncertainty, with an average distance of 30 km (18.64 mi.), a minimum of 3 km (1.86 mi.), and a maximum of 75 km (46.60 mi.).

The OSCC has two main components; the matrix and the straw bundle. The materials used in the composite are listed in [Table 1] showing the amount of each material needed per functional unit. In the production stage, oriented straw cable composite was assumed to be extruded at the site of the wheat straw harvest. When the straw is used for the composite, its normal processing – tilling into the soil - is prevented, so the environmental burdens from tilling were counted as negative burdens, or credits, to the life cycle inventory.

Table 1. Inputs per 3.05 m (10 ft) composite beam used for the LCA

Inputs per Functional Unit	**Amount kg (lb)**
Cementitious Matrix :	
Clay-bearing subsoil	23.7 (52.2)
Recycled newspapers	2.3 (5)
Portland cement	1.1 (2.5)
Mortar Clay	2.5 (5.4)
Straw Cable	
Straw	16.8 (37.1)
Polyester Yarn	0.04 (0.1)

4.3 Environmental Burden Results

The environmental burdens of the components of the OSCC beams were compared. The contribution of the matrix was higher than that of the straw bundle in all impact categories except eutrophication and ecotoxicity. The high contributions of the straw bundle in these categories were due to fertilizers required to replace the nutrient content of wheat straw that was not tilled into the soil, because it was used in OSCC. As a benefit of this avoided tillage of straw, the straw bundle showed negative contributions to the categories of global warming, HH criteria air pollutants, and smog. Extrusion of the beam had its highest contribution in HH criteria air pollutant category, mainly due to air emissions resulting from cutting the extruded OSCC composite.

The components of the matrix materials were more thoroughly investigated for their contributions to the environmental burden of the composite beam [Table 2]. Clayey subsoil was the critical component of the cementitious matrix for global warming, acidification, HH criteria, and smog categories. Portland cement was the critical component for the HH cancer and non-cancer categories and mortar clay caused the highest impact in the ozone depletion category. For the composite beam, the cementitious matrix was the critical component according to the impact scores for most impact categories. The composition of the matrix can be modified using products carrying lower environmental burdens.

Table 2. Percent contribution of each matrix component to the impact score for the categories considered in the LCA study.

Impact category	Portland Cement	Clayey subsoil	Old Newspaper	Mortar Clay	Matrix Mixing
	Percentage %				
Global Warming	3.05	49.10	3.21	43.40	1.24
Acidification	15.60	55.00	21.10	7.18	1.10
HH Cancer	99.60	0.03	0.04	0.320	5.18E-4
HH Non-cancer	99.10	0.29	0.30	0.35	2.25E-3
HH Criteria Air-Point Source	2.79	72.90	5.05	18.20	1.05
HH Criteria Air-Mobile	2.88	71.80	5.61	18.70	1.04
Eutrophication	16.10	57.40	19.40	5.95	1.17
Ozone Depletion	6.15	0.12	0.14	93.60	2.14E-3
Ecotoxicity	69.50	2.32	2.69	25.40	0.04
Smog	5.77	67.50	20.10	5.27	1.38

5 DURABILITY ASPECT

The durability of OSCC is an important property for both mechanical behavior and environmental impact aspects. The exterior coating-the matrix- of the OSCC specimens that were exposed to weathering were observed to disintegrate with time. The application of exterior coatings used in the buildings like paint, stucco or plaster will help enhance the durability performance of the material for outside conditions. The durability characteristics of some organic materials in cement matrix such as wheat straws are found to be in desirable limits (Soroushian, 2004).

6 CONCLUSIONS AND FUTURE WORK

The oriented straw cable composites can be used as low cost structural components manufactured with locally available materials. The experimental and environmental investigations into the oriented wheat straw cable composites have provided a basic understanding for the overall properties of the material. Introducing the oriented straw cable composite as a building material would be a challenge because it is a new material and there is no design method developed; however, this work shows that natural fibers are feasible candidates as a reinforcement to cement matrix for affordable housing. Straw fiber reinforcement increased the compressive strength of low strength cementitious matrix material. They are also degradable and energy efficient, especially compared to some materials currently used in construction. These characteristics are highly advantageous for a building material as environmental considerations are a growing concern in most countries.

More detailed experimental investigations are needed to define the material behavior parameters and thus allow modelling the behavior of OSCC. A larger number of replicate tests are necessary to account for the high deviations in the material behavior and to allow statistical analyses that should be performed to increase the reliability of testing data. The proper design code should be developed for

the materials. The material's performance related to the dynamic loading and time dependent structural behavior, thermal and sound insulation characteristics and durability should also be studied.

Comparisons of other biodegradable materials with conventional materials should be performed. The methodology should be applied to compare the composite with load bearing and non load bearing elements used in the construction market. Optimization of the OSCC composite design will be an interdisciplinary process where structural and environmental efficiency has to be balanced to approach a better composite in both areas. Sensitivity analyses should be performed for various assumptions made in the LCA model, such as impact assessment method, impact categories used. Uncertainty analyses should be performed to investigate the effect of data uncertainties on the model.

Improvements in the cement matrix composition can easily enhance the durability characteristics of the material. The aging characteristics of the OSCC are not investigated in this paper but it is definitely necessary to examine the variation of mechanical properties with age in future studies.

ACKNOWLEDGEMENTS

The authors wish to thank David Ward, Norton Smith and Martin Lee from Ashland Prototypes. We also would like to acknowledge the support provided by Dr. S.H. Aung and graduate students of the former Tulane University Civil and Environmental Engineering Department.

Experimental Study of Geopolymer Concrete Resistance to Sulphuric Acid Attack

Robert Munn [1]
Xiujiang Song [2]
Marton Marosszeky [3]

T 18

ABSTRACT

Geopolymer concrete is well known for its high chemical resistance. Class F fly ash was firstly activated in a highly alkaline sodium silicate environment to obtain Geopolymer, which was further mixed with silica sand and aggregates to make Geopolymer concrete. The resultant Geopolymer concrete developed a compressive strength of 70MPa at age of 28 days, after being initially cured at 70ºC for 12 hours. The Geopolymer concrete samples at age of 28 days were exposed in either a 10% sulphuric acid for 8 weeks or a 1% sulphuric acid for up to 18 months. The visual appearance, mass loss, residual compressive strength and acid neutralisation depth were measured regularly. The mass loss was about 5% while the compressive strength reduction was about 30%. It was also found that the sulphuric acid attack on Geopolymer concrete samples in a 10% acid for 8 weeks resulted in an equivalent degree of loss (in terms of compressive strength reduction and acid neutralisation depth) as the Geopolymer concrete samples exposed to a 1% acid for about 14 months. Finally the SEM-EDS analysis indicated that acid affected Geopolymer concrete mainly consisted of silica gel, differing from the aluminosilicate structure present in the original Geopolymer before acid exposure test. Moreover, the silica gel in the acid affected Geopolymer concrete was still able to fulfil a cementitious function, which agrees with the observation that the Geopolymer concrete samples remained structurally intact after sulphuric acid exposure.

1 INTRODUCTION

An accelerated test is normally used in a laboratory for acid resistance test of concrete. The Los Angles County [Redner et al 1998] examined the sulphuric acid resistance of concrete by exposing concrete samples to a 10% sulphuric acid for 8 weeks. When tested by a similar method, fly ash based Geopolymer concretes have been noted for its high acid resistance [Song et al 2005]. The low mass loss of about 5% agrees with the acid exposure testing undertaken by Bakharev (2005). Both tests indicated the high resistance to degradation of Geopolymer concretes in acidic environments and suggested it be a promising binder against acid attack in sewer pipes as corroded sewer pipes have been reported to have the sulphuric acid concentration of about 1% [Thistlethwayte et al 1972]. In order to reduce assessment time, it is important to compare the acid resistance of Geopolymer concretes in a 1% sulphuric acid for a relative long term with the results in an accelerated test (i.e. in a 10% sulphuric acid) for a short term. The comparison is made by examining four properties; visual inspection, mass loss, compressive strength reduction and acid neutralisation depth after acid exposure of Geopolymer concrete samples.

2 MATERIALS AND METHODS

2.1 Materials and Geopolymer Concretes

The Geopolymer binder used in this investigation was synthesised from two Class F fly ashes and a mixed alkaline activator of sodium hydroxide and sodium silicate. The median particle size was 20.4 micrometers for the fly ash No.1 and 3.14 micrometers for the fly ash No.2. The sodium hydroxide solution had a concentration of 14M (moles per litre). The sodium silicate solution was composed of 30.6% of SiO_2, 9.5% of Na_2O and 59.9% of H_2O by mass. Table 1 shows the mix design of the Geopolymer concrete used in this experiment. All raw materials were locally sourced and met the requirement of respective Australian standards.

Table 1. Mix proportions of the Geopolymer concrete.

Material types	*Fly ash No.1*	*Fly ash No.2*	*Aqueous NaOH*	*Aqueous Na_2SiO_3*	*Silica sand*	*10mm Basalt*
Mass ratio (%)	13.5	4.9	3.4	4.1	26.2	47.9

Geopolymer concrete samples were cast in 50mm steel cubic moulds and wrapped with plastic sheets. The samples were initially cured at 70˚C for 12 hours in an oven followed by air curing in the laboratory at approximate 23˚C. The resultant Geopolymer concrete had its 28-day compressive strength of 70MPa. Samples of a Portland cement based concrete with the similar strength grade served as the reference concrete.

2.2 Acid Exposure Tests

A modified ASTM C267 test method was used for the sulphuric acid exposure tests.

Sulphuric acid solution, 10% or 1% by mass, was directly diluted from 98% concentrated sulphuric acid with tap water. The ratio of the sulphuric acid volume to specimen exposure area was fixed at 8 ml/cm^2 [Chang et al 2005]. The acid concentration was monitored via titration and adjusted weekly.

Masses and compressive strengths of concrete cubes were monitored regularly over the acid exposure period. At age of 28 days, twelve Geopolymer concrete cubes were immersed in a 10% sulphuric acid solution. Three cubes were weighed for mass change and the rest were crushed to test for residual

compressive strength after being immersed in sulphuric acid for 1, 4 and 8 weeks. Meanwhile, eighteen cubes were immersed in 1% sulphuric acid solution, three of them for monitoring mass change and the rest for crushing to determine compressive strength after acid exposure of 2, 6, 9, 12 and 18 months.

The acid neutralisation depth was determined using the following method. At age of 21 days, twelve concrete cubes were coated with an acid resistant epoxy and only one surface of each sample was left uncoated for exposure to acid. The samples were immersed in a 10% or a 1% sulphuric acid when the concrete was 28 days old. At the end of each period of acid exposure (in the 10% acid after 1, 4, 8 and 12 weeks and in the 1% acid after 2 and 14 months) two concrete cubes were removed and rinsed slightly with tap water.

The epoxy coat was ground off and the exposed concrete surfaces were then sprayed with the Universal pH Indicator to detect the degree of alkalinity by colouration. Three distinct layers, in the colour of pink, yellow and light blue, were normally observed on the sample sections with the pH value of approximate 3, 7 and 11 respectively. The depth of the pink and yellow layers was measured from the acid exposed surface. The average of six readings taken from two samples was recorded as the "acid neutralisation depth" after each period.

2.3 Microscopic Examination and Analysis by SEM-EDS

Acid affected Geopolymer samples were prepared and a Hitachi 4500II Scanning Electronic Microscopy (SEM) coupled with an Oxford Energy-dispersive Spectrometer (EDS) was used to examine microscopic images and to undertake the semi-quantitative analysis of the chemical composition of the resultant Geopolymer.

3 RESULTS

3.1 Visual Inspection

In distinct contrast to the damage of the control concrte observed in Figure 1, samples of Geopolymer concretes remained intact after acid exposure, though some fine cracks has developed. This comparison demonstrated that the Geopolymer matrix is far superior to Portland cement paste in resisting sulphuric acid attack.

Figure 1. Visual comparison of concrete samples after acid exposure (left) Control concrete in a 10% sulphuric acid for 4 weeks, (middle) Geopolymer concrete in a 10% sulphuric acid for 8 weeks, (right) Geopolymer concrete in a 1% sulphuric acid for 18 months.

3.2 Mass Change

Further to the visual inspection, the mass change (average of three concrete cubes) was compared with that of the control concrete in Figure 2. The negative values indicate mass loss. The mass change in Figure 2 is shown as proportion of the dry mass, which is intended to eliminate the influence of adsorbed water in the open pores in the acid affected layer.

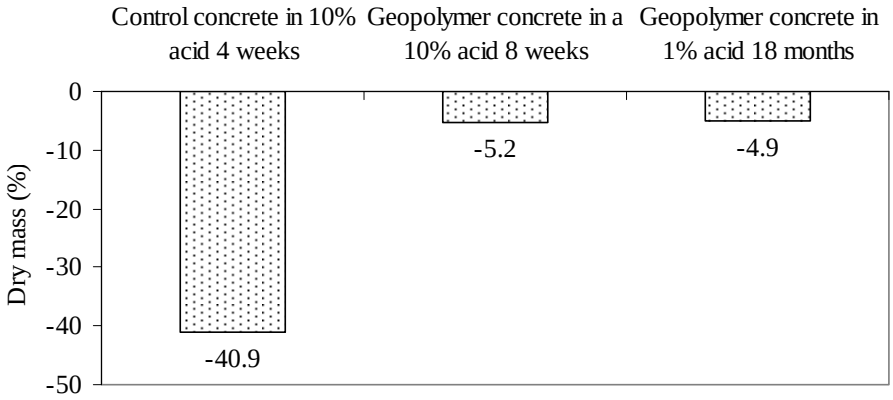

Figure 2. Dry mass comparison of concrete samples after sulphuric acid exposure for different times (negative values indicate mass loss).

In addition to the dry mass change as shown in Figure 2, the change of saturated surface dry (SSD) mass was also measured. It is intended to observe the relationship between the SSD mass loss and the exposed time. The SSD mass loss was the average of three concrete cubes tested in accordance to ASTM C267.

As seen in Figure 3, Geopolymer concretes lost mass at higher rates at the beginning of the acid exposure test, whilst the mass loss became almost constant after a longer period of acid exposure (i.e. in the 1% sulphuric acid after 224 days).

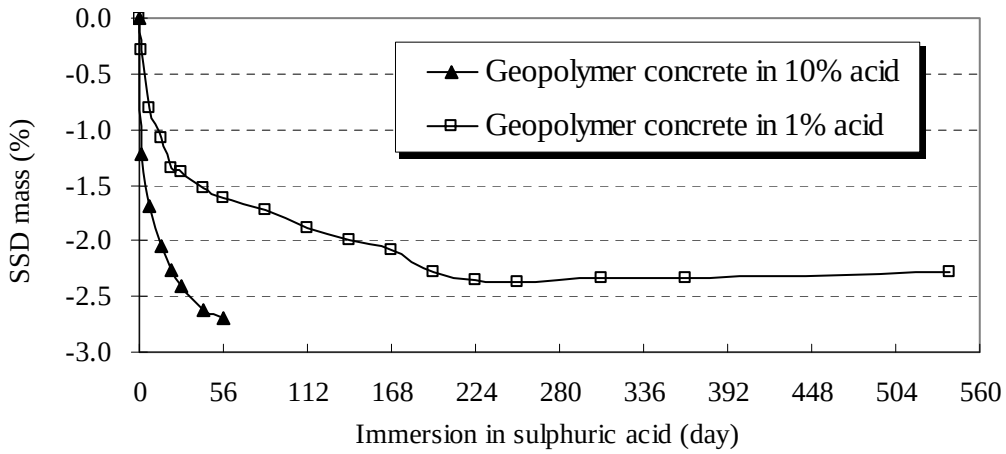

Figure 3. SSD mass comparison of Geopolymer concretes in a 10% sulphuric acid for 8 weeks vs in a 1% sulphuric acid for 18 months (negative values indicate mass loss).

Unlike the dry mass, the SSD mass contains the absorbed free water in the open pores. As a result, the total SSD mass loss in Figure 3 is smaller than the dry mass loss in Figure 2. However the advantage of using SSD mass change is to monitor the mass change with exposure time without risking any undesired side effects on the samples during the immersing-drying process.

3.3 Compressive Strength Reduction

Following immersion in sulphuric acid, the Geopolymer concrete cubes were tested to detect the change in structural characteristics as indicated by changes in the compressive strength. The residual strengths, expressed as a percentage to the initial strength (before acid exposure) and after exposure in 1% or 10% sulphuric acid are compared in Figure 4. It was observed that Geopolymer concretes recorded strength reductions of about 33% after 8 weeks exposure in a 10% acid. It took about 14 months to achieve the same percentage of strength reduction in a 1% sulphuric acid.

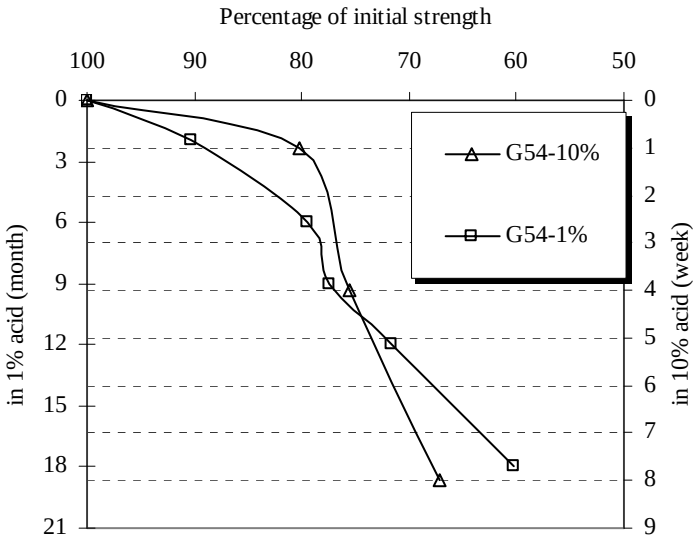

Figure 4. Residual compressive strength comparison of Geopolymer concretes in a 10% sulphuric acid for 8 weeks vs in a 1% sulphuric acid for 18 months.

3.4 Acid Neutralisation Depth

The hardened Geopolymer concretes were found to be alkaline with pH values of about 11. However, this alkaline environment was gradually neutralised when the material came into contact with acid solutions. The Universal pH indicator was employed to identify the changes in alkalinity in Geopolymer concrete matrices after exposure to acid.

As shown in Figure 5, after exposure in sulphuric acid, the alkalinity of the outer concrete layer (bottom
part) was neutralised as demonstrated by the pink colouration. The concrete in this layer was considered to be “severely affected” because its pH value dropped to 3 (the lowest range of the Universal indicator) or lower. By contrast, concrete at the far inner layer (top part) had a pH value of about 11, close to its original alkalinity. The concrete in this layer is thus called “unaffected”. The transition layer was a very thin yellowish layer with a pH value in the range of 6 ~ 7. The thickness of the “severely affected” and “transition” layers are described as the “neutralisation depth” because the pH values in these two layers have been reduced to a value less than 7 after acid exposure.

It was noticed that the neutralisation depth in Figure 5 was about 10 mm after the Geopolymer samples were exposed in a 10% sulphuric acid for 8 weeks. A similar depth of about 11 mm was measured after exposure in a 1% sulphuric acid for 14 months.

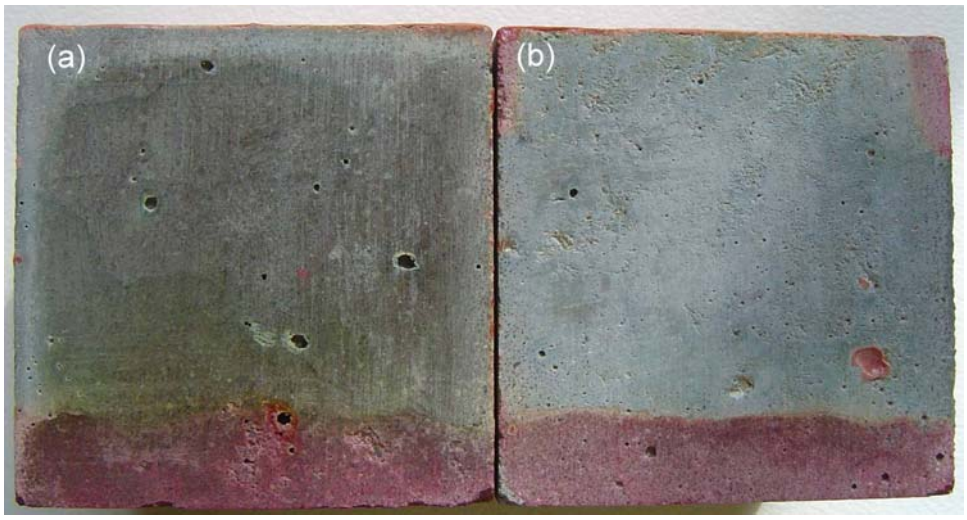

Figure 5. Acid neutralisation depth comparison of Geopolymer concretes (a) in a 1% sulphuric acid for 14 months vs (b) in a 10% sulphuric acid for 8 weeks.

4 DISCUSSION

As seen in Figure 1, Geopolymer concretes have high sulphuric acid resistance. The mass losses reported in Figures 2 and 3 agree well with observations by visual inspection. The reason for the significant mass loss observed in the control concrete is simply due to the dissolution of the paste by the acid. The mass decrease of Geopolymer concrete is considered to be mainly due to the dissolution of minor components from Geopolymer concrete. In general, it was found that the mass loss of the Geopolymer concrete after sulphuric acid attack was quite small. The dry mass loss was about 5% (Figure 2) while the SSD mass loss was about 3% (Figure 3).

This lower mass loss in current research on Geopolymer concretes agrees with the published data in the technical literature, such as about 1.13% [Wastiels et al 1993], about 3% [Silverstrim et al 1997], and about 2% [Bakharev 2005] over similar periods of exposure.

Despite the small mass losses of the Geopolymer concretes (about 5%), the compressive strength reductions were much more significant. This appears to suggest that the microstructure of Geopolymer in the outer layer of the concrete samples must have been damaged to some extent due to sulphuric acid attack, although the visual appearance of the Geopolymer cubes in Figure 1 still remained unaltered.

As can be seen in Figure 4 the Geopolymer concretes show similar trends in strength reduction as compared by the respective lines for 1% and 10% acid. It was observed that Geopolymer concrete in a 10% acid for 8 weeks had a similar strength reduction to those samples of the same concrete soaked in a 1% acid for about 14 months. Moreover, the neutralisation depth of Geopolymer concrete in a 10% sulphuric acid for 8 weeks is similar to that in a 1% acid for 14 months as shown in Figure 5. The similar behaviours of the strength reduction shown in Figure 4 and the acid neutralisation depth shown in Figure 5 indicate that exposing concrete to a 10% sulphuric acid for 8 weeks is indeed a valid accelerated test method and may replace the traditional acid exposure method, based on exposure in 1% acid for 14 months to determine the acid resistance of concrete.

The microstructural images and elements of Geopolymer gel, before and after acid exposure, are compared in Figures 6 and 7. As seen in Figure 6, the original Geopolymer looks sound and has three primary elements typically silicon, aluminium and sodium. These features were changed substantially as a result of acid attack. The images in Figure 7 show that after acid attack the material looks soft and

has very low sodium content but contained more silicon and sulphur compounds. The appearance of sulphur indicates the ingress of sulphuric acid into Geopolymer matrix. The important finding from Figure 7 is the silica gel that has the appearance of a "sponge-like substance". However it still maintains a cementitious function binding the aggregate and undissolved fly ash particles. This explains the visual observation that the outer layer of Geopolymer concretes in Figure 1 still had a stable shape after being neutralised by sulphuric acid.

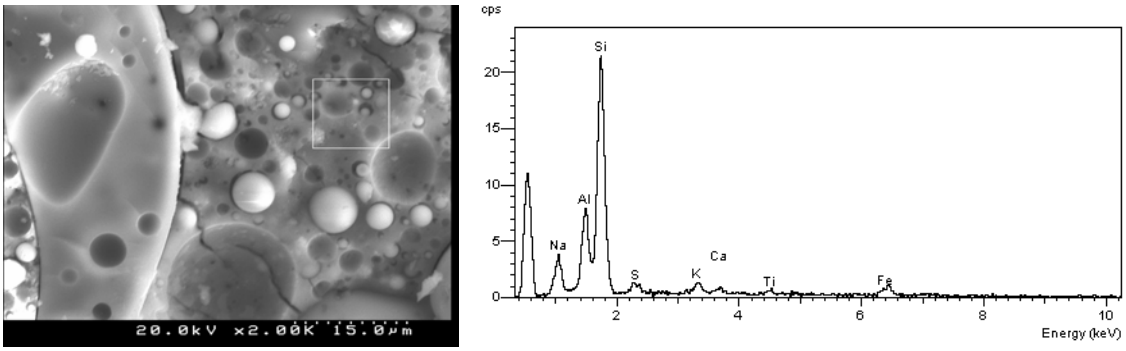

Figure 6. SEM-EDS of Geopolymer gel before acid exposure.

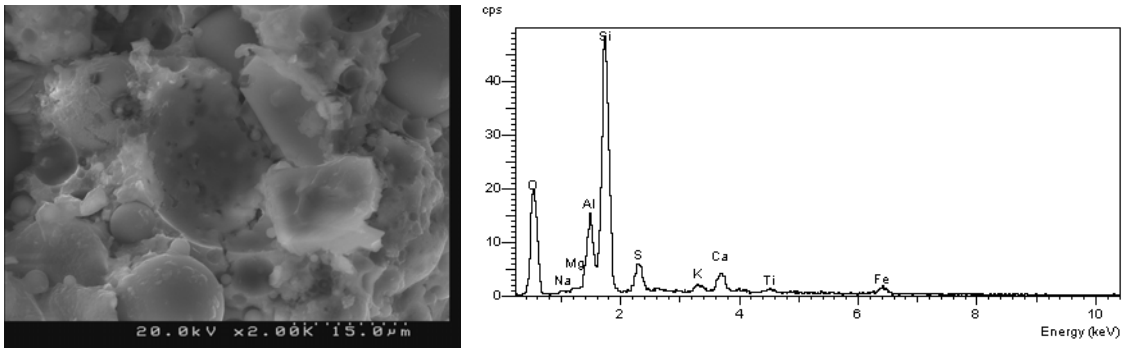

Figure 7. SEM-EDS of acid affected Geopolymer gel.

4 CONCLUSIONS

This test confirmed that Geopolymer concrete has high sulphuric acid resistance following immersion in a 10% acid for 8 weeks or in a 1% acid for 18 months. Sulphuric acid has penetrated into Geopolymer matrix about 10mm. However, Geopolymer test samples remained structurally intact. The mass loss was about 5% but the compressive strength was typically reduced about 30%.

Exposing concrete to a 10% sulphuric acid is proposed as a valid accelerated test method to examine the acid resistance of concrete. It was found that immersion in a 10% acid for 8 weeks achieved similar results, in terms of compressive strength reduction and acid penetration depth, to immersion in a 1% sulphuric acid solution for about 14 months.

The SEM-EDS analyses showed that due to acid attack, the aluminosilicate Geopolymer has converted into a soft sponge-like substance with much less sodium but more silicon and sulphur compounds present. This residual silica gel is still able to maintain the function of a cementitious binder in the acid affected Geopolymer concrete.

ABSTRACT

The incorporation of tire rubber granules into concrete has been studied for several researchers as an alternative disposal of this material. In this study, a control mix (without rubber addition) was set against mixes with rubber aggregates, obtained from shredded non-reusable tires, in five treated and untreated contents (2%, 4%, 6% 8% and 10% rubber contents). An acrylic polymeric admixture was used in order to improve the bonding between rubber and cement paste. The samples were investigated about the mechanical and physical properties, including permeability. It was verified that both rubber content and surface treatment did not influence significantly the properties. Such findings have demonstrated that the contents of non-reusable tire rubber can have viable applications, because there was no damage to the physical and the mechanical properties of the concrete.

1 INTRODUCTION

The environmental and social gains are important features for using non-usable tire rubber in concrete mixes. Some of them are the reduction of natural resources consuming and the diminution in ecological and public health problems, due to increasing amounts in waste tires at the dumps.

The incorporation of tire rubber into cement-based composite has been studied for several researchers all around the world in order to get different applications. Benefits such as increase of the tenacity and the capacity of deformation have been observed. However, the studies have shown that the main problem in the combination of these materials is the bond weakness between the cement matrix and tire rubber particles, which is revealed through the reduction of the material strength [Topçu [1995]; Toutanji [1996]; Khatib & Bayomy [1999]; Hernández-Olivares *et al.* [2007]].

Rubber tire is a non-hydrophilic material and, consequently, when incorporated to fresh concrete it creates a barrier against the cement paste which obstructs the hydration reaction in the interfacial transition zone (Segre, 1999). Tests were conducted in order to modify the rubber surface and to improve the cement paste / rubber interface. Some successful tests were observed; meantime, these surface treatments imply higher material and processing cost [Rostami *et al*. [1993]; Li *et al*. [1998]; Segre & Joekes [2000]; Marques et al. [2005]].

A certain amount of caution is advisable at this point since making comparisons between the studies is a hard task because several authors carried out diverse types, dimensions and methods to incorporate tire rubber into cement based materials. At the same time, there are some points in which there is some agreement:

- tire rubber fiber (from retreading) or granules (from non-reusable tire grinding);
- maximum 4.8 mm - size tire rubber particles use;
- tire rubber use in replacement of aggregate volume fractions;
- steady the cement consumption value and the water/cement ratio;
- workability control through plasticizer admixtures.

The present work is part of a wide-ranging project, developed in the Technological Center of Civil Engineering of Furnas Centrais Elétricas S/A, in the context of the Civil Engineering Post-Graduation Program at the Federal University of Rio Grande do Sul (UFRGS), being financially supported by the Electrical Power National Agency (ANEEL) and by the National Council of Scientific and Technological Development (CNPq –Brazil).

2 EXPERIMENTAL PROCEDURE

Pilot tests were performed in order to assess the most suitable way of incorporating the tire rubber into the concrete in a way that could minimize the decrease in compressive strength and maximize the reduction in elasticity modulus. The results have indicated that the use of tire rubber particles in place of sand volume fractions contributes more to attenuate the reduction of mechanical properties than a total aggregate replacement [Albuquerque et al. 2004]. This behavior was also observed by Akasaki et al. [2001].

Subsequent experiments on tire rubber particles replacing 5% to 25% of the sand volume have indicated a higher increasing resistance about 0% and 10%. It was also observed that tire rubber granules promote better workability than tire rubber fibers and that among surface treatments, the acrylic polymer was the most efficient for attenuating the diminution of strength [Albuquerque et al. 2005].

In this work, one of the the goals was to identify the ideal tire rubber content (until 10%) that replaces the sand volume. Therefore, the following independent variables were selected:

- tire rubber content in place of sand volume: 0%, 2%, 4%, 6%, 8% e 10%;
- maximum 1.5mm - size tire rubber granules;
- treated and untreated with acrylic polymer tire rubber granules;
- age of test.

The material description, examined properties and mixtures are presented in the Tables 1 and 2, respectively. Variance analyses (ANOVA) were performed in order to calculate significant differences on the obtained results. According to ANOVA, the averages will be statistically different if *p-value* < 0.05, and the more this difference will be the more the *F value* with reference to *critical F* will be.

Table 1. Materials.

Materials	*Investigated Properties*
Portland cement - Ordinary Portland Cement	Compressive strength
Coarse aggregate – 19 mm and 38 mm MSA - Crushed granite	Modulus of deformation
Fine aggregate- Natural sand	Splitting tensile strength
Crumbed tire rubber - Granules : ∅ 1.5 mm	Axial tensile strength
Chemical admixtures - Super plasticizer and Air entrainer admixtures	Specific gravity
Admixture based acrylic polymer for surface treatment of tire rubber	Permeability

3 EXPERIMENTAL RESULTS AND DISCUSSION

Mechanical Properties

All mix proportions behaved as usual cement-based materials. It was observed the influence of the age on the increase of mechanical properties on all specimen. This understanding seems to corroborate results obtained by analysis of variance (ANOVA) whose *p-value* < 0.05 and great *F value* as seen on Figs 1 to 4.

Mixes with treated and untread tire rubber have shown similar performance. There were few differences, but ANOVA test demonstrated that *surface treatment* have no or little effect on the

studied properties. This indicates *p-value* > 0.05 (Figs 1 and 2) or *p-value* < 0.05 but with low *F values* (Figs 3 and 4).

According to the tests, when there is an increase of *rubber content* the mechanical properties of concrete tends to reduce. However, this fact is not significant enough as it was confirmed by ANOVA results: p-value < 0.05 but low F values (Figs 1 to 4). In this investigation was possible to obtain until 10% of reduction on elasticity modulus having little effect on tensile and compressive strength.

Entrained air ratings strongly affects concrete mechanical properties. Some researchers have detected that bigger tire rubber content makes entrained air content gets higher levels. (Albuquerque et al. 2004b, Macedo 2005). In this work, all mixes were inoculated with entrainer air admixture in order to obtain 3% to 4% of air entrained content. This procedure was taken to minimize the action of this variable on the results. Table 2 shows that the entrainer air admixture amount is inversely proportional to the tire rubber content.

Other authors have shown that compressive strength of rubberized concretes usually drops in a drastic way when rubber content is raised (Eldin e Senouci 1993, Topçu 1997, Turantzine at al. 2003). Keeping strength levels is important because it can avoid the increase in cement consumption and, consequently, put final product costs up. On the other hand, elasticity modulus reduction can be suitable for structures in which toughness and strainability are required. In this present work was possible to combine elasticity modulus reduction and resistance levels maintenance.

Physical Properties

Age and surface treatment have had no significant influence on specific gravity or permeability of the studied concretes. ANOVA test reports p-value > 0.05 or small F value (Figs 5 and 6).

Rubber content have had significant influence on specific gravity or permeability. ANOVA test reports p-value < 0.05 (Figs 5 and 6).

Some specific gravity reduction was expected as a result of the increase of the rubber tire content. This behavior is common because of two factors: 1) tire rubber specific gravity is smaller than sand specific gravity and 2) when rubber tire content increases, it makes the entrained air content get higher levels. In this investigation, as the entrained air content in the concrete mixes was controlled, any variance observed can be attributed exclusively to the difference found between rubber tire and sand relative density. In this case, only the 10% rubber tire content mixes have demonstrated specific gravity significantly lower than the one in the control mix.

All mixes presented pressurized water permeability at level of 10-13 m/s to 10-12 m/s, that can be considered good numbers and were also observed by other researchers for conventional concretes (FURNAS, 1997). According to Choinska et al. (2007), the fluid flow occurs in a porous network, that includes, not necessarily connected, the initial porosity of the material and the micro and macro cracking induced by mechanical loads, environment and time effects.

In this investigation, the mixes with tire rubber exhibited smaller pressurized water permeability than the control (Figure 6). This behavior indicates that rubberized concretes may have greater resistance to the penetration of aggressive agents and hence greater durability than conventional concrete. However, tests of durability over time are needed to confirm their performance.

4 CONCLUSIONS

In this paper, rubberized concrete mixes as well as concrete control were examined, under different contents and treated and untreated surface treatment. After analising all results, the following conclusions are feasible :

- *rubber content and surface treatment* have had no significant influence on mechanical and physical properties of the concrete;
- the use of tire rubber granules in substitution of until 10% of sand volume was viable and do not imply any harm to physical and mechanical properties;
- mixes with treated and untreated tire rubber have similar performance;
- was not possible to evaluate the effect of the surface treatement with acrylic polymer;
- the use of tire rubber particles tends to reduce the pressurized water permeability.

T 18

ABSTRACT

The possibilities of using waste materials from different manufacturing activities in the preparation of innovative mortar and concrete is the aim of this paper. Two kinds of waste were identified: marble sludge, from marble processing, and cement kiln dust. The use of these wastes was proposed in different percentages both as an addition to and as substitution of cement, for the preparation of Self Levelling Mortars. As comparison, two mixtures containing natural aggregates were also prepared, one using limestone powder as a mineral addition and the other with no addition. A total of sixteen different mixtures were prepared containing 10, 20 and 30% of wastes compared to the total quantity of aggregates and 10, 15 and 20% compared to the amount of cement. The two residues were characterised from a chemical, physical and morphological point of view. The prepared mixtures were then studied in terms of their properties both in fresh and in hardened state. In particular, compressive strength, water absorption and capillary absorption tests were conducted on the mortars cured for 28 -day water curing and after 500-day immersion in a sodium and magnesium sulphate solution.

1 INTRODUCTION

Nowadays, the ecological trend aims at limiting the use of natural resources in the field of building materials. Thus, there is an increased interest in the use of alternative materials , mainly wastes coming from industrial activities, which presents significant advantages in economic, energetic and environmental points of view.

Only in Italy, the concrete industry uses about 100 million tons of aggregates with an extremely high environmental impact [CRESME Research Centre, Italy, 2003].

Moreover, the Italian legislation decree 22/97 was passed with the aim of incentivating the recycling of industrial solid waste as alternative to landfill disposal. Subsequently, the Italian ministerial decree DM 5/2/98 supplied the technical indications needed to implement the recycling procedures and indicated the preliminary treatments to be carried out for different types of wastes. In particular, one of the main form of recycling suggested is their reuse in road foundations.

Two important aspects need consideration : although the possibilities of using waste in the preparation of road foundations is great, it is unimaginable that all types of waste could be used in such applications. Some particular categories of wastes, with specific physico-chemical and mechanical characteristics, would be under utilized were they to be used in such applications.

For instance, residues such as marble sludge from stony material manufacturing and cement kiln dust are characterised by an average diameter in the order of a few microns at the end of the industrial processes from which they come from [Colangelo, F *et al.* 2004.1]. This important physical characteristic makes them potential candidates for use in the production of self-levelling mortars (SLMs) and self-compacting concretes (SCCs). These building materials can be compacted under their self-weight, with no external action, providing considerable time and energy saving [Collepardi, M., 2002, Ouchi, M. & Okamura, H., 1999, Colangelo, F. *et al.* 2004.2].

These products require much higher quantities of fine components than traditional concretes, making them potentially capable of incorporating large quantities of fine wastes [Colangelo, F. *et al.* 2003]. Very often the production of SCC envisages an expensive material such as powdered limestone as a filler. Therefore, recycling fine wastes in SLMs and SCCs has both environmental and economical advantages, provides incentives for their development currently hampered by a higher cost in respect to ordinary concretes.

The feasibility of the waste material recycling process is particularly influenced by the fulfilment of the economic, technical and normative aspects for each field of use. In fact, once the economic convenience has been assessed, the experimentation must verify that the physico-chemical characteristics attained after treatment are suitable to the specific proposal for which they are intended.

This work proposes the use of industrial wastes, such as marble sludge from stony material manufacturing activities and cement kiln dust, in an innovative Self Levelling Mortar preparation. A limestone filler has also been used to provide a reference benchmark.

The aim of the work is to investigate the influence of the above wastes on the rheology of fresh mortars and on the physical-mechanical properties of hardened self-levelling mortar before and after immersion in a sodium and magnesium sulphate solution.

2 MATERIALS AND METHODS

The cement employed was CEM II/A-LL 42,5 R, according to European Standards EN 197/1, made by the Cementi della Lucania factory (Potenza, Italy), and its chemichal composition is shown in table 1.
The aggregate used was a 4 mm maximum size siliceous sand. Powder limestone employed had about a 99% $CaCO_3$ content .

The superplasticizer (SP) used was an acrylic one with 40% solid content and a specific gravity of 1.2 kg/dm^3. It was used in all SLM mixtures and its amount was proportioned to ensure a constant workability. The water content of the superplasticizer was considered during the mix-design phase.

To enhance stability, an inorganic Viscosity Modifying Agent (VMA) was also used in all SLM mixtures

Table 1. Chemical composition of cement.

SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	SO_3	L.O.I.
20.55%	3.20%	4.90%	60.95%	1.64%	2.76%	5.73%

The extraction and processing of stony material inevitably results in the production of a huge mass of wastes of different natures and characteristics [Colangelo, F. *et al.* 2003., Miletic, S. *et al.* 2003]. In fact, stone extraction produces a yield in blocks which usually does not exceed 60% of the extracted material, so waste accumulation is a major problem, causing damage to environment and landscape. Their possible recycling would thus offer sensible and multiple advantages, as reported by Colangelo et al. 2004.1.

In this work, the sludges from twenty Southern Italian marble processing factories was characterized and proposed for use as a filler in SLM.

The results of chemical and physical characterization performed on different samples show the presence of $CaCO_3$ in weight percentages ranging between 96% and 98%, as well as more modest percentages of SiO_2 (0.8-1.2%), Al_2O_3 (0.1-0.3%), Fe_2O_3 (0.06-0.09%), MgO (0.6-0.8%), etc. The sludge employed is characterized by a diameter at 90% equal to 10.1 μm.

The main constraints in recycling industrial waste are linked to the qualitative constancy of the following parameters: chemical composition, very small size and absence of heavy metal.

Marble sludge morphological analysis was performed by a scanning electron microscope, (SEM) ands as shown in figure , SEM images reveal an irregular shape of all particle, some of them are also sharp-edged.

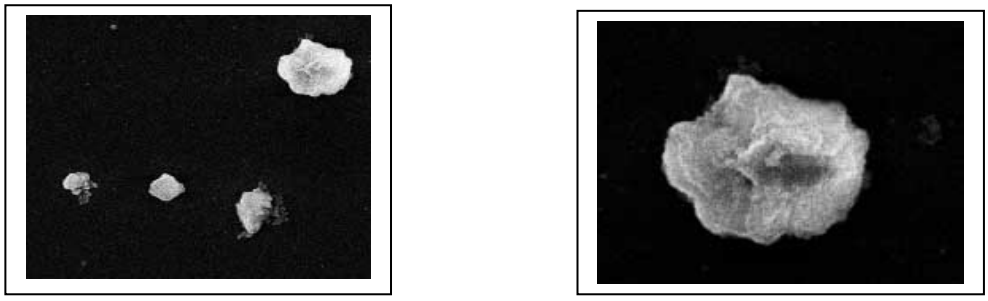

Figure 1. SEM pictures of marble sludge (left), SEM particular of marble sludge (right).

Cement kiln dust (CKD) is a waste generated by the cement industry. It is a powder mainly composed of micron-sized particles collected from electrostatic precipitators during the manufacture of cement clinker. The CKD chemical composition and particle size depend on the raw materials used to produce clinker, fuels and kiln types. The USA Environmental Protection Agency (EPA) estimated that the amount of CKD could range from 0 to 25% of the clinker produced, depending on the above-mentioned factors.

A huge quantity of CKD is produced every year throughout the world; for example, USA alone produces 4 to 12 million tons [Duchesnea, J. & Reardonb, E.J. 1998]. In this work CKD supplied by Cementi della Lucania, Potenza, Italy, was used. The CKD chemical composition is shown in Table 2.

Table 2. Chemical composition of CKD.

SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	SO_3	Na_2O	K_2O	L.O.I.
14.65 %	2.13 %	4.75 %	41.72 %	1.12 %	0.72 %	0.9 %	0.6 %	32.30 %

The fineness of CKD power is quite high with a Blaine specific surface area greater than 5000 cm^2/g . CKD grading curve and density population are shown in Figure 3.

The morphologic analysis was performed by a scanning electron microscope, as shown in figure 2. Both images show that CKD particles seems quite regular and rounded.

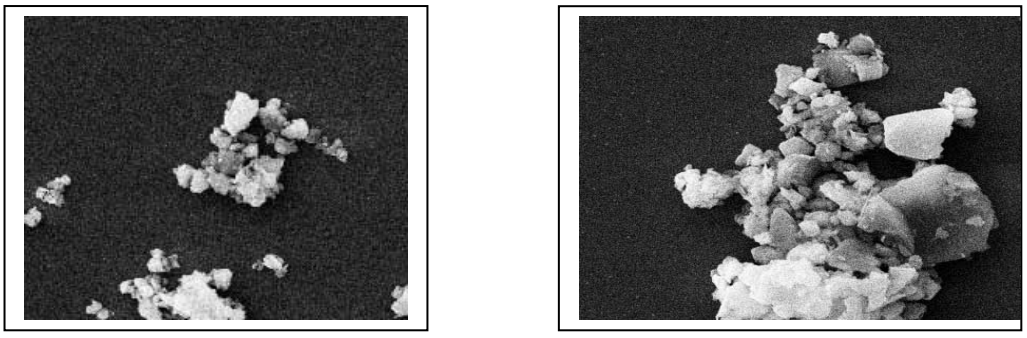

Figure 2. SEM picture of CKD (left) and SEM particular of CKD (right).

Twelve mixtures were prepared employing, alternatively CKD and marble sludge both in addition to cement, in substitution of the natural siliceous aggregate, and in replacement of cement. A reference mixture (B), without industrial waste, was also prepared.

Moreover, mixtures containing marble sludge, in partial substitution of the sand (in addition to cement), were compared with similar powdered limestone based ones.

Table 3 shows mixture proportions for all the mortar specimens. In this table the first part of the mixture code gives information on the waste and the addition contained in the mortar (S for marble sludge, L for limestone, C for cement kiln dust), the second letter (A or S) indicates the usage of the CKD, sludge and limestone (addition to cement or its substitution).

Table 3. Mortar mixture proportion.

	Composition, g

SA30	945	500		405		27.3	0.5

In order to prepare all the mortar mixtures, a 5 dm^3 mixer was used. After mixing, fresh mortar was employed for the determination of slump flow. The slump flow test measures the mean diameter of concrete spread after the removal of the slump cone. A spread of at least 250 mm is required for self-levelling mortar [Bignozzi, M.C. *et al.* 2003]. All the mixtures prepared were characterized by slump values according to this limit and did not show any segregation phenomena. By varying the amount of superplasticizer the same value of 260 mm was reached for all mixtures.

To evaluate the strength development, compressive tests were carried out after 28 days of water curing. The specimens were kept during the first 24 hours in a curing chamber at 20 ±1 °C and R.H. ≥ 98 %; after this period, they were removed from the mold and cured in water, maintained at 20±2 °C, until the test age. The specimens were dried in air for half an hour before testing. Four specimens were tested for each data point. A 150 kN capacity compressive testing machine was used according to Standard EN UNI 196/1.

Water and capillary absorption were also measured, according to the procedure Italian Normal -11/85 Water absorption and capillary absorption of the mortars.

The above two kinds of tests were carried out after 500-day immersion in a sulphate solution and at fixed times during sulphate immersion period, respectively. Furthermore, the compressive stregth was also determine after 500-day immersion in a sulphate solution. Hardened specimens for each mix were immersed in a combined sulfate solution (mixed solution of 10% sodium sulfate and 10% magnesium sulfate). The cylinders were fully immersed in solutions in stainless steel baths. The cylinder was kept apart at a distance of 5 cm. The stainless steel baths were covered in order to minimize the evaporation. The solutions were replaced once a month with fresh ones and the pH was maintained at 7 during 500-day test.

3 RESULTS AND DISCUSSION

Table 3 reports the amounts of superplasticizer (SP) added to the mixtures in order to obtain the same workability without changing the water to cement ratio. It can be seen that in the case of the mixtures containing CKD in partial substitution of cement, CS10 required the same amount of SP as reference mixture B. Furthermore, in the case of CS15 and CS20 mixtures the amounts of SP are slightly higher than that employed in mixture B.

When the same waste was used in addition to cement (in partial substitution of the aggregates) the fresh behaviour of the mixtures was different. The increase in the amount of SP was equal to about 14%, 14% and 43% for the mixtures CA10, CA20 and CA30, respectively. In particular, the CA30 mixture was very cohesive and no addition of viscosity modifying agent was required.

The amount of SP added to the mixtures SS, prepared with marble sludge in partial substitution of cement, was similar to that required for the reference one. While in the case of the SA mixtures, prepared with marble sludge in addition to cement (in partial substitution of aggregates), the increase in the amount of SP was equal to 12%, 13.7% and 17.2% for mixtures SA10, SA20 and SA30, respectively. The SA mixtures required smaller amounts of SP than the CA ones. This is probably due to the smaller mean diameter of CKD particles. These are 3.62 and 4.45 μm for the CKD and marble sludge, respectively.

Particle morphology did not significantly affect workability, probably due to the very small dimensions of waste particles. In fact, it is well known that the workability of mixtures significantly depends on the shape of the larger particles.

Figures 3 and 4 report the compressive strength results after 28-day water and 500-day immersion in sulphate solution of all the kinds of mortars. After 28-day water curing (Figure 3) a significant increase in mechanical strength is observed with respect to the reference mortars in the case of waste being employed in addition to cement (in partial substitution of aggregates).

It is important to point out that, after 500-day immersion in sulphate solution, the increases in compressive strength for the mixtures CS10 and SS10 compared to the reference mixture was equal to 8% and 5%, respectively. After 28 day of curing in water all the CS and SS mixtures showed values of compressive strength lower than that of the B mixture, as reported by other authors for the concrete containing CKD [Shoaiba, M.M. *and al.* 2000, Ravindrarajah, R., 1992].

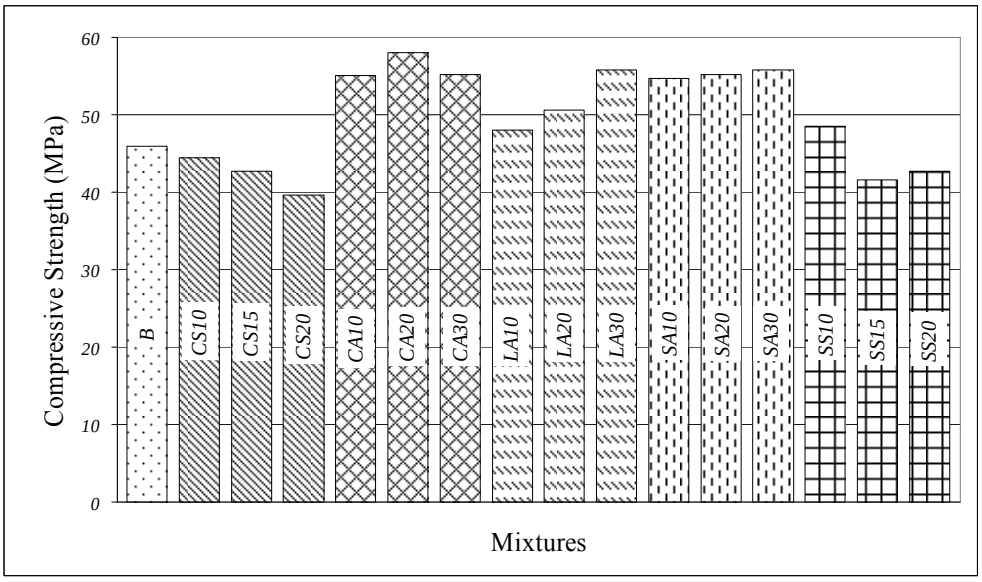

Figure 3. Compressive Strength after 28-day water curing.

In comparison to L mixtures, prepared with limestone filler, the SA mixtures showed higher values of compressive strength for all the amounts of wastes added both after 500-day immersion in sulphate solution (Figure 4) and 28-day water curing (Figure 3).

Figure 5 reports the values of the capillary absorption development with age during sulphate solution immersion. These data are very useful to predict the behaviour of mortars and concrete in the presence of capillary phenomena which can be responsible for decay caused by aggressive solutions.

Lower water capillary absorption coefficient values were observed for the mixtures containing the higher amount of wastes employed in addition to cement and in partial substitution of aggregates (CA20, CA30, SA20, SA30) compared to reference mixture B. Whereas when the wastes were used in partial substitution of cement the same coefficients were similar or slightly higher than those of the mixture B.

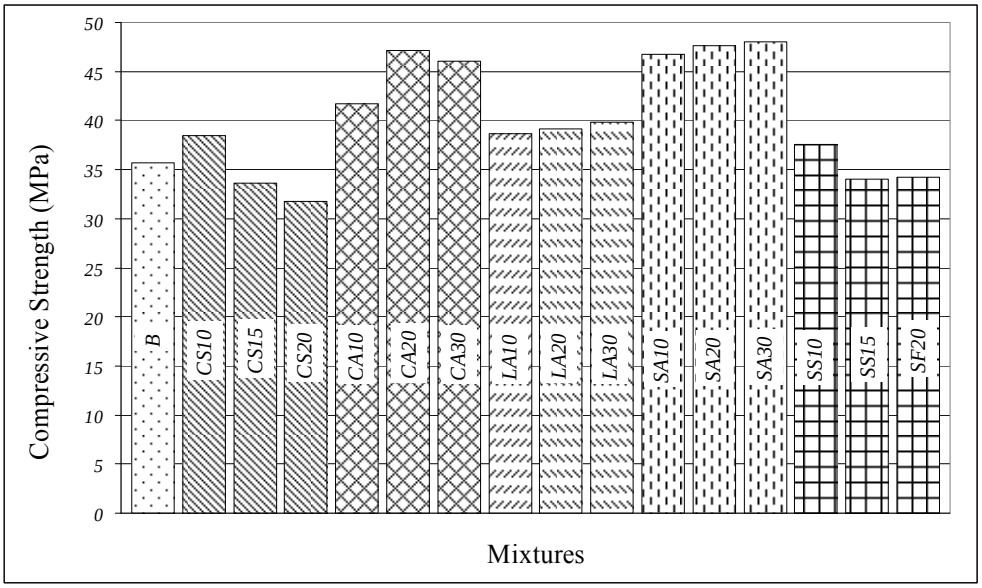

Figure 4. Compressive Strength after 500-day immersion in sulphate solution.

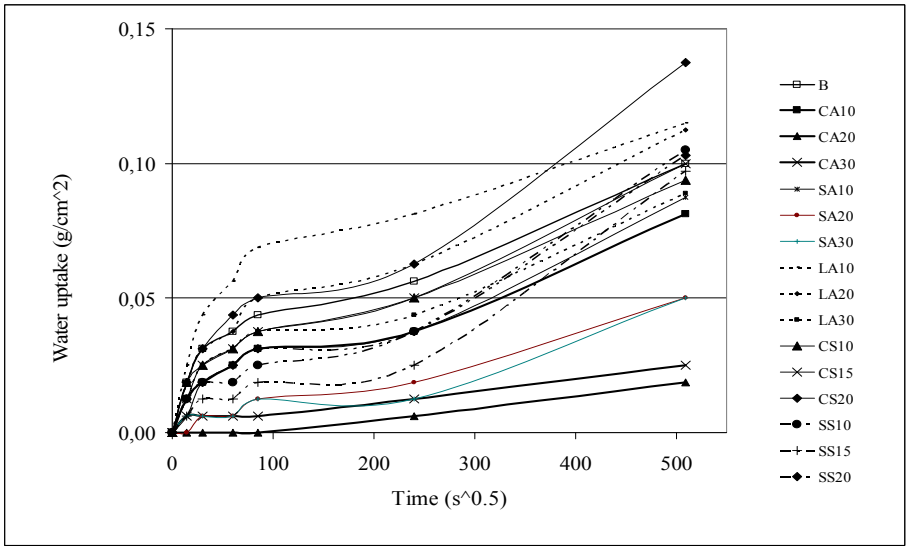

Figure 5 Capillary absorption development during the immersion in sulphate solution.

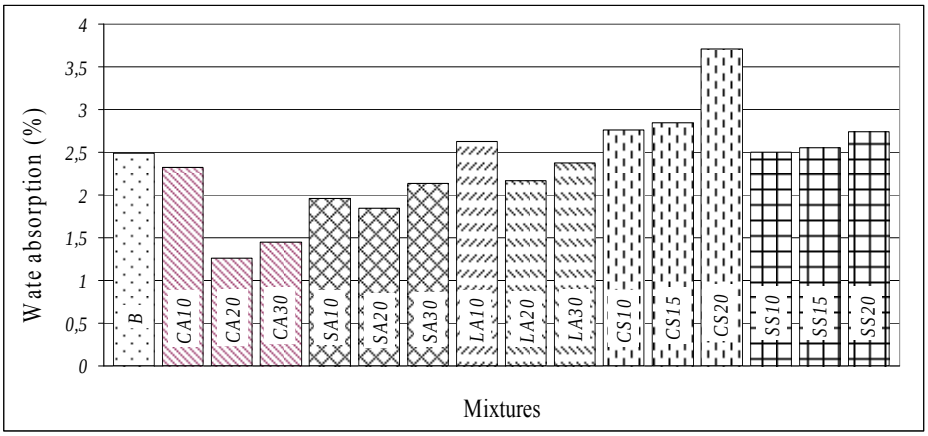

Figure 6. Water absorption after 500-day of immersion in sodium sulphate solution.

The values of water absorption coefficient after immersion in sulphate solution are shown in Figure 6. Also in these cases the presence of wastes in addition to cement improve the properties of hardened mortars in terms of lower permeability when immersed in water. In fact, it is well known that the values of water accessible porosity is an important factor in assessing the durability of mortars and concrete. In particular, slightly and much lower values were observed for SA and CA mixtures respectively. In the case of the CA20 mixture a 50% decrease was observed.

3 CONCLUSIONS

All the experimental data show that it is possible to use both selected wastes in the manufacturing of self-levelling mortars. Furthermore, in many cases, the addition of the wastes improves the physical and mechanical properties. These results are of great importance because this kind of innovative mortar requires large amounts of fine particles.

When the wastes are employed in addition to cement and in partial substitution of aggregates, amounts up to 30% can be used to provide mortars of higher physical and mechanical properties than the reference ones. Furthermore, attention to water demand must be taken into account, especially in the case of addition of CKD.

The use of the wastes in partial substitution of cement is possible for lower amounts than the cases described above. The maximum substitutions are 10% in the case of marble sludge, while the presence of CKD results in a decrease of properties for all quantities used.

Furthermore, experiments conducted on these specimens immersed in sulphate solution show that the presence of CKD and marble sludge in the manufacture of self-compacting concrete make mortars with high chemical resistant to aggressive solutions.

ABSTRACT

In impressed current CP systems, an insoluble anode is used on the surface or within the concrete structure, and in some parts an electrical connection between the anode and rebars are established. The most frequently and widely used anode material is titanium covered with noble metal oxides. Meanwhile much work is carried out to replace the anode material or improve the application technique such as using conductive coatings and paintings. In this regard, carbon fiber meshes have been introduced as an alternative for the last decade.

By studying the Pourbaix diagram of carbon, one could conclude that it is a not a stable material in alkaline solution at its own corrosion potential. Unfortunately, scientific work and publications concerning electrochemical properties of carbon embedded in concrete are scarce. Hence, a series of experiments have been designed and carried out in order to improve knowledge of its behavior as anode.

As a first step, polarization behavior of carbon was investigated and the results are presented in this paper. The polarization curves, from 20 mV up to 5000 mV polarization, indicate that carbon has a passive-active-passive behavior in alkaline solution. It is in passive condition up to 500 mV polarization and then enters to active area up to 2500 mV. From that point, it starts the second passive condition. The effect of addition of 1% and 3% chloride ions has also been investigated. The addition of chloride ions into the solution would increase the corrosion rate of the carbon but it seems that it is due to the characteristic of chloride. In other words, the amount of chloride has a very slight effect on the corrosion.

1 INTRODUCTION

During the last decades, widespread problems of deterioration of civil engineering structures have been experienced in many countries. The major portion of these structures consists of reinforced concrete and the corrosion of reinforcing steel is the principal cause of deterioration. Therefore the registered need for rehabilitation and repair and the associated costs is a matter of great concern for those responsible for assessment and maintenance of affected structures. Due to this matter, several protection and prevention methods and technique have been developed.

Cathodic protection and prevention are one of the effective techniques in this regard. Cathodic protection (CP) of steel reinforcement in concrete structures, as schematically illustrated in Fig.1, is obtained by applying a direct current through the concrete from an anode system which is usually applied on the concrete surface. Anode material is connected with the positive terminal of a low voltage direct voltage source towards reinforcement; in this case rebars are acting as cathode and connected with the negative terminal [Pedeferri 1996]. The anode material is perhaps the most critical component of a CP system, because it serves to distribute the protective current across the structure and provides the locations for anodic reactions to take place in lieu of the reinforcing steel. Therefore, while the system is in service, the anode, instead of the reinforcing steel, will degrade. There are some materials which are used as anode. Although the most frequently used anode material is titanium mesh covered by activated metal oxides, as a more recent anode material the carbon fiber meshes have been used for some years in some countries.

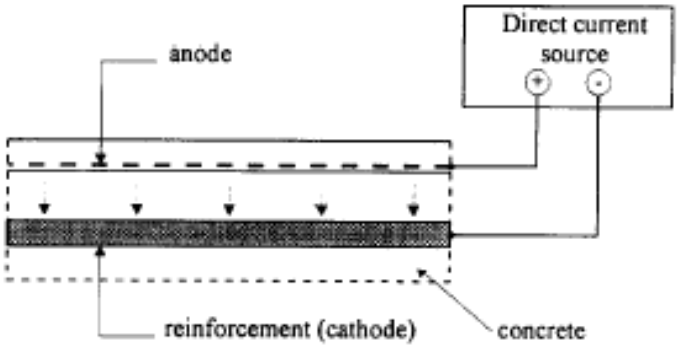

Figure 1. Schematic illustration of CP system [Pedeferri 1996].

By studying the Pourbaix diagram of carbon (graphite), which is illustrated in Fig.2, one could conclude that it is a not a stable material in alkaline solution at its own corrosion potential [Pourbaix 1974]. Unfortunately the published papers about this anode material are scarce [Chini 2007]. Hence, a series of experiments have been designed and applied in order to improve knowledge of its behavior as anode. In this paper the first results are presented. Potentiostatic behavior of carbon in simulated concrete pore solution and also in present of different amount of chloride would be illustrated.

2 TEST DESIGN

The first property of carbon interested was corrosion current density in different polarization potentials (E-I plot). In order to reach that, the corrosion current density of carbon was measured in different anodic polarization potential from open circuit corrosion potential as 20, 40, 60, 100, 150, 300, 500, 750, 1000, 1500, 2000, 2500, 3500, 5000 mV. These measurements were operated by Electrochemical Interface 1287 from Solartron Company. By using Solartron 1287 the potentials were continuously applied and the data was stored. A titanium mesh was used as counter electrode and the reference electrode was SCE (Hg/Hg_2Cl_2 in saturated KCl).

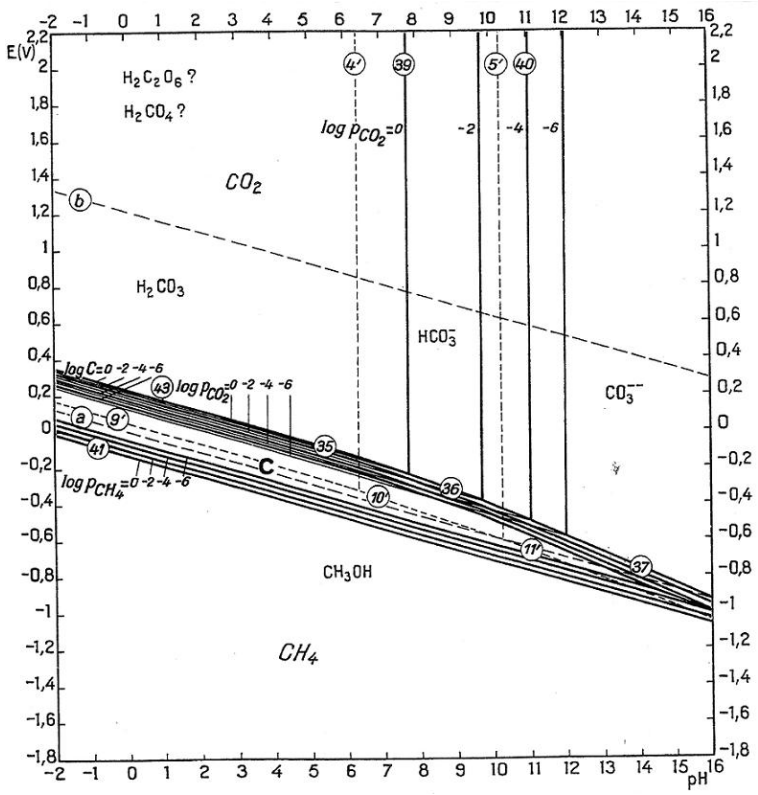

Figure 2. Pourbaix diagram of Carbon.

Since existence of chloride ion plays an important role in corrosion process, effect of different amount of chloride were also investigated. Therefore measurements were also made in chloride contents of 0, 1 and 3 percent of solution volume.

3 SPECIMENS AND SOLUTION PREPARATION

In CP system the carbon is used as mesh. The applied anode material is a continuous, highly flexible mesh woven of carbon fibers. This makes the anode easy to install. The threads may consist of thousands of filaments with a thickness of 7 µm of each filament. In a common industrial product, a thread consists of 6000 or 24000 filaments which make a very narrow thread [Vennesland et al. 2005]. Since it was impossible to find a carbon rod from industry, it is very difficult to measure the corrosion current density among longitude of fibers, due to the fact that it is impossible to measure the exact surface area of exposed fibers. Although some techniques have been introduced [Mork et al. 2006], there are still uncertainties on measurement of surface area. Hence, in order to have more accurate active surface area after various experiments, the cross section corrosion monitoring was designed.

In this method 10 bundles of 24000-filament thread were cast in a non-conductive epoxy. Transparent pipe was used as mold in order to monitor the accuracy of the procedure. After molding, the specimen was cut and ground to have a smooth and clear cross section. This method gives a surface area of around 10 mm^2. A chamber was also designed for this method. It is a rectangular prism with dimensions of 15cm length, 12.5 cm width and 12 cm depth which is filled by 1.75 liter solution. Figure 3 shows the final version of sample. New samples were made by cutting 4 to 5 millimeters from the head of the used specimen. Therefore 20 cm length specimen could be used for several experiments.

To reach a stable status in polarization the following procedure was applied. First, system was run in open circuit condition for 2 hours to stabilize the carbon in this alkaline solution. After that anode was

polarized between 30 minutes and 150 minutes, depends on polarization value. All procedure was monitored and saved by Solartron 1287.

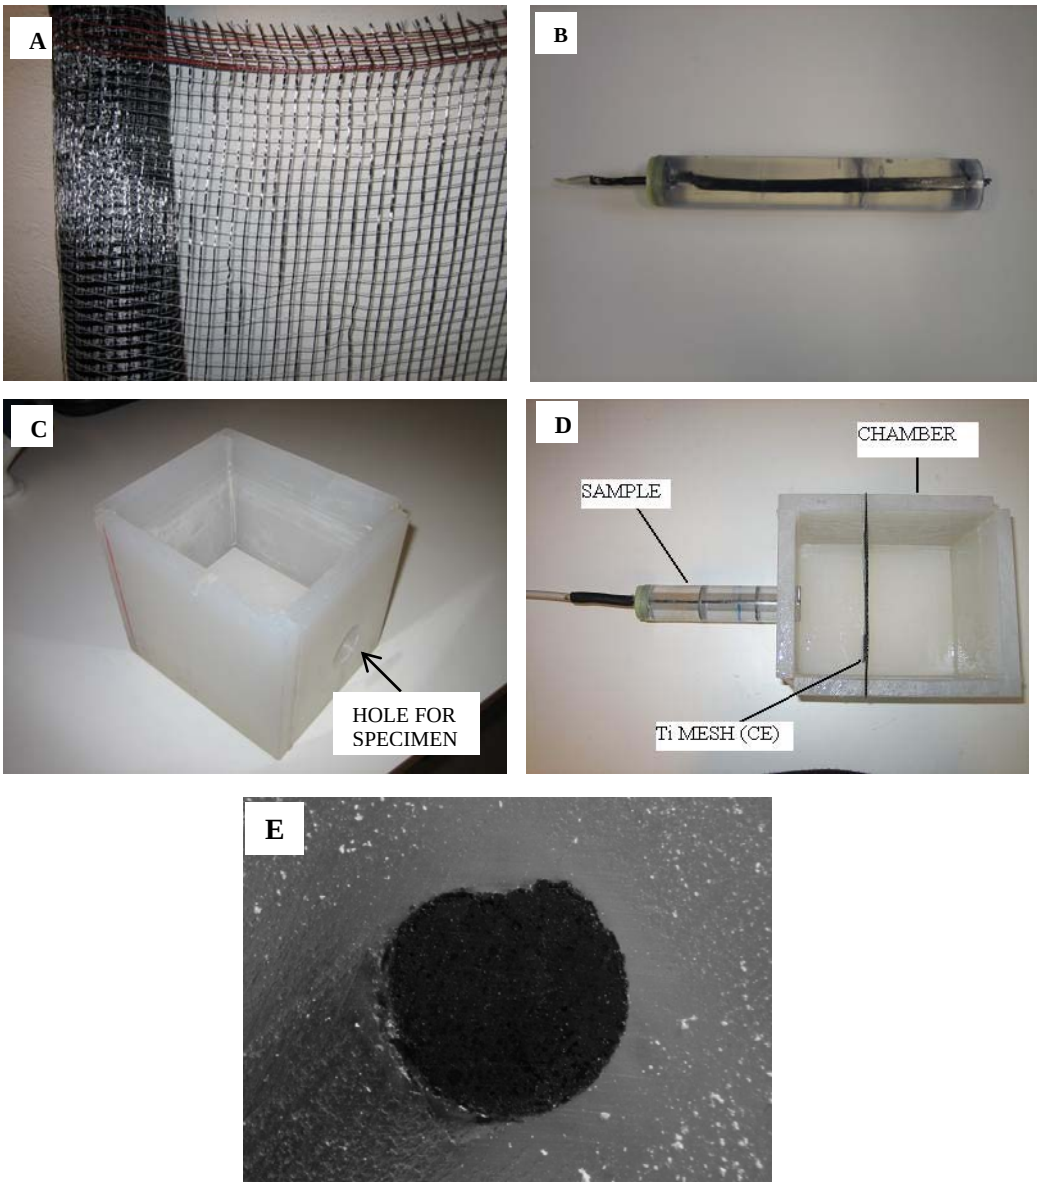

Figure 3. Photos of specimen and chamber.
A) Carbon mesh. B) Carbon specimen. C) Chamber. D) Test setup E) Cross section.

To simulate the concrete pore solution, a mixture of sodium, potassium and calcium hydroxide was used. pH of the solution was 13.2 and the measurements made in room temperature between 22 and 25 centigrade. Chloride ions were added as NaCl to make 1% and 3% chloride solutions.

4 RESULTS

The potentiostatic results were measured for different chloride contents. Figures 4 and 5 show examples of open circuit curve and 750 mV-polarization curve in 3% chloride solution. The E-I plot (potentiodynamic curve) for all 3 different chloride contents is illustrated in Fig. 6. Unfortunately the last read in 3% chloride content was out of range due to destabilization of the system. The result for

applied potential less than 500 mV are showed in separate plot. As it is observed in Fig. 4, before exposing the carbon to the alkaline solution, it is in immune area. After exposing by passing time, it eventually reaches to its open circuit corrosion potential. The open circuit value for testing carbon material is around -410±10 mV vs. SCE. Moreover during polarization, it took time to stabilize the current and that depended on polarization amount (Fig. 5).

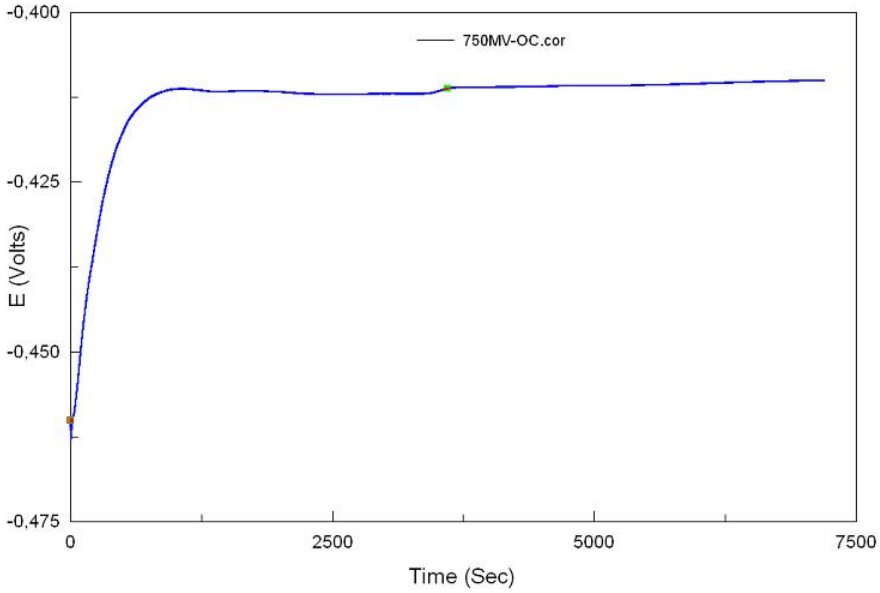

Figure 4. Open circuit measurement in 3% chloride content.

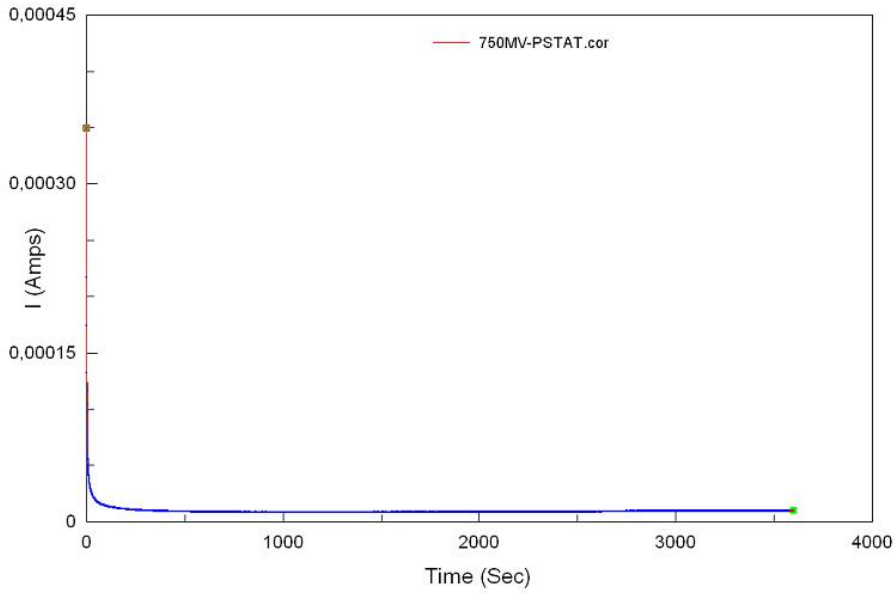

Figure 5. Potentiostatic measurement in 750 mV polarization and 3% chloride content.

As it is showed in Fig. 6, behavior of carbon in different chloride contents was mostly the same. There is a very small shift in curves to right by increasing the chloride content. In all three conditions there is a small area of passivation up to 300 mV polarization. In this area the corrosion current density is low, between 2E-8 ~ 7E-8 A/mm^2. It is more obvious in non chloride contaminated condition. After that carbon has an active behavior with a very rapid slope up to 2500 mV polarization. In this point, corrosion current density reaches to values of 1E-3 A/mm^2. After this point there is another passive

area in non-chloride content solution. But is both 1% and 3% chloride content this passive area is started after a jump from 1E-3 to 1E-2 A/mm2 in 2500 to 3500 mV polarization respectively.

It should be also mentioned that the oxygen reduction theorically should happen in 220 mV vs. SCE. This potential is equal to 630 mV polarization for the test material. During tests formation of bubbles on the surface of the carbon was observed after 750 mV polarization. Unfortunately monitoring the changes in pH value of the solution due to oxygen reduction could not be possible because of small surface area of working electrode compared with solution volume.

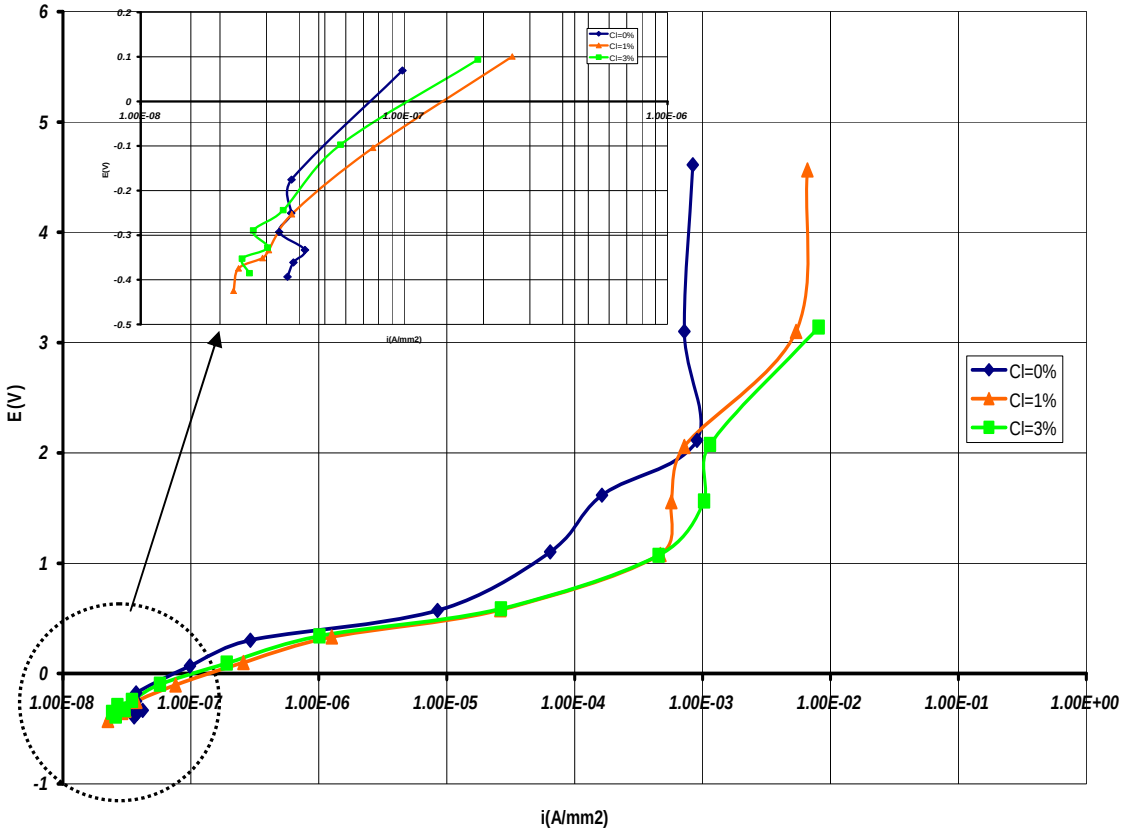

Figure 6. E-i plot for different chloride contents.

However the formation of corrosion products was observed on the surface of the samples after 1500 mV polarization, but these products were solid and didn't released to the solution in non-chloride solution case. But in 1% and 3% chloride contents conditions, changing color to brown around the working electrode surface was observed from 3500 mV and 2500 mV polarization respectively by researcher.

5 CONCLUSIONS

The results have been presented of carbon fibre material which could be used as an anode material in CP systems. To improve the knowledge about behavior of this material in alkaline media, the polarization tests were fulfilled.

The performed investigations have shown that carbon has a passive-active-passive behavior in alkaline solution. It is in passive condition up to 500 mV polarization and then enters to active area up to 2500 mV. From that point, it starts the second passive condition.

Corrosion current density is 2E-8 A/mm^2 in low potentials up to 1E-3 A/mm^2 in high polarization potentials. This value would be increased up to 1E-2 A/mm^2 by adding chloride ions in the solution. Addition of chloride into the solution increases the corrosion current densities in high polarization values. But it seems that this effect is slight in low polarization values and amount of chloride ions do not play a great role in that.

Oxygen reduction has been observed from 750 mV polarization. It could make some mechanical damage to the surface of the carbon. But the change in solution color to brown was monitored just only in very high polarization potentials.

ABSTRACT

Nowadays design procedures in the sphere of architectural culture are generally focused on environmental issues, and more and more often it is finally accepted at least the need of looking for alternative systems aimed at saving energy from fossil fuels, and studying and testing various options in the production of components and materials for construction able to create a better environment, an higher vivibility and a less polluted planet. The paper we present reports some results from a research aimed at testing a number of these systems, which could create a valid alternative to those conventional components and materials that happen to be increasingly toxic for the users' health, damaging for the biotic and a-biotic parts of the earth ecosystem, and requiring great amount of fossil fuels for running. In particular the research has been focused on a peculiar field of systems, which can employ vegetable materials as a base for the production of building components, because these materials, having a very high level of naturality, being very durable, and capable of re-entering the circularity of the earth processes, will save energy, will reduce the environmental load, will create an healthy environment and thus a better way of living for humans. The research shows that the use of such materials as wood, cork, bamboo, cellulose or rammed earth, will require a different way of thinking, of designing, of constructing the architecture, depending mainly on the fact that a number of components made out of these materials have different characters from the usual conventional systems in concrete, steel and plastic. Great sensibility of the designer is then required any time the selection of vegetable material is considered an option in order to integrate the building in the circle of nature. The study here presented, beginning from the analyses of such characters of these natural materials, will define in the end a number of guidelines as basis for helping the designer to do the right choice according to different using purpose. The results of such studies could help to promote the production and the use of these vegetable components and to outline the procedures for employing new methodologies of application in architectural intervention.

1 INTRODUCTION

The building market proposes a large range of industrial products with higher and higher performances; although one of the aspects that seems to be more attractive for the professional figures involved in the design process (enterprises, designers and users) is the ecological character of the element, i.e. its capacity to minimize negative impacts on ecosystems and users and its ability to cut energy consumption by fossil fuels. According to the latest European and Italian law this latest aspect seems to prevail so much that often the real performance levels are defined only as far as energy consumption is concerned, ignoring the other environmental loads that, during all the life cycle, from the pre-production till the recycling, the component provides. Nonetheless we think that the duty of researchers and designers will be to grasp the real eco-sustainability and bio-compatibility characters of such components, not only during production, transport, etc., but also and mainly during the employment, which represents the longer and the more polluting phase, both for the users and the ecosystems, and the only one in which the building role, combined with the various produtcs, can actually answer in an olistic way to the comfort needs.

2 VEGETABLE MATERIALS AS ALTERNATIVE CONSTRUCTION SYSTEMS

The environmental questions had achieved, in the latest years, a vital importance, not only in the specific bulding field, but also in the political, economical and cultural sphere. Nowadays speaking about sustainable design seems almost pointless, since the sustainability should be included in any type of intervention. The problem of cutting energy consumption in buildings is today widely discussed and studied, nonetheless the same approach does not often occur in the eco-sustainibility and bio-compatibility of building materials.

In a changing world, flexible, re-generative, intelligent and sustainable materials and solutions are required for architecture. Vegetable materials seem to be a good answer for such a goal.

The need of employing these alternative materials, rather than more conventional ones, such as steel, concrete and others, is due to a great number of reasons, mainly belonging to the sphere of socio-economical and technical fields.

Figure 1. Cork.

Table 1. Energy in MJ for the production of 1 mc per unit strength [MPa].

Material	MJ/m^{9}MPa
Steel	1500
Concrete	240
Wood	80
Bamboo	30

The first one includes production of low cost construction materials; very low amount of energy needed for the production [Table 1]; substitution of the whole or part of polluting materials with environmentally friendly ones; new design possibilities using non-conventional materials and techniques; use of local materials; protection of non-renewable energy resources; very high potentiality of recycling.

Technical reasons can be focused on the chance of having simple processing materials and higher mechanical properties and performances (i.e. the bamboo) similar to those of conventional building materials.

Nevertheless, there are also some limits for the employment of vegetable materials. It is possible to distinguish three different kind of limits: biological, technical and temporal. The first ones are due to the growth of the upper plants; the technical limits are various but the most frequent are related to the problem of root compenetration; finally the time limits are linked to the need of working within or without the growth time [Figure 2].

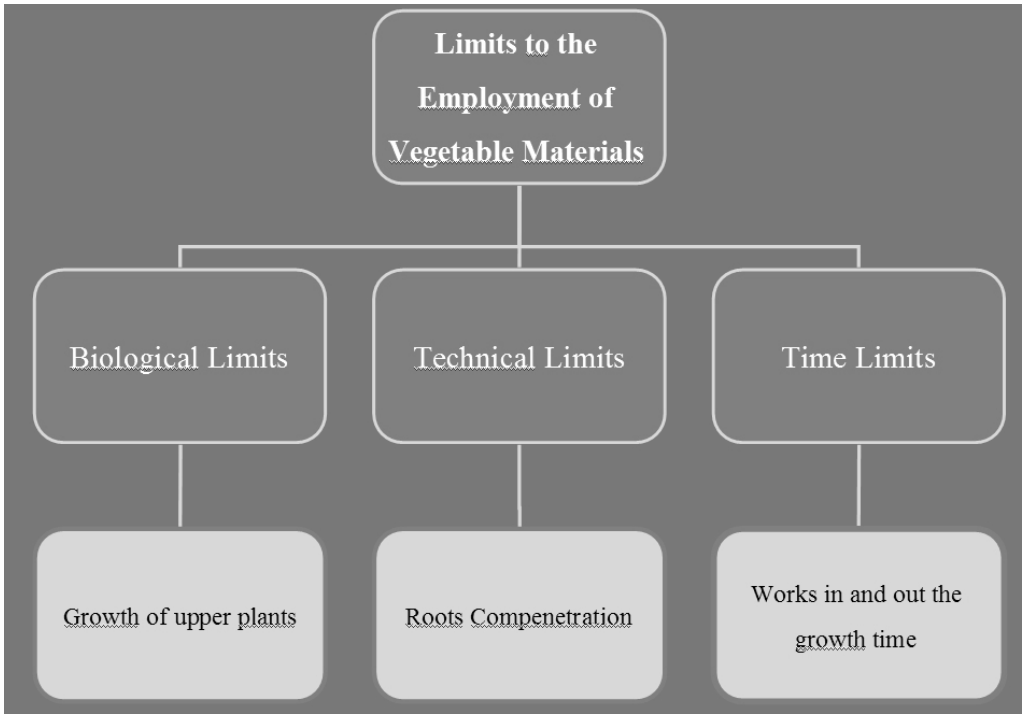

Figure 1. Limits to the employment of vegetable materials.

3 BAMBOO

One of the vegetable materials, lately come unto fashion again among designers, the bamboo, has been investigating as far as its potentialities are concerned. The term "bamboo" describes a range of woody perennal evergreen plants (Family Poaceae, Sub-family Bambusoideae), mainly diffused in the tropical zones, but also in the temperate and sub-tropical zones. It includes 1250 species, most of which have a very fast growth, reaching their maturity in less than five years. Upon time different types of bamboo were used all over the world for variuos purposes depending on cultures, traditions and climatic characters [Janssen, 2003].

In Europe the use of such material began more than 300 years ago, but it remained neglected till few years ago when the designers had started again to look at bamboo as a building material. Nowadays many European researchers (for example the Eindhoven University, Holland) are performing tests for checking the structural potential of this material (Table 2). These bamboo researches are aimed to establish its physical and mechanical behaviour so as to make possible its employment as a substitute of the structural steel.

Table 2. Comparative properties between bamboo and others conventional building materials.

Material	Strength N/mm2	Mass/ Volume	Ratio	Emodulus MN/m2	Mass/Volume	Ratio
Concrete	8	2.400	0.003	25.000	2.400	10
Steel	160	7.800	0.020	210.000	7.800	27
Wood	7.5	600	0.013	11.000	600	18
Bamboo	10	600	0.017	20.000	600	33

Among vegetable materials, bamboo is the one on which the scientific community - linked to construction sector - has better hopes for an efficient structural use.

Thank to the arising consciousness about the serious environmental crisis in which we currently live, the research for new building materials is still developing. So far the bamboo seems to be very interesting for its physical and technical properties: in fact, like all vegetable building materials with circular section (wood, straw, sugar cane, etc.) it offers a very high tensile and torsion strengths, as well as elastic properties independent form shape and load distribution [Hidalgo, 1981].

Frei Otto, within the programme of activities carried out for the Institut für Leichte Flächentragwerke, had extensively shown how the bamboo is more resistant and lighter than other "conventional" building materials. For these reasons is now impossible to ignore a material that offers a twice bigger strength compared with the glass fiber and six times an higher lighthness than the steel, and it can also be reminded that it is not a chance bamboo is called "the vegetable steel". Moreover, its ecological features are very interesting. It is the plant with the higher growth rate (some bamboo species can grow up to 1 meter in a day). Thus, the employment of bamboo guarantees a large availability, also in brief times, and at the same time insures a regular control over the oxygen/ carbon dioxide balance in the atmosphere. In particular, the Guada Angustifolia specie is one of the essences that offers an higher percentage of carbon dioxide particle absorption, giving an helpful hand to the fight against global warming [Cusak, 2000].

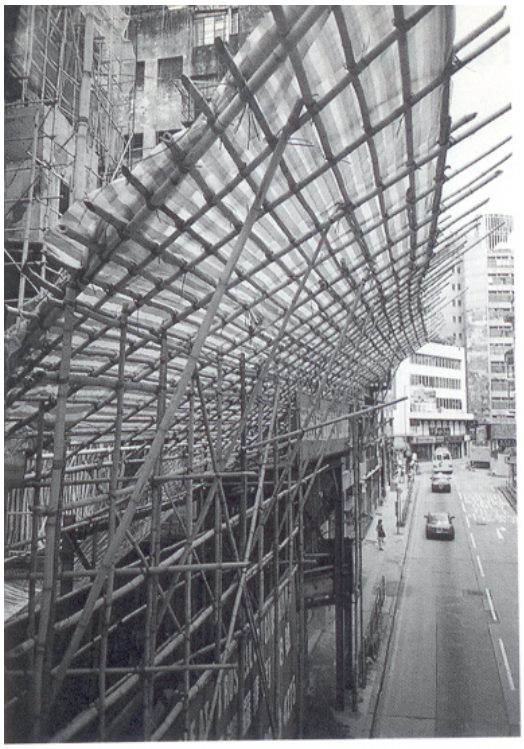

Figure 3. Bamboo used as scaffolding.

The use of bamboo in building sector can play an important role also in relation to the well-known deforestation problem and can provide, in brief times, enough material for building houses for millions of people that live in the developing areas of the world. Building with the bamboo, also in Europe, becomes nowadays a task with a benefit for environment, next generations and poor commuities that fund their economy on its production. The chance that had allowed the meeting between Occident and the bamboo culture was the Hannover Expo (2000), where the architect Simon Velez realised the Padiglione Zeri, the bigger bamboo structure ever built, measuring 40 meters by 9. In the 2002 the Vergiate Municipality (near Milan) commisioned the EmissioneZero society (the same who built the Padiglione Zeri) by doing a huge structure in bamboo, inside the Ticino Park, that was the first permanent bamboo building in Europe.

4 CLASSIFICATION AND EVALUATION

The first stage of our research was meant to classify those vegetable materials, that are usually employed in architecture and urban planning, in two big categories: living vegetable materials and organic dead materials. The first one includes seeds, scions, grass, plants with roots and, generally, all the vegetable materials that are used in landscape architecture. The second one, instead, includes building materials such as wood, coconut and juta fiber, cork, etc. [Figure 4].

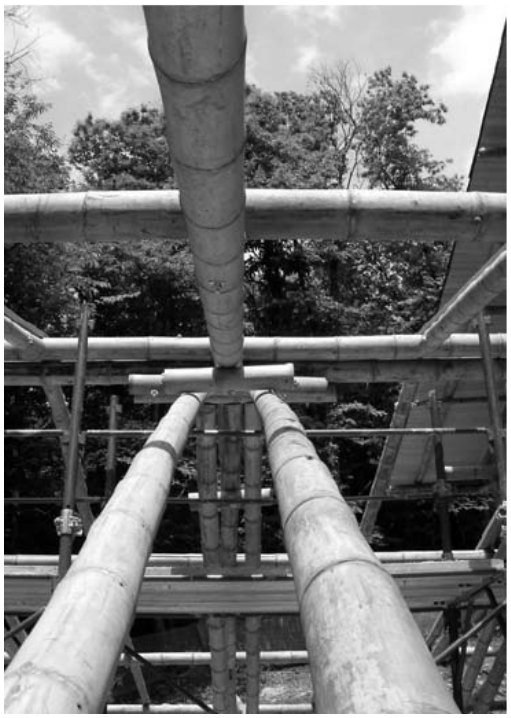

Figure 2. The bamboo structure of the public space built in Vergiate (near Milan)

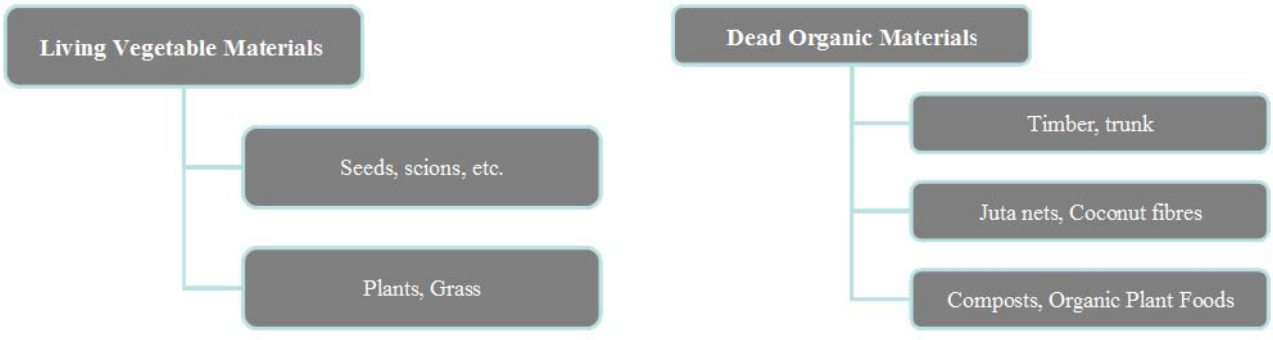

Figure 3. Classification of vegetable materials.

The following table [Table 3] shows some important characters (linked to their ecological aspect) of the principal vegetable materials. For each of them, thermal conductivity, energy consumption values, chance for the product to be recycled or to be made by recycled elements and finally some notes about the physical performances, are listed.

Table 3. Characters of the principal vegetable materials.

Material	Thermal Conductivity (λ)	Energy Consumption in Production	Recycling	Characters
TIMBER FIBER CARDBOARD	$\lambda \sim 0.0050$	Very low	Yes as fuel	Transpiring, antistatic, toxic emissions free
CORK	$0.030 \leq \lambda \leq 0.100$	KWh/m= 30-60 (+ 30 for cardboard depth)	Yes	Good insulation, Impermeable to the water, transpiring, good fire resistance, toxic emissions free, no need of adhesives.
MINERALIZED TIMBER CARDBOARD	$0.050 \leq \lambda \leq 0.100$ $\lambda \geq 0.100$	KWh/m= 30-50	Yes as inert for concrete	Transpiring, antistatic, toxic emissions free
COCONUT FIBER	$\lambda = 0.045$	KWh/m=30		Resistant, transpiring, antistatic. Good resistance to insects, mold and humidity. Inflammable, high costs.
JUTA FIBER	$\lambda = 0.055$	Very low		Transpiring, antistatic. Inflammabale. Low costs.
NATURAL WOOL	$\lambda = 0.033$	Very low	Yes, often is already produced by recycled wool	Good insulation (thermal and phono), transpiring. Fears attacks from parasites and mites. High costs.
CELLULOSA FIBER FLAKES	$\lambda = 0.032$	KWh/m=6		Good insulation (thermal and phono), transpiring. Excelent resistance to parasites, insects and rodents. Toxic emissions free. Fire resistant, Fears water.

The output of this research is the creation of an evaluation method for the sustanibility of the vegetable materials, which can be applied to other materials. Such method consists into a format divided in two classes: ecosustinability and biocompatibility [Francese, 2007]. The first is related to the impacts that the material/product provides on the environment (in terms of material and energy consumption and of polluting emissions), the second instead to the impacts provided on the users' health (in terms of emissions, radioactivity, smells, etc.).

Any class can be identified by a number of parameters, which define performances and requirements of the employed material. Each parameter is, on its turn, specified by qualitative and quantitative indicators, to which a value will be given. The points for each indicator are given considering a defined range of values, every range corresponds to a determinated point, from 1 (worse performance) to 5 (best performance).
In the next table, a sample of thus type of classification is shown for some indicators.

Table 4. Examples of ranges and values.

Indicator	Values
Permeability/Impermeability	1 - perm. > 2 μg/N s 2 – 1 μg/N s < perm. < 2 μg/N s 3 – 0,5 μg/N s < perm. < 1 μg/N s 4 – 0,067 μg/N s < perm. < 1 μg/N s 5 – perm. < 0,067 μg/N s
Thermal Conductivity	1 – C > 1,3 2 – 0,75 < C < 1,3 3 – 0,1 < C < 0,75 4 – 0,05 < C < 0,1 5 – 0,02 < C < 0,05

The satisfaction level of performance for each indicator provided by each material is thus represented by the specific value (from 1 to 5) appointed to the indicator. Moreover different weights are provided for each class and for groups of parameters, according to their importance (as known in the AHP method). So the ecosustainability class has a weight corresponding to the 45% of the total, and the biocompatibility weights for the remaining 55 %. The weights for the parameters are shown in the Table 5.

The final result will be provided as a comparison value within the multicriteria method, for the ecosustainability and biocompatibility of two different materials.

5 THE CASE STUDY: BAMBOO HOUSE (ARCH. KENGO KUMA)

We have tested our evaluation method analazying one of the most famous bamboo buildings: the Bamboo House by Kengo Kuma.

The building was part of an initiative to develop a series of houses, all by Asian architects along the Great Wall of China. His composition is based on a central zone called bamboo lounge: it is a common space with gardens and water; around it all the rooms are articulated. Two small paths link the bambo lounge with the daily and the nightly zones. Kuma varied the spacing and thickness of the bamboo canes creating the walls of the house, each defining a different level of fluidity from one space to the next. Dappled light penetrates between the thin stalks. Kuma is in a sense a traditionalist, aiming to restore the historical Japanese buildings.

Figure 6. The Lounge Bamboo (Bamboo House).

However his approach is a modern one, in which he focuses on “light and natural materials to get a new kind of transparency.” [Pavarini 1999].

The evaluation method tested on the Bamboo house had shown the evidence that bamboo can be considered, at a first sight, an ecological and healthy material, due to the high values for both the requirement classes, the ecosustainability and the biocompatibility.

Both from the point of view of secutiry and friendly features, it has a good chance to become the material of the future. Durability and environmental resistance contribute to provide it with high quality and appeal.

Table 5. The case study: evaluation of the use of bamboo in the Bamboo House by Kengo Kuma.

5 CONCLUSIONS

Sustainable construction will be more and more challenging in the next years, first of all because it appears as the only possible way of reducing the big impact on the planet health in terms of both energy and material consumption, and then because the European as well as other continent regulations are increasing the mandatory requirements for environmental tasks.

The field of research should, in the future, be aimed at investigating new technological solutions and new materials for achieving the result of a low environmental load during the whole life cycle of building process. The first aspects on which such a reasearch focused regard environmental and social performances of those innovative technical solutions: this is in fact one of the aim of the reasearch we are presenting, which is mainly oriented at demonstrating that vegetable materials, being recyclable, durable, clean, ecological and healthy, could represent an actual alternative to oil derived solutions. At the same time any innovation in the field of vegetable material should be tested and investigated so as to find out their real ecosustainable and biocompatible performance. The example of the bamboo, whose performance we had started to evaluate with our verification method, provide a good sample of such a direction in the research, because it is demonstrated that the impact on earth and human health is minimum, and at the same time its technical properties could really be compared with other more conventional but more polluting materials. Moreover the high levels of social as well as sustainable characters of vegetable materials will push the building market into the direction of assuming and employing these innovative technical solutions as good challenge for future architectural design.

The research will go on, with the aid of our laboratory (LICA) in which deeper and various investigating procedures are planned and arrange for verifying bamboo performances, such as monitoring its thermal properties, its structural characters and its environmental care degree.

The last stage of our research will be outlining a number of guidelines useful for designers who wants to employ such materials, as the vegetable ones and in particular the bamboo in which the connection with the evaluation tool will help to take the decision in the direction of environmental care.

We believe in fact that not only the formal, strategic, bioclimatic approach to architecture is expected to be employed for future improvement of the building sector, but also the selection of the appropriate solutions and materials can provide the planet with an holistic view for achieving sustainable development.

Hikotsugu Hyodo [3]

T 18

ABSTRACT

Lowering water to cement ratio (W/C) is a popular way to enhance durability. Ultra-high strength concrete having compressing strength over 100 MPa is usually made by using nano-size silica fume and expected very durable. Excepting pozzolanic effect of silica fume, the foundamental role is to fill the fine spaces where cement particles are not able to filfull because of its limited particle size distribution in nano order. From foundamental point of view, other powder that has similar particle size with silica fume is expected to work similarly to silica fume. One candidate is nano-size limestone powder (LSP).

In this study, nano-size LSP is made from commercial LSP having an average particle size of 8 μm by using ball mill. Various powders having average sizes from 0.3 to 2.3 mm and BET specific surface area from 19.9 to 3.2 m^2/g, respectively were produced.

These LSPs were added as mineral admixture by replacing 10 mass% of cement. The addition of LSP improve the fluidity at very low W/C around 13–16 %. The most suitable size of LSP was around 1 μm. The performance of fluidity and compressive strength that was around 140 MPa at 28 days and comparable with silica fume. This limestome powder is also effective after drying. Another characteristic point of LSP was the significant shortening effect of setting time.

1 INTRODUCTION

In order to realize high durability, increasing strength by lowering water to cement ratio (W/C) is a popular method. Simultaneously, workability should be maintained constant. Limestone powder (LSP) is sometimes used as a kind of mineral additives [JCI Committee 1995]; [Ramachandran & Zhang 1986]; [Pera *et al.* 1999]; [Sato & Beaudoin 2007] for high strength concrete in order to improve the workability. Silica fume (SF) has pozzolanic reactivity and this contributes better durability. Besides this effect, SF is also important to make ultra-high strength concrete of very low W/C less than 20 % from the aspect of workability. Although ultra-high strength concrete is expected as very durable, without the addition of SF, the mixture of cement and water is too stiff even if plenty amount of superplasticizer is added. By the additio of small amout of SF around 10 mass% of cement, the cement paste starts to show fluidity. This effect has been considered as filling effect of missing particle grade of cement in the finer part.

Usually, cement has an average grain size of 10 several μm and the ratio of particles less than 1 μm is very limited. Some amounts of water trapped among the spaces made of these relatively larger particles can be released by packing finer particles in these spaces and the trapped water is changed to media for particles to move.

If this mechanism is correct, the kind of particle is not the essential factor but only the size is expected to be important. The particle shape may have a secondary effect. In order to verify this assumption, LSP is selected as the material for study.

There are two reasons to select LSP. One is the grindability. Calcite, main component of limestone, is easy to grind compared to other materials such as blast furnace slag, fly ash, and silicate rocks. Usually it is not easy to grind inorganic materials less than 1 μm because of the surface charge that makes particles flocculated. Calcite is not so hard compared to other silica or silicate minerals and is expected easy to grind to fines and to control the average size easily to check the most suitable size to maximize the fluidity of cement paste. Another interesting characteristics of calcite is the supression of decreasing hydration speed of C_3S after second peak of hydration. After the initiation of second peak of cement hydration, crystals of C-S-H deposit on C_3S and C-S-H forms a kind of layer to prevent its dissolution. For hydration progress, water or dissolved ions must diffuse through this layer to dissolve from C_3S and to precipitate C-S-H in the surrounding space of C-S-H covering C_3S. Therefore, with the progress of hydration, the thickness of C-S-H becomes more and the required time to diffuse this layer becomes longer and the hydration speed of C_3S decreases. In this hydration process, calcite takes one interesting role. C-S-H can be precipitate on calcite but not or limited on SF or maybe not on fly ash. Blast furnace slag may act like calcite in some degree. Because C-S-H precipitates on calcite, the thickness of the C-S-H layer on C_3S becomes less and the increase of required time to diffuse C-S-H layer is expected less. Then, the hydration of C_3S in the second peak and in early ages is increased.

In order to make ultra-high strength concrete, plenty amount of superplasticizer is added. For this purpose, special superplasticizers whose retarding effect of cement hydration is minimized are used. However, the dosage is so much and significant retardation is typical phenomena. Then, the addition of LSP is expected to shorten the retardation and the effect is estimated to correlate the surface area.

Based on these background and technical estimation, in this study, limestone was ground by a wet process and nano-size limestone was used as a candidate of fine powder. The optimum particle size was investigated and the effects of fluidity, setting time and strength were examined.

2 EXPERIMENTS

2.1 Materials

For mortar and paste tests, cement used was low heat portland cement (LPC) for fluidity evaluation and normal portland cement (NPC) for the evaluation of heat generation. Both were commercial products and specified by JIS. The original LSP was commercial one (LSP1) having 1.5 m^2/g of Blain specific surface area and was made by dry ball milling from limestone. For comparison, chemically synthesized calcite LSP2 and SF were used. Two kinds of SF used were commercial available products and their BET specific surface area was 10.8 and 22.4 m^2/g. The characteristics of cement, LSP, and SF are shown in Table 1. The superplasticizer used was a commercial product specialized for ultra-high strength concrete. The main component is polycarboxylate polyether polymer.

2.2 Grinding Procedure of Limestone Slurry

Limestone slurry, SL was prepared by a following procedure. In a ceramic pot mil, limestone, water, superplasticizer, and alumina balls having a diameter of 5 mm were added and the pot was rotated on a rotating mill for certain time and several SL having different particle size were obtained. One SL was dryed in a dryer at 105 ℃, ground and sieved to pass 0.077 μm. The information of particle size is summarized in Table 2.

2.3 Evaluations

Hydration heat was evaluated by a conduction micro calorimeter. 5 to 10 mass% of NPC was replaced by 0.3μmSL and 8μmLSP. Cement paste having 0.30 of W/P was mixed with a superplasticizer with the amount of 2 mass% of powder and the heat generation was measure for 56 hours. Particle size was evaluated by three methods, *i.e.,*BET specific surface area using one point N_2 adsorption, scanning electron microscope, SEM, and Lazer diffraction scattering particle size distribution method.

Fluidity was evaluated by mortar. In a Hobart mixer, 900 g of LPC, 1350 g of JIS standard siliceous sand, 2.5 mass% of superplasticizer against powder, and mixing water containing 1 mass% of defoamer against powder were added and mixed for 10 min at the low speed. The dosage is usually plenty enough to have saturated dispersing effect. The flow by using a cone having 10 cm of bottom diameter and 5 cm of height was measured to evaluate the workability. For the evaluation of the adding effects of LSP and SF, 10 mass% of LPC was replaced by them.

3 RESULTS AND DISCUSSIONS

3.1 Particle Size of LSP

In Figure 1, SEM photos of ground LSP1 and SF1 are shown. As is shown, the original 8 μmLSP (LSP1) was ground to smaller particles. The particles size of the finest 0.3μmSL is comparable with SF.

In Figure 2, the particle size distributions of LSP are shown. The particle size distribution of 8μmLSP is relatively wide and by milling the distribution became narrower.

In Figure 3, the particle size distributions of LPC and LPC mixed with LSP are shown. The particles less than 1 μm in LPC is limited.

By the addition of 1.5mmSL or 0.3mmSL, the lack of fine particles are compensated.

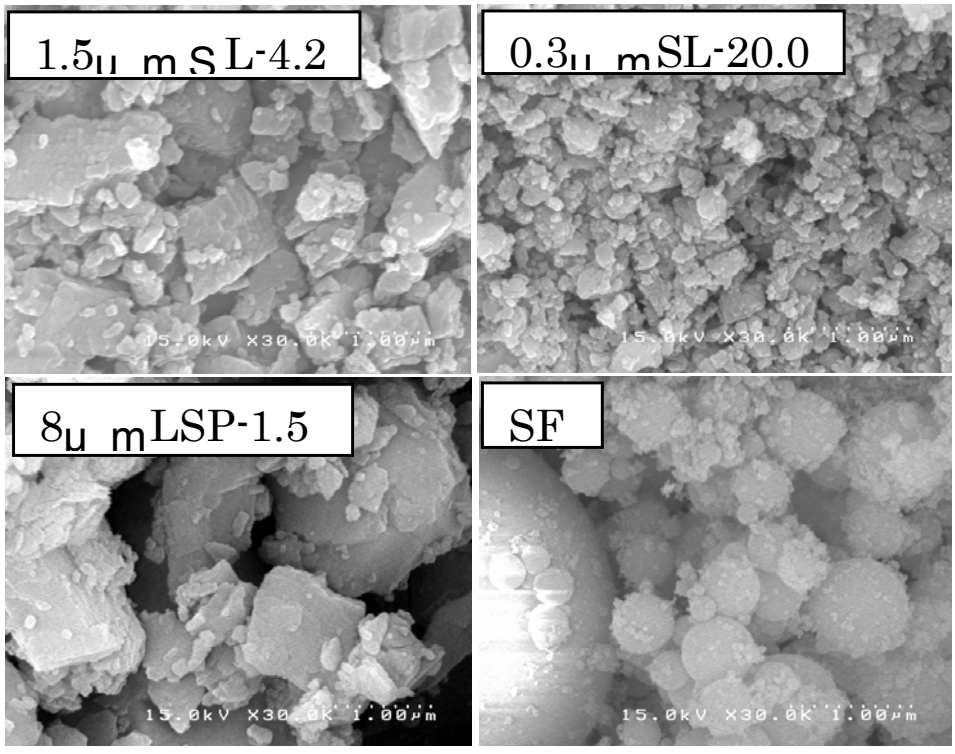

Figure 1. SEM photos of ground LSP and SF1.

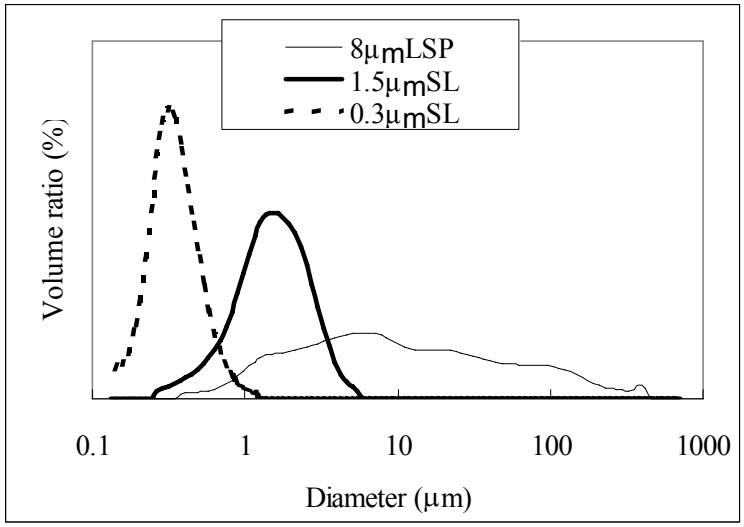

Figure 2. Particles size distribution of LSPs.

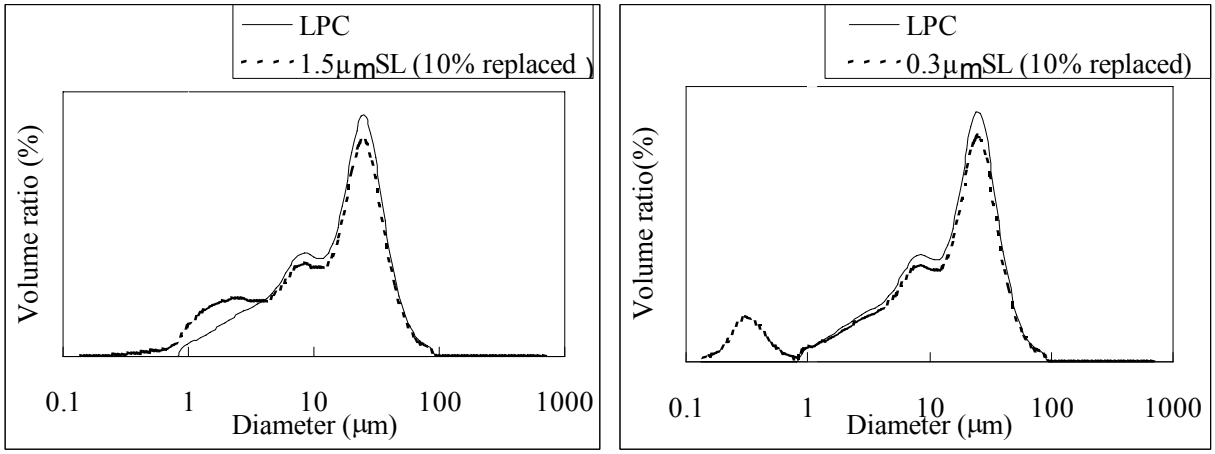

Figure 3. Particle size distribution of LPC and mixed cement with 10 mass% of 1.5μmSL-4.2.

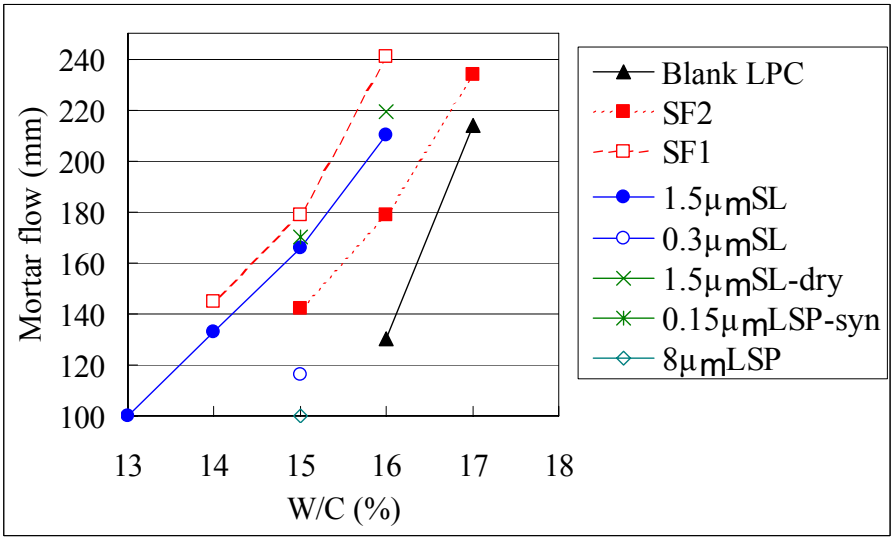

Figure 4. W/C and Mortar flow.

3.2 Effects of LSP Addition on Fluidity at Very Low W/C

Figure 4 shows the correlation between W/C and mortar flow. Without LSP or SF, blank LPC did not show fluidity at W/C lower than 15 %. At 15 % of W/C, the addition of 8μmSL showed almost no fluidity increase. By the addition of 1.5μmSL, the fluidity was improved and in the range of W/C larger than 13 %, some level of fluidity was obtained. The adding effects were almost the same for 1.5μmSL-dry and 0.15μmSL-syn but less for 0.3μmSL. Regarding SF, the finer SF2 showed less fluidity than the coarser SF1. There are suitable particle size to show high fluidity. By wet-grinding process, around 1.0 μm is the best particle size in this experiments. However, when producing method is different, the optimum particle size may be different because 0.15μmSL-syn showed relatively high fluidity even it has finer particle size. For SF, 10 m^2/g of BET specific surface area is preferable than the finer 22 m^2/g.

The results obtained indicates that there is an optimum particle size corresponding to the kind and the procuding process of powders. At least, SF and LSP with appropriate particle size showed the similar fluidity. The effect of shape on the fluidity is expected limited. SF is round in shape and LSP is relatively rectrangulr. Therefore, when the particle size distribution is optimized, this shape effect becomes visible. However, the optimization of grading is thought to be the more important factor. The fluidity improving effect of SF is not the intrinsic character of SF but just the matter of appropriate particle size because LSP having average particle size around 1 μm showed the similar fluidity with SF. Furthermore, some preliminarly fine tuning of particle size distribution by the combination of 0.3 and 1.5 μm SL was carried out but no better fluidity was obtained at this moment. It is effective to fulfill the missing submicron particles of portland cement by some other particle. However, there seems to be a limitation of this method in the range of 10–100 nm order. One interesting point worthy to mention is the required time to show fluidity. When mortar is mixed, at first they are only wet powders. After several 10s seconds or several minutes, the mixture becomes to one stiff lump. After more several minutes, the mixture starts to show fluidity. Interesting point is the required time to show this behavior. Even the final mortar flow is same, the required time for mixign is considerably different sometimes. SF1 and 1.5μmSL showed relatively shorter time. This is one of the crucial factors for actual production.

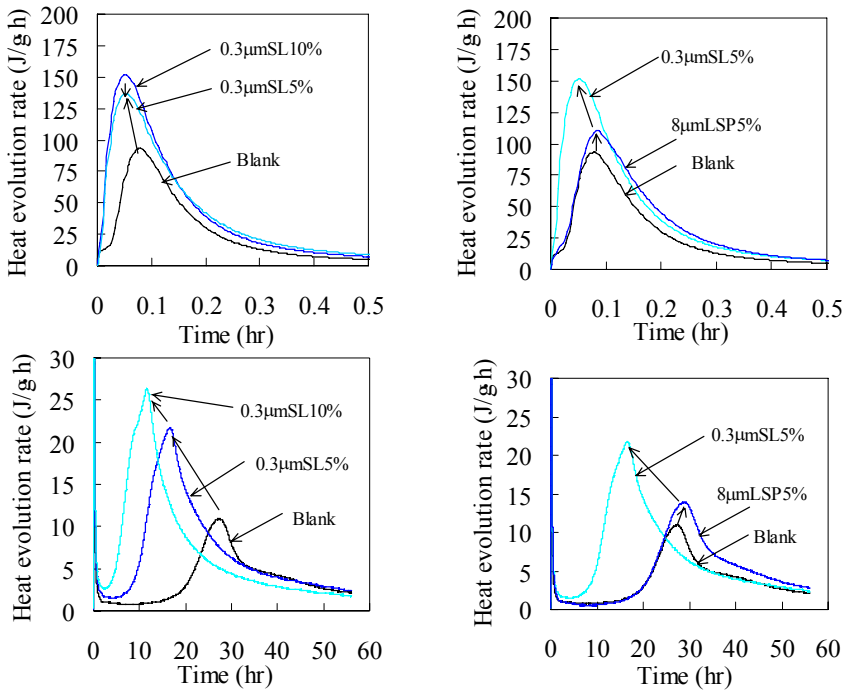

Figure 5. Heat generation behaviors of LSP replaced by 0.3μmSL and LSP1. Upper: 1st peak, lower: 2nd peak.

3.3 Heat Generation Behaviors

In Figure 5, the heat generation behaviors of LPC partially replaced by SL and LSP1 are shown. By the more addition of finer limestone powder, the first and second peaks appears the earlier and higher. These effects are estimated as the hydration acceleration of C_3A and C_3S by fine calcite.

3.4 Behavior in Concrete

The adding effect of SL should be confirmed by concrete tests because the mixing efficiency and the grading of the total particles are completely different. By the preliminary tests of concrete, flowable concrete having 650 mm of slump flow was obtained at 13 % of W/C for the mixiture of 10 mass% replacement by 1.5μmSL and SF1. The setting time of 1.5μmSL was 5 hours faster than 13.5 hrs of SF1. The compressive strength were almost the same level of 145 MPa at 28days. From the view point of durability, the behaviors of autogeneous shrinkage are significantly different each other. During first several days, 1.5μmSL-concrete showed more shrinkage but the shrinkage tends to saturated. Later, SF1-concrete continuously shrunk and after 10s days it showed more shrinkage than 1.5μmSL-concrete. Further evaluations are now under examinations.

4 CONCLUSIONS

(1) 1.5μmSL showed fluidity enhancing effect at very low W/C around 13–16 %. The performance was comparable or betther than SF. This effect is considered as the filler effect fulfilling the finer parts around and less than 1 μm range of the particle distribution of portland cement. There is an optimum particle size to improve the fluidity. For the combination of LPC and LSP, the LSP have an average particle size around 1μm is preferable.

(2) Hydration behaviors indicated by the first and second peaks of heat generation are enhanced by finer and more amount of LSP. This effect was much more characteristic for LSP than SF as confirmed by preliminary concrete test of setting time.

(3) Low W/C concrete having 650 mm of slump flow is possible as low as around 13 % by using SF1 and 1.5μmSL. Compressive strength at 28 days concrete including 10 mass% of LSP or SF are almost same around 145 MPa.

Heat Transfer in the Thermo-Efficient BIPSE Bricks

Yuri Z. Totoev [1]

T 18

ABSTRACT

According to Australian Greenhouse Office, energy consumption in Australia will increase by 60% from 1990 to 2010. Almost 40% of energy used in households is for space heating and cooling. It is believed that these numbers are even higher in other developed countries with climate not as mild as Australian. There is a great potential to achieve significant savings in energy consumptions, costs, greenhouse effect etc. by increasing passive solar efficiency of structures including brick walls.

Passive solar efficiency works in several ways. Solar radiation is absorbed and stored by materials with high thermal mass (usually masonry and concrete) in a house. It is re-released at night when it is needed to offset heat losses to lower outdoor temperatures. Passive shading allows maximum winter solar gain and prevents summer overheating. This is simply achieved with orientation to the sun of appropriate areas and well designed eaves or other external devices. It is possible to achieve the same or even better effect on masonry walls not by using external devices but by building the principles of passive solar efficiency into brick design.

A new design for brick with built in passive solar efficiency was developed at the University of Newcastle, Australia. This brick absorbs more heat in winter because the external area of the brick exposed to solar radiation is significantly increased in comparison to a conventional brick and also because of reflection. It also absorbs less heat in summer because the area exposed to direct sun is significantly reduced. The new brick design also has some potentially unique architectural properties.
Thermal properties of new bricks were studied experimentally. This paper will present details of the thermo efficient brick and also first results of experimental comparison to conventional bricks.

1 INTRODUCTION

Household energy demand is increasing following the increase in the number of electrical appliances used and also due to larger building floor areas. Passive energy efficient design philosophy appears to rise and fall in popularity with increasing and decreasing energy prices. It is also generally recognised that the passive energy efficient design philosophy is not only beneficial financially but environmentally beneficial too.

The following quote from Underwood and Yik [2004] is a good introduction to a new design for bricks with built-in passive solar efficiency. “Buildings consume between 40 and 60% of all energy used in most developed economies and an increasing proportion in many developing and emerging economies… …what is not in doubt is that our current dependency on carbon based fossil fuels for providing comfort and amenity in buildings cannot be sustained and that alternative strategies require to be explored, designed, implemented, tested and demonstrated in the immediate years ahead. At the heart of this is the need to both extend and improve our knowledge of the processes of energy exchange in buildings whether they be ‘high tech’ commercial buildings in the centres of our cities or the simpler and often naturally ventilated buildings and residential habitats that surround them”.

1.1 Building Energy Use

Average household energy demand in Australia is rising. A study in by the Australian Greenhouse Office [AGO, 1999] indicated that by 2010 household energy demand could be 160% of 1990 value. Approximately 40% of household energy use is for space heating and cooling. Residential energy use accounts for approximately 10% of total energy use. This means that residential space heating and cooling accounts for approximately 4% of total energy use in the country.

1.2 New Energy Regulations

The Building Code of Australia [BCA, 2005] sets out minimum requirements for energy efficiency of new buildings. At the moment, different Australian states require different star ratings (out of five stars) for new buildings to be met. A blanket five star rating will probably be included in any new release of the BCA.

Software programs are used to calculate the energy ratings of buildings; the two most common in Australia are NatHERS and FirstRate. Both computer programs are versions of software developed by CSIRO. A nation-wide trial of a new improved program, AccuRate, is currently being implemented to replace both NatHERS and FirstRate.

All these developments show that the government is determined to reduce energy consumption. This can only be done through legislation that will enforce the use of “cleaner” energy sources

1.3 Basics of Passive Energy Efficient Design

Passive technology in building design involves the use of natural energy flows to maintain a comfortable living environment in the building. A passive system is concerned with controlling the capture of incidental solar radiation and controlling captured energy through the thermal mass and insulating properties of different building materials and through air movement.

Much research has been done in the area of passive design. The focus of this research has been on:

- Building orientation;
- Building plan;
- Window arrangement;
- Insulation techniques;

- Airflow patterns;
- Energy capture and release from the building materials.

All these aspects have been considered with respect to the dynamic nature of the building environment over time in the particular space and with respect to each other in a systems design approach. However, design of a brick with built-in passive solar efficiency presented in this paper is primarily concerned with the first and the last aspect from the list above.

Building orientation is important for gaining maximum benefits from the control of incoming solar radiation. Positioning a building so that the side with the largest surface area faces the sun will allow the building to capture more solar radiation during the colder period of the year. A trade-off however is that potentially it will also capture more unwanted solar radiation during the hot period of the year. To cut unwanted solar radiation designers use shading devices. For example, the design of the eaves of the building with respect to the windows is important in providing maximum solar penetration to thermal masses in winter when there is a low sun angle and minimum solar penetration in summer when there is a high sun angle as shown in Figure 1.

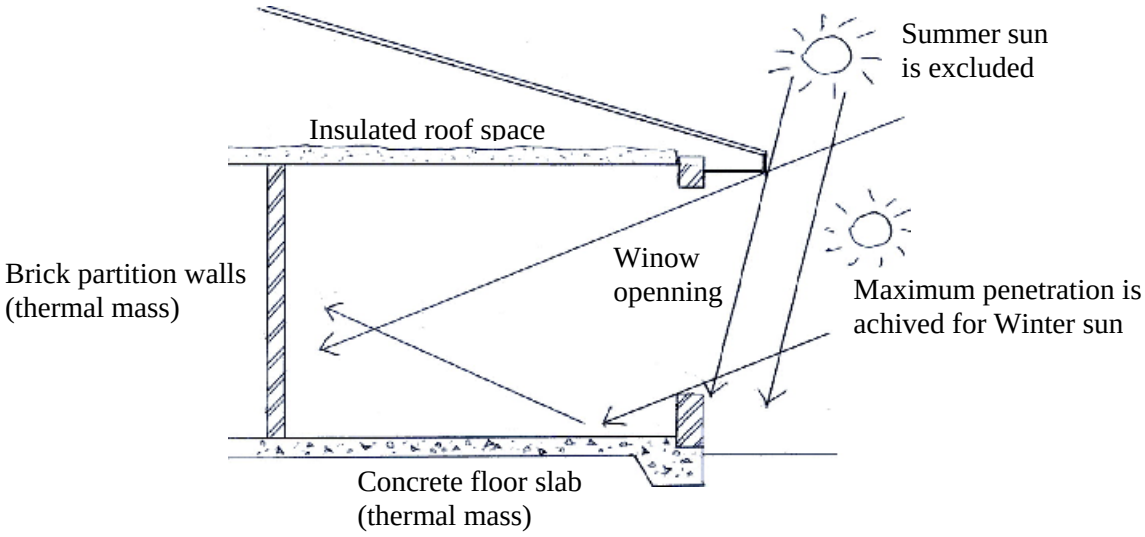

Figure 1. Key principles of passive solar design

Also important for passive design is the thermal mass of the building material. In mild climates where it is mostly the day-night cycle of warm days and cooler nights that requires the use of space heating or cooling, thermal mass is quite effective at averaging out the day-night temperature fluctuations. Brick is one of the most suitable materials to act as thermal mass and maintain comfortable temperature within the building. When the external temperature is hotter than is comfortable, external brick walls can absorb large amounts of energy with a small increase in temperature keeping the internal environment cool. When the external temperature is colder than is comfortable they will release energy keeping the internal environment warm. Windows can be used during colder periods of the year to allow internal walls to absorb solar energy in the day time and then release it at night as the temperature decreases. During hot periods of the year windows can be screened to prevent energy absorption by internal walls. The house is opened up at night and building materials release their energy to the cooler night air. During the heat of the day their thermal mass allows them to stay cool for longer.

2 BRICK WITH BUILT-IN PASSIVE SOLAR EFFICIENCY (BIPSE BRICK)

The major idea for development of a new brick was to achieve on the northern (mostly exposed to the sun in Australia) masonry walls better solar energy absorption in winter and better shading in summer

not by using large windows and external shading devices but by building the principles of passive solar efficiency into brick design. The design (Australian Patent No. 2005902375 Building Cladding Element with Built-in Passive Solar Efficiency) proposed by the author in 2004 is shown in Figure 2.

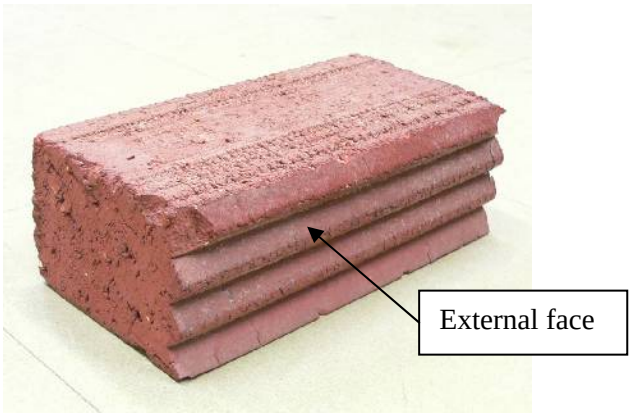

Figure 2. Extruded clay brick with built-in passive solar efficiency

The external face of the brick is not flat as in a traditional brick, but has horizontal ribs designed to increase the brick surface exposed to solar radiation in winter and reduce exposure in summer. It is also designed to capture in winter time some of the solar radiation reflected by the ribs back onto the brick surface as shown in Figure 3.

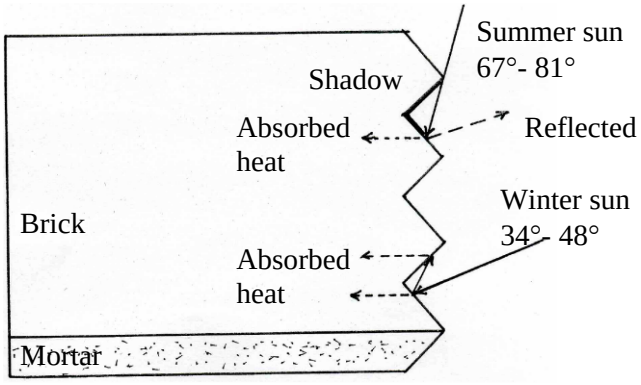

Figure 3. Principles of built-in passive solar efficiency (for Sydney latitude)

The angles of the ribs are designed to work best at certain latitude. Figure 4 on the next page show how a brick wall built out of new solar efficient bricks would look at midday in summer and winter. This new brick design will have some implications in brick manufacturing, brick storage and brick laying. It will also have some architectural benefits apart from improved energy efficiency.

2.1 Implications for Brick Manufacturing Industry

- Clay bricks will be extruded as usually. There will be one additional operation – ribs on the external surface of fresh bricks will be formed by rolling them with a specially designed gear;
- Dry pressed bricks or moulded blocks must be formed with the external ribs at the bottom of a mould form;
- There will be approximately a 5% saving in the material for bricks with the overall width of 110mm.

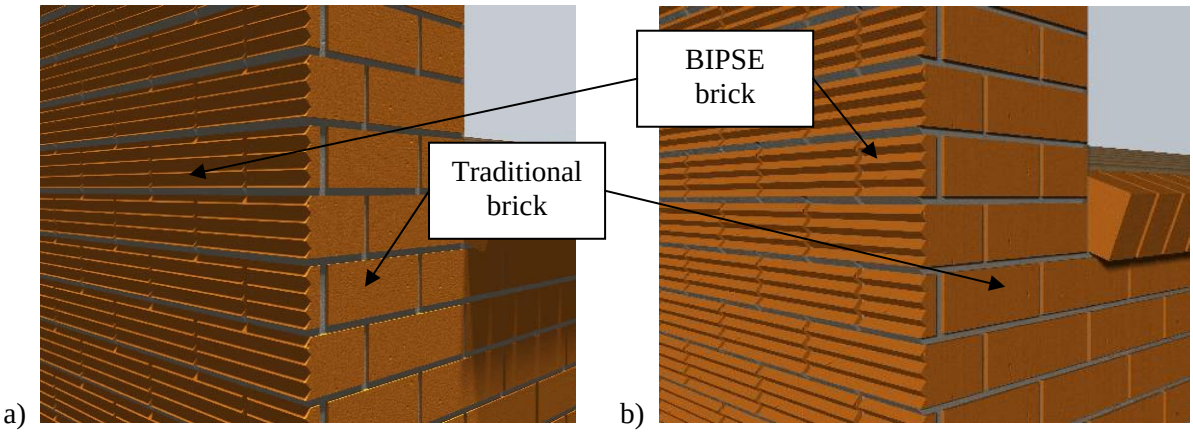

Figure 4. Computer simulation of passive shading on the northern wall at midday for Sydney: a). in summer; b). in winter.

2.2 Implications for the Brick Laying

- Struck bed joints are preferred because mortar joint forms the lower surface of every forth rib;
- At the external corners of walls conventional quoin bricks, or both new and conventional, or bricks cut at 45^{o} can be used;
- A bricklayer's trowel needs to be modified – corners near the handle need to be approximately 90^{o}.

2.3 Additional Architectural Benefits of BIPSE Bricks

This new design of brick completely changes the appearance of such a traditional material as brickwork giving to an "old" material a new face. A wall made of BIPSE bricks will have horizontal articulations in the form of ribs. This contemporary articulated look will be amplified in summer by horizontal shadows on the wall. If glazing is used on the upper surface of ribs, a brick wall will appear to have a different colour depending on the view angle. The colour of the wall will also appear to change when the observer moves to or from the wall. These architectural features of BIPSE bricks, although by-products of original solar efficient design, may prove popular among house designers and consumers.

3. COMPARISON OF THERMAL PERFORMANCE OF CONVENTIONAL AND BIPSE BRICKS

Laboratory tests were performed at the University of Newcastle (Australia) to compare the thermal performance of BIPSE bricks and conventional bricks. Tests on the heat absorption were performed by Mr. Mathew Turner [2004] as a part of his final year civil engineering project. These results were summarised and analysed in [Totoev, 2006]. Tests on the heat conduction were performed by Mr. Ryan Tranter [2007] as a part of his final year civil engineering project. Both sets of results are presented in these paper for completeness. The objective of tests was to assess the heat absorption and heat conduction capacity of new bricks in comparison to conventional bricks by measuring heat flux through the brick.

3.1 Principles of Heat Transfer Theory for Bricks

It is commonly accepted that heat transfer though the brick occurs by conduction due to the temperature differential on external and internal surfaces of the brick. The convection of hot air though pores of the brick, although theoretically possible, is assumed negligible in comparison to the

heat conduction. Most of the heat energy is delivered during the day time to the external surface of a northern wall by solar radiation. Part of it is absorbed into the brick and the remainder is reflected away from the wall. Absorbed and reflected parts are believed to be comparable in magnitude. Part of the absorbed energy heats the brick and the rest of the energy passes through the internal surface of the brick. At night this process is usually reversed because external temperature is lower than internal. Brick walls at night radiate energy back to the external environment.

3.2 Test Specimens

Test specimens were single bricks. Bricks were extruded solid clay units. Four types of bricks were tested for heat absorption:

- Conventional brick with flat external face;
- BIPSE brick with 50º inclination of the upper face of ribs;
- BIPSE brick with 60º inclination of the upper face of ribs;
- BIPSE brick with 70º inclination of the upper face of ribs.

First two types were also tested for heat conduction.

The thickness of the conventional brick was reduced to achieve the same volume as BIPSE bricks. This was done to ensure that exactly the same amount of energy is used to heat all the bricks. Therefore the amount of energy passing through the internal surface of a brick was proportional to the amount of energy absorbed into the external surface of a brick.

In the Sydney/Newcastle area an angle of 50º for the inclination of upper face of ribs on the northern wall was expected to be the most efficient at midday. However, before and after midday the sun is lower in the sky. Two other angles of inclination designed to work better with a reduced incident angle of the sun were tested.

3.3 Testing Rig

A purpose-built testing rig was developed for the laboratory heat conduction tests. Similar arrangement was used previously for heat absorption tests. The testing arrangement is shown in Figure 5.

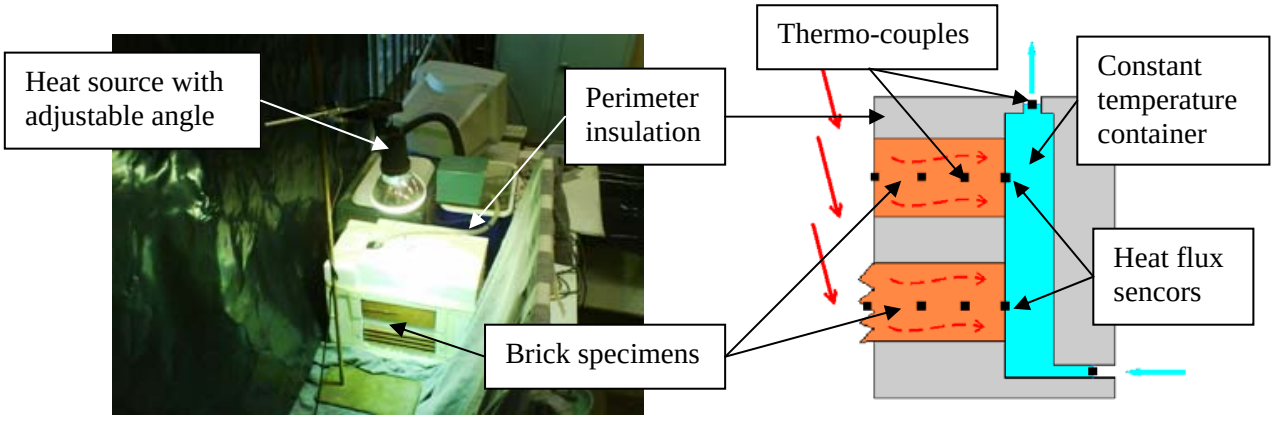

Figure 5. Rig configuration for heat absorption and heat conduction tests

Alternative test methods based on in situ atmospheric measurements have been considered. Laboratory testing was preferred at the first stage because it has less expensive set up and because it is easy to repeat this test with exactly the same heat input into specimen.

Bricks were placed on the aluminium water container. The water in the container was kept at a constant temperature of 22ºC for heat conduction tests and 25ºC for heat absorption tests. These

temperatures are from a comfortable temperature range in a house. The heat flux sensor was attached to the back of the test brick. The heat transfer compound was used to dismiss of any air gaps between the specimen, the flux sensor and the water container. A foam box was installed around the perimeter of the specimen for insulation leaving only the external face of the brick exposed to heat. The insulation box was glued to the water container and a gap filling compound was used between it and the specimen to minimise the heat losses though the sides of the specimen.

A 275W light globe was used in these tests as a heat source. In preliminary tests it was found that this heat lamp if positioned 620mm from the centre of the brick is capable of heating the specimen's external surface to a temperatures between 30 and 50ºC depending on the inclination angle of the lamp. This temperature range was comparable to temperatures recorded on northern walls of masonry buildings in spring. The inclination angle of the lamp was adjustable to represent the incident angle of the sun.

The set up was instrumented with a heat flux sensor and thermo-sensors. The heat flux sensor measured the heat transfer through the internal surface of the specimen. Thermo-sensors were positioned to measure temperature temperature through the depth of the brick. The laboratory air temperature and the water temperature in the container were also constantly measured. All sensors were connected to the data taker and continuously uploaded to the computer.

3.4 Testing Procedures

3.4.1 Heat Absorption Tests

Each specimen was tested at six different angles of lamp inclination: 30º, 40º, 50º, 60º, 70º, and 80º. For reference, the highest summer sun angle in Sydney is approximately 81º and the midday winter sun can be as low as 34º. It should be noted that before and after midday in winter and for walls not directly facing true North this angle is lower than 34º.

Each test was 24 hours long. Heat flux measurements recorded at night were more consistent than daily measurements because at night all energy input into the specimen was from the heat lamp radiation without any interference from the sun radiation and also because it was easy to maintain constant room air and water temperatures. After an initial transient period of approximately 2 hours, daily fluctuations of the heat flux were up to 25%. Nightly fluctuations were less than 5%. Therefore nightly records were used for comparison.

3.4.2 Heat Conduction Tests

Specimen was tested over six consecutive days in complete darkness; no radiant heet was absorbed into the external surface of the bricks. For the first three days the room temperature was bellow the water temperature in the tank. It was done to generate conduction of heat from internal to external surface of the brick as it happens during the colder time of the year and at night. For the next three days the room temperature was above the water temperature in the tank. This conditions generated conduction of heat from external to internal surface of the brick as it happens during the hot time of the year and during the day time.

3.5 Test results

3.5.1 Heat Absorption Tests

Test results for the heat absorption tests are summarised in Figure 6. In this Figure the heat flux through the internal surface of bricks is plotted against the angle of the heat radiation source.

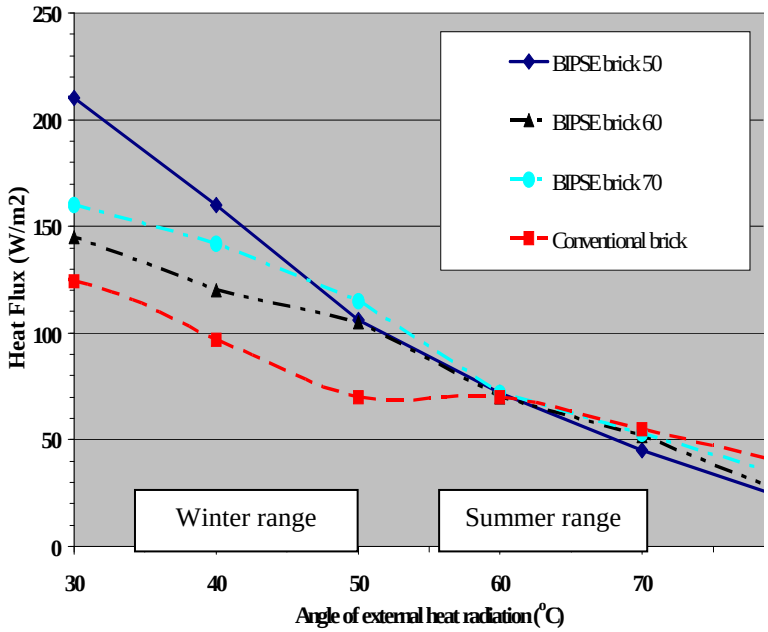

Figure 6. Summary of the heat absorption test result

In these tests all BIPSE bricks outperformed the conventional bricks at both ends of the heat source angle range. They absorbed more heat at low angles of the heat source and less heat at high angles of the heat source.

As was expected, the highest efficiency overall have BIPSE bricks with a 50º inclination of the upper rib face. The maximum heat flux of 210 W/m2 was recorded through BIPSE50 bricks. The maximum heat flux was achieved at a 30º angle of the heat source. At this angle of heat source the heat flux through the conventional brick was 124 W/m2, which is 41% lower than for BIPSE50 bricks. The minimum heat flux of 23 W/m2 was also recorded in BIPSE50 bricks at an 80º angle of the heat source. Corresponding heat flux in the conventional brick was 39 W/m2, which is 59% higher. In the middle of the heat source angle range (approximately 50º-60º) the heat flux though BIPSE70 bricks was higher than though other bricks.

3.5.2 Heat Conduction Tests

Test results for the heat conduction tests are summarised in Figure 7. In this Figure the heat flux through the internal surface of bricks is plotted over six days. Also in this Figure included plots for the room air temperature and for water temperature in the tank.

In these tests BIPSE brick was conducted more heat in both directions. It was expected because of its larger external surface. During the simulated “hot” days, the net effect of heat conduction was almost zero. BIPSE brick conducted more heat then the conventional brick from the external environment during the day. But it also conducted more heat into external environment at night. During the simulated “colder” days, heat conduction was unidirectional from internal to external surface of both bricks. BIPSE brick conducted approximately 70% more heat both during the day and at night.

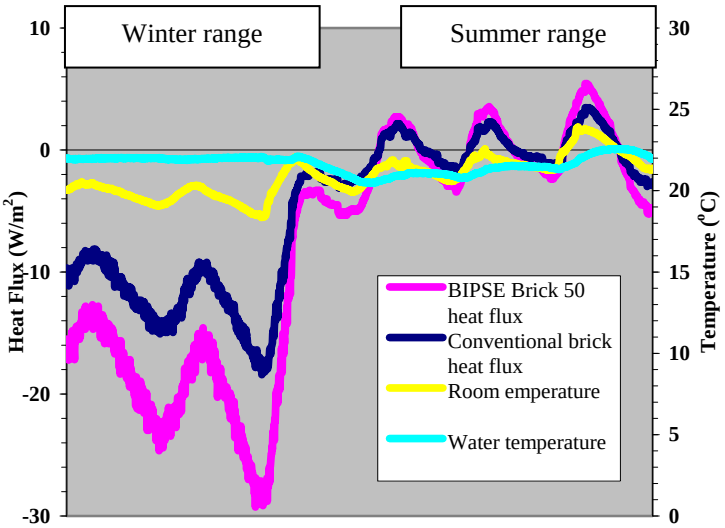

Figure 7. Summary of the heat conduction test result

Comparison of the heat absorption results in Figure 6 and the heat conduction test results in figure 7 reveals that the net effect in colder environment could be much smaller than observed in heat absorption tests.

4. CONCLUSION

A new brick with built-in passive solar efficiency (BIPSE brick) was designed at the University of Newcastle, Australia. The external face of this brick is not flat as in traditional brick but has horizontal ribs designed to increase the brick surface exposed to solar radiation in winter and reduce summer exposure.

BIPSE bricks can be made with minimal implications for the manufacturing industry and do not require any special bricklaying techniques. Apart from the improved solar efficiency BIPSE bricks have some additional architectural benefits: shades, texture, colour effects, contemporary appearance etc.

The experimental set up was developed to perform the heat conduction and the heat absorption tests and to compare thermal performance of traditional and BIPSE bricks. In this test the heat flux though the internal face of brick is was measured at different incident angles of the heat radiation on the external side of prisms or at different temperatures of external and internal surface of brick.

A series of heat absorption tests were performed on conventional and BIPSE bricks with different angles of inclination of the upper face of ribs. In these tests BIPSE bricks demonstrated better heat absorption properties to the conventional brick at both ends of the heat radiation angle range. They absorbed more heat at low incident angles of the heat radiation and less heat at high angles of the heat radiation. From these results it is possible to conclude that BIPSE bricks can potentially absorb up to 40% more solar energy in winter and up to 60% less solar energy in summer in comparison to traditional bricks.

A series of heat conduction tests were also performed on conventional and BIPSE bricks with 50^{o} angle of inclination of the upper face of ribs. In these tests the net heat flow through the brick was almost zero in warm environment. In colder environment BIPSE brick conducted approximately 70% more heat from the internal to the external surface both during the day and at night.

It is concluded that more testing is required and that the long term atmospheric in situ tests could be a better indicator of thermal efficiency of BIPSE bricks.

BIPSE bricks would be better suited to temperate or subtropical climate regions with mild winters and hot summers. The angle of rib inclination needs to be designed depending on a region's latitude. T 18

ABSTRACT

The use of electrical conductors such as graphite powder (GP) as mortar admixtures in order to obtain conductive cement-based materials suggests the idea of designing multifunctional materials for specific purposes. The main goal of the present work is to evaluate the effect of GP admixtures in the mechanical properties of cement mortars fabricated with different types of graphite powder. Four different types of GP were used as admixtures to Portland cement mortar samples: two of them are commercially available products and the other two are by-products of the fabrication of graphite electrodes. The carbon ingredients have been added both as an addition to the mix and as a substitutive of a portion of cement weight.

For all studied graphite powder types the mechanical properties decrease as the addition rate increases. For addition rate of 3%, the loss of compressive strength is between 0 and 10%. Therefore it is possible to obtain conductive mortars without important loss of mechanical properties.

1 INTRODUCTION

Concrete is a very versatile material because its properties can be changed by incorporating to the mix ingredients such as chemical products, mineral materials, fibers, etc. The mixes so obtained make it possible multiple applications of the new material using its new properties. Traditionally the research on cement-based materials for building and civil construction have been oriented to the material strength because of their main structural function. However in recent years new research lines have been conducted in order to obtain complementary functions of such materials, that is to convert them into "multifunctional materials" [Chung 2004]. Different categories of cement-based multifunctional materials can be distinguished. One of them is the electrically conductive cement-based materials. As regular concrete is a poor conductor (dielectric), different electrical properties can be obtained by the addition of conductive materials, for example graphite powder (GP) or carbon fibers. This way the resulting composite materials have special physical and chemical properties that make them suitable for new technologically advanced products [Chung 2000].

Even though the use of these materials means an important cost increase, the highly promising benefits that can be obtained, apart of the mechanical properties improvement, make them interesting. Among the functions that a conductive cement-based material can realise are the self sensing of internal strain, electromagnetic signal arrestor (EMI shielding) and deicing action on frozen pavements [Chung 2003].

The electrical resistance of concrete have been under study for many years [Hammond & Robson 1955]. Its efficiency as electrical isolator was demonstrated by the use of concrete sleepers for railways. It has been reported that concrete behaves as a dielectric when perfectly dry and shows resistivity values in the range of semiconductors when is humid or water-saturated.. In the latter conditions it has been demonstrated that that the internal pore system was the responsible of the conductive path [Monfore 1968]. Under the influence of an electrical field the migration of ions in the pore dissolution occurs and the material becomes an electrical conductor. Further studies have demonstrated that the concrete resistivity is closely related to the cement hardening and hydration progress [Roberts 1980] and that resistivity is a key control parameter in the reinforcing steel corrosion [Alonso *et al*. 1988], because it is dependent on the degree of water saturation of the pore system.

The residual service life of a concrete structure depends on the state of both the conglomerate and the reinforcing steel. In spite of the potential advantages that the addition of carbon material provide, there are very few references in the specialised literature on the effect that different types of carbon additions in concrete mixes produce on the mechanical properties and particularly in the corrosion rates of the reinforcing steel [Hou & Cheng 2000, Garcés *et al*. 2005].

Consequently, the objective of the present study is to provide an insight knowledge of the strength properties of mortars fabricated with different types of carbon materials. Four types of graphite powder (GP) were used in this research: two commercial types and two by-products of the graphite electrode industry.

2 EXPERIMENTAL

2.1 Materials and Methods of Mortar Specimens Fabrication

Portland cement type CEM I 52.5 R (CP) and silica sand normalised under UNE-EN 196-1 standard were used for all mortar specimens. Figure 1 shows the SEM images of the carbon materials used. Note the irregular particle shape. Sofacel graphite powder (PGS) is a commercial

brand of Le Carbone Lorraine Company with particle size lower than 0.63 mm. Figure 2 shows PGS in detail. The marked lamellar structure and the rough surface can be observed.

No. 9 Graphite Powder (PG9) is a commercial brand supplied by Superior Graphite Company, particle size lower than 75 µm, also shown in Fig. 2. The morphological differences between PGS and PG9 are notorious.

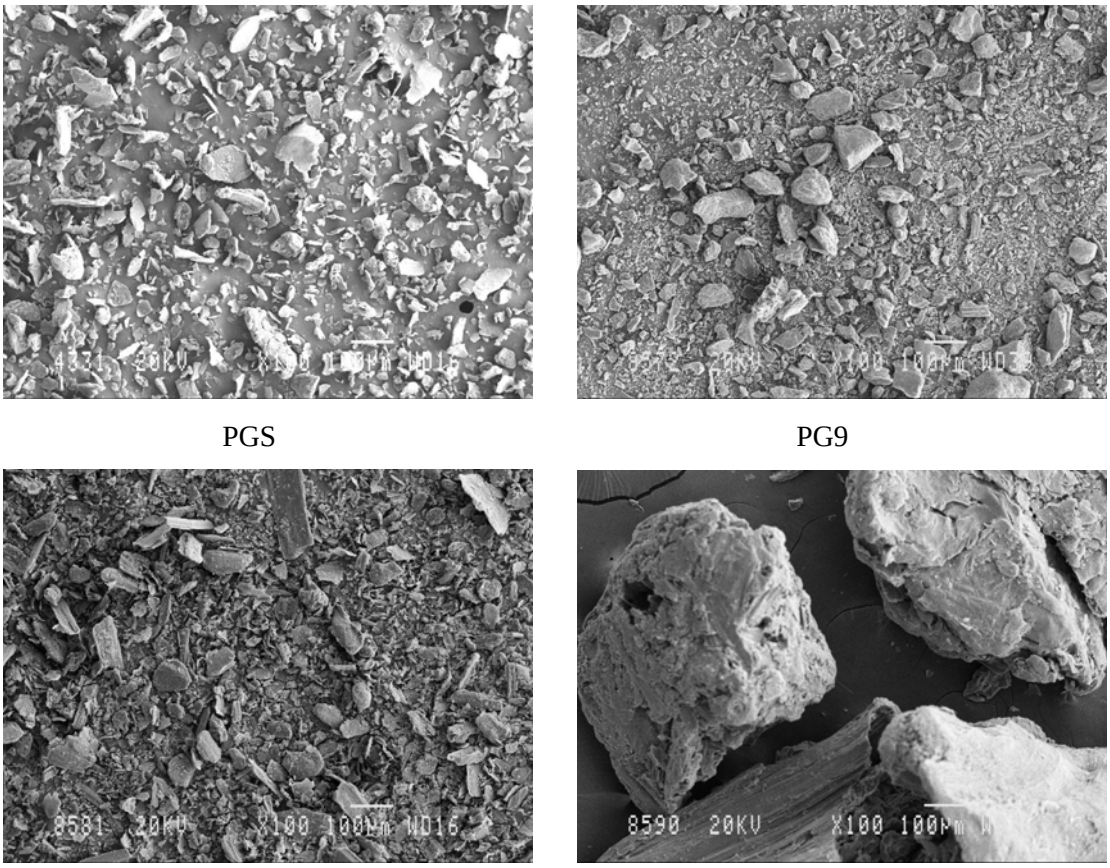

Figure 1. SEM images of carbonaceous materials.

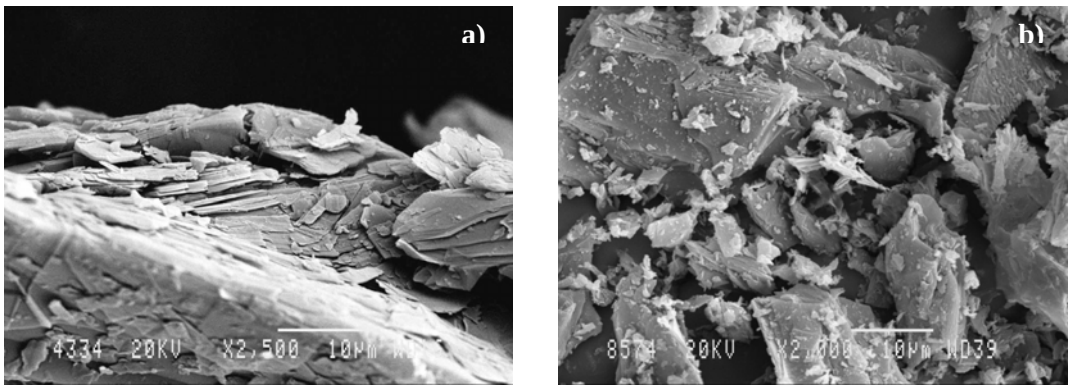

Figure 2. Details of (a) PGS and (b) PG9.

The graphite electrode maker Grafitos Barco has supplied two types of by-products of the fabrication of furnace conductor electrodes for the steel industry. Both have identical composition and the difference is based on the particle size distribution. PGA type contains a minimum 90% of particles under 50 µm size, whereas PGC type contains a 90% of particles with average size in

the range 0.5-1 mm. Table 1 shows the element composition of each type of graphite powder. The high content of carbon in all of them (more than 98%) is to be noted.

Table 1. Chemical analysis of carbon admixtures.

Sample	*Elemental Analysis (% wt.)*			
	C	*H*	*N*	$(S+O)_{dif}$
PGS	99.35	-	-	0.65
PG9	99.00	-	-	1.00
PGA and PGC	98.48	-	0.05	1.47

Figure 3 shows the particle grading curves obtained by laser light diffraction of the materials used in mortar fabrication. Only the fraction of sand passing through 0.16 mm sieve was used. The mean size value D50, that is the size value in µm under which 50% of the particles lay, is as follows: 15.9 µm for cement, 28.1 µm for PG9, 28.8 µm for PGA, 41.2 µm for PGS, 79.7 µm for sand and 355.7 µm for PGC. With the exception of PGC all graphite powder types have grading curves laying in between the cement and the sand grading curves. A filler effect can then be expected for those materials.

All paste and mortar specimens were fabricated and cured at 20ºC. The GP was included in the mix either as an additional component of the binder or as a substitute of part of the cement mass. In the first case the binder is only the cement mass, whereas in the latter case (substitution) it has been considered that the binder is the cement mass plus the content of GP. With these premises the weight ratios used in the mix formulation were 0.5 for water/binder and 3.0 for sand/binder. For strength testing the GP weight ratios in mortar specimens were 0% (reference), 0.5%, 1% and 3% both as addition and as cement substitution.

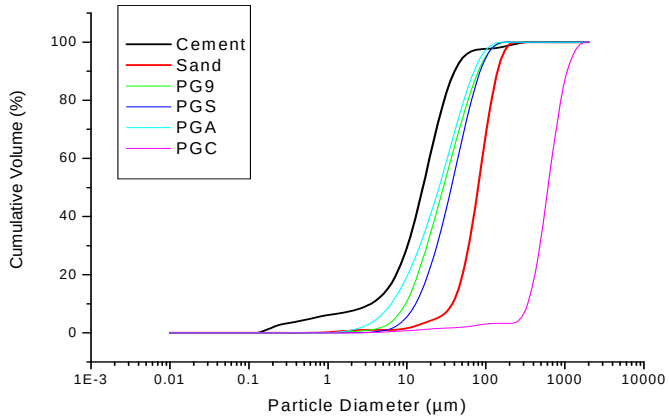

Figure 3. Particle size distributions of the GP types, cement and sand in the experiments.

2.2 Mechanical Tests

The mortar consistency was determined according to standard UNE 1015-3. The mechanical tests were performed in laboratory ambient conditions according to standard EN 196-1. Prismatic mortar specimens of 4x4x16 cm size were fabricate in two layers with mechanical compaction. Specimens were cured submerged in water and the tests were carried out at ages of 2, 28 and 120 days. Flexural and compressive strengths as well as accessible porosity were determined in the mechanical test specimens.

3 RESULTS

Chart of Fig. 4 shows the 120 day flexural strength results of mortar specimens fabricated with 0.5%, 1% and 3% of GP (relative to cement weight), for each of the GP types under study. Chart values are the ratio Rf_i/Rf_0, where Rf_i is the strength result of the specimen and Rf_0 is the strength of the reference sample. The chart reveals that with only 0.5% addition of any type of GP some improvement of flexural strength was obtained, being clearly GPC the type with the highest strength gain.

When the addition rate is increased to 1%, the flexural strength still improves, except for PGS type. The lamellar structure of this type of GP could be responsible for this result. However for 3% addition rate, none of the studied GP types reach the flexural strength of the reference specimens, with strength drops of 7%, 6%, 2% and 1% for types PGA, PGS, PG9 and PGC, respectively. The lack of continuity of the cement paste is not beneficial for the flexural strength when the GP addition rate exceeds some threshold value between 1% and 3%.

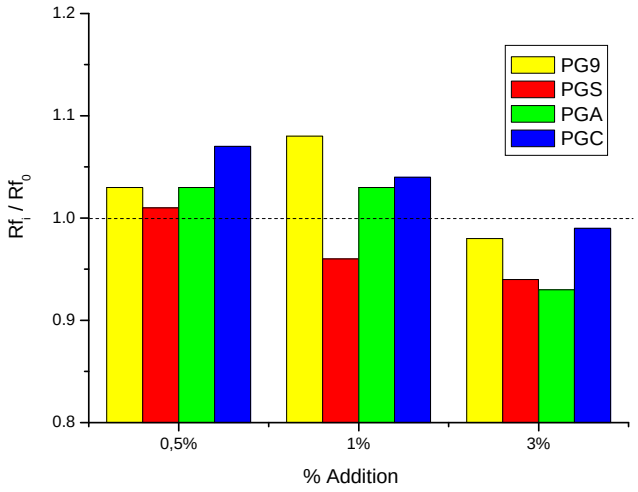

Figure 4. 120-day flexural strength of mortars with different GP types used as admixtures in various ratios. Y-axis values are Rf_i/ Rf_0, that is the ratio of specimen strength (Rf_i) to the reference mortar (no GP) strength (Rf_0).

Figure 5 shows the compressive strength values (Rci) at 120 days of mortars fabricated with different types of PG with addition rates of 0.5%, 1% and 3% of the cement weight. Y-axis values are Rci/ Rc0 where Rc0 is the compressive strength of the reference mortar (no PG). PG9 and PGS significantly improve the reference mortar strength for addition rates up to 1%. By-products PGA and PGC are only beneficial for addition rate of 0.5%. For higher addition rates of 3%, only the PG9 type reach the strength of the reference mortar. PGS, PGC and PGA types added at 3% rate produce strength losses of 8%, 9% and 10%, respectively.

Therefore, with the exception of PG9 type, the addition of GP in rates exceeding 1% produce a significant reduction of strength.

Table 2 shows the average diameter of consistency tests (mm) and the porosity values at 120 days of mortars fabricated with 3% additions of the four types of GP. The specimens with lower diameter show high porosity. These results are consistent with the ones of the compression tests because, with the exception of PGS, the drier is the mortar mix (lower diameter) the lower is the compressive strength.

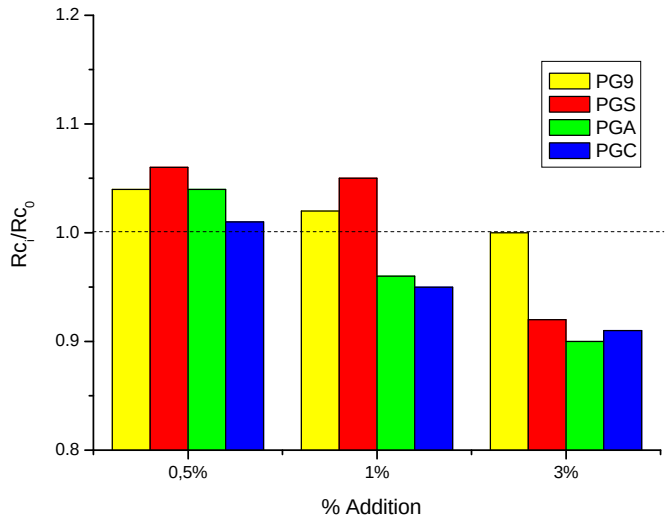

Figure 5. 120-day compressive strength of mortars with different GP types used as admixtures in various ratios. Y-axis values are Rc_i/ Rc_0, that is the ratio of specimen strength (Rc_i) to the reference mortar (no GP) strength (Rc_0).

Table 2. Average consistency test diameter values (mm) and porosity (%) of mortar fabricated with 3% of different types of graphite powder.

Parameter	*Control*	*3% PG9*	*3% PGS*	*3% PGA*	*3% PGC*
Slump (mm)	184	178	162	170	173
Porosity (%)	16.8	16.5	18.4	18.3	16.5

In general, it can be observed that the mortar strength decreases when the addition rate increases. According to Fig. 1 and Fig. 2, the shape of particles, rather similar for all types, does not seem to be responsible for the different behavior. The GP particle size does not explain it either, because the strength values trend is not consistent to the mean GP particle size trend and the grading curves are closed to each other and in between the curves of sand and cement. The differences in strength are then attributed to the different graphitation level of GP types (higher in the commercial types).

Figure 6 shows the 120-day compressive strength values, Rc_i of mortars fabricated with substitution of of 0.5%, 1% and 3% of cement weight by the four different types of GP. Y-axis values are expressed as the ratio Rc_i/Rc_0 with respect to the reference mortar (no GP) values, Rc_0. For 0.5% substitution rate, all types reach the reference mortar strength, except type PGA that shows a strength loss of 10%. For substitution rate of 1%, the loss of strength is 3% for all types, except for PGS that equals the reference mortar value. For substitution values of 3% all types show strength losses in the range 5%-10%.

Consequently, with strength loss smaller than 5%, it can be concludes that the substitution of cement by GP in rates up to 1%, it is possible to fabricate mortars in accordance to the mechanical prescriptions of standard UNE en 197-1.

This way it is possible to put in market value some graphite by-products (PGA and PGC) for the fabrication of mortars with cement content savings.

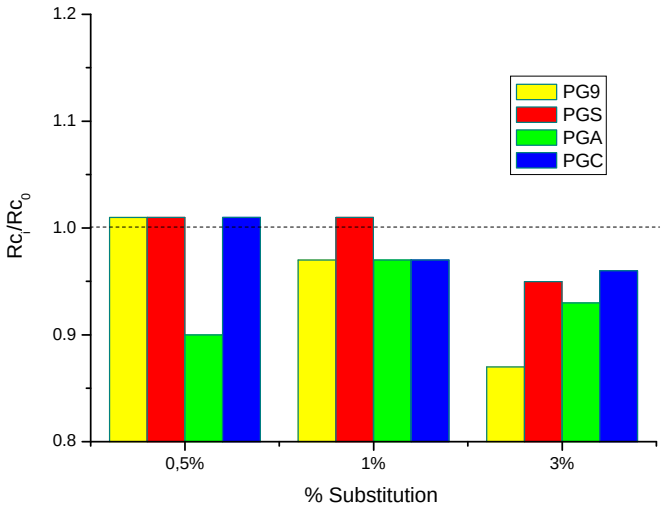

Figure 6. 120 day compressive strength of mortars with different GP types used as cement substitution admixtures in various ratios. Y-axis values are Rc_i/ Rc_0, that is the ratio of specimen strength (Rc_i) to the reference mortar (no GP) strength (Rc_0).

Nevertheless, the purpose of the fabrication of these mixes, specially with commercial types, is not to obtain gains in the mechanical behavior , but changes in the electrical conductivity of the resulting materials. The inclusion of a conductive material, such as GP transforms the non conductive mortar into a conductive mortar or concrete, making it possible the use for other functions and becoming a multifunctional material.

4 CONCLUSIONS

The overall review of the results allows the following conclusions.

1) For all studied graphite powder types the mechanical properties decrease as the addition rate increases. For addition rate of 3%, the loss of compressive strength is between 0 and 10%. Therefore it is possible to obtain conductive mortars without important loss of mechanical properties.

2) For the by product GP types (PG9 and PGC) the results show that their use for conductive mortars with some cement savings is feasible. This can be a contribution on sustainability and can be a way of making some GP products more valuable.

Seismic Rehabilitation of an Ancient Masonry Infill Steel Frame Building

Nouredine Bourahla [1]
Salim Tafraout [2]

T 21

ABSTRACT

Ancient buildings constructed in urban areas, particularly in Algiers, are typically 4 to 6 storey high and are made of stone masonry walls or infill light steel framing. These types of buildings are reputed to be vulnerable to seismic effects.

This paper presents a study on the renovation and required seismic upgrading of a 100 year old masonry infill steel frame building located in the centre of Algiers. The building is to be renovated for use as a modern art museum. The structure primarily consists of a light steel structure made of riveted steel trusses and columns having thick stone and brick masonry walls along its perimeter. The basement floor is made of shallow arches supported by steel beams (jack arch system) and the upper floors are wood-framed diaphragms. The building endured several moderate earthquakes that occurred in proximity to Algiers and as well sustained no significant damage from the Boumerdes earthquake (M 6.8) that occurred in 2003. The structure was numerically simulated using 3D finite elements models. The data, obtained from an extensive program of non-destructive and destructive tests on the constituent materials, were introduced into the numerical models and a series of ambient vibration tests together with modal analyses were performed to validate the mathematical models. A linear elastic analysis was carried out on the calibrated numerical model of the structure using the most recent elastic spectrum of the Algerian seismic code (RPA99 rev.2003).

Results of load combinations helped identify critical regions and seismic deficiencies. On the basis of these findings upgrade strategies and a solution for strengthening the structure are proposed.

1 INTRODUCTION

In seismic prone areas, structural masonry is seldom used for new buildings since most collapses and deaths in recent earthquakes are due to inadequate performance of unreinforced masonry buildings. However, most of ancient buildings constructed in those regions are made of stone or brick masonry walls or infill light steel framing in which masonry panels play dominant role in resisting lateral forces. Research on the seismic behaviour of masonry structures is nowadays almost entirely dedicated to existing buildings and to the issues related to assessment and reduction of their seismic vulnerability [Magines G. 2007]. Because of different degrading agents, old masonry buildings become even more fragile and need to be strengthened. The determination of the material characteristics in terms of stiffness, strength and energy dissipation capacity (cyclic behaviour) is required to assess the actual resistance capacity and to design an efficient retrofit scheme [Bourahla & al. 2002]. In this context fiber reinforced polymer (FRP) materials offer viable solutions to solve or lessen the effects of overloading. Extensive research work investigated the seismic behaviour of rettrofitted masonry structures both analytically and experimentally [Triantafillou T. C. 1998, Tumialan G. Et al. 2001, Elgawady M. 2006, Shrive N. 2006]. This paper focuses on the structural diagnostic of an old masonry infill steel frame to identify the structural degradations and assess the overall dynamic and damping characteristics using ambient vibration testing. On the basis of the dynamic analysis, critical zones were identified and a strengthening technique based on fibre-reinforced polymers was adopted.

2 DESCRIPTION OF THE BUILDING

The edifice is an ancient building constructed in 1909 and intended to be used as a modern art museum. The construction is an L shaped four storey building located in the centre of Algiers. It comprises two patios in the middle with a roof incorporating five domes made of steel frames with glass infill. A 16 m height minaret is located at one corner of the building (Fig. 1).

Figure 1. Interior and exterior views of the building.

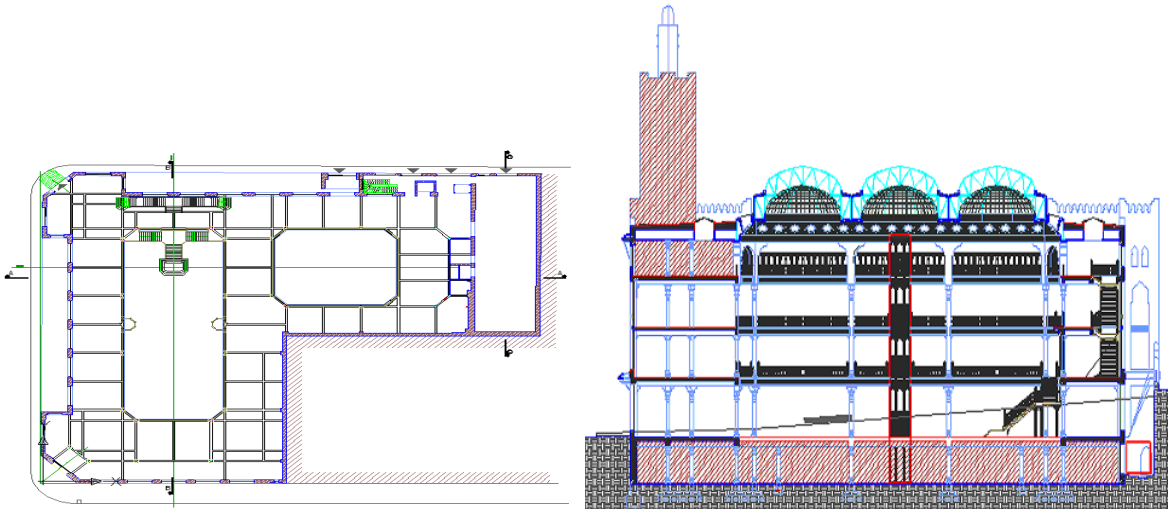

Figure 2. a- Plan view of the building b- Elevation view of the building

The edifice is supported by riveted light steel framing with peripheral stone/brick masonry walls of 90 cm thick used as a structural element to resist horizontal forces and part of the vertical loads. These walls are perforated by numerous window and door openings.
The slender steel columns are embedded in circular micro concrete sections to enhance their stability performance.

The building withstand several moderate earthquakes that occurred in the vicinity of Algiers and recently a major far field earthquake that occurred in Boumerdes 2003 about 40km away. An investigation of the building was carried out by a multidisciplinary engineering team. Beside the classical tests for material characteristics identification, a special attention was particularly made to investigate the building physically in search of any imprint the earthquakes might have left. The structural damage consists almost exclusively of widespread corrosion observed on certain steel elements because of humidity in areas subjected to water leak and exposed to sea environment. (Fig. 3).

Figure 3 a- Typical steel element corrosion b- column cross section

Damage inflicted by earthquakes is insignificant. It is thus somewhat extraordinary for such type of old building ---especially one with very tall stories, no substantial cross walls, a spacious multi-story interior sanctuary space and an irregular domed and gabled roof --- to resist the seismic activity for more than a century with almost no damage. On the basis of our studies, we conclude that certain specific dynamic characteristics of the structure and the exceptionally high material quality are largely responsible for this performance.

3 AMBIENT VIBRATION TESTING

The assessment of the structural resistance of existing constructions uses often mathematical models whose parameters can hardly be precisely estimated by analytical procedure only. Therefore, the elastic, mass and damping characteristics of the structure to be assessed must be known to a sufficient degree of accuracy in order to evaluate the actual structural capacity of the construction. The elastic dynamic properties, particularly the natural frequencies and the corresponding mode shapes are a combined measure of the structural characteristics of the construction. These model characteristics can be successfully estimated, especially in elastic range, using the well known ambient vibration testing. In this paper we present briefly the main issues pertaining to this particular modal testing; FRF measurement techniques, testing procedure, and modal parameter estimation method.

For this particular case preliminary modal analyses were first carried out and the fundamental modes were predetermined. On the base of these results optimum sensor locations were chosen nevertheless additional measurement points were also included to take account of any other modes that were not predicted by the analytical model. Measurement near the nodal point of any of the modes will omit that particular mode and aliasing effect is to be prevented by avoiding intersection regions of the fundamental modes to be identified.

The tests were performed using three degrees of freedom seismometer type Lennartz electronic (Le3Dlite) and a data acquisition system type City Shark II. The measured signals were processed using the GEOPSY program [Wathelet 2005] capable to perform most of the signal processing operations for the analysis of ambient vibration data. The sensors were located and oriented according to the previously defined test programme. The recording time for each sequence was set to 10 mn and found to be largely sufficient to obtain smooth transfer function curves. In total 24 measurement points were performed. Figure 4 shows the locations and the orientations of the sensors on the top floor.

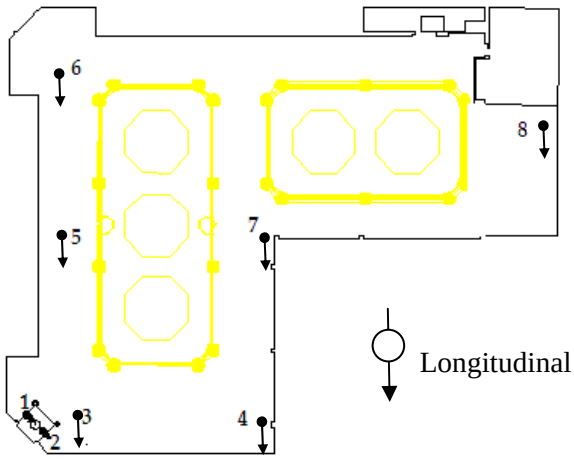

Figure 4. Locations and orientations of the sensors on the roof and the minaret

The natural frequencies of the structure were simply identified using a “peak cursor” on the Frequency Response Functions (FRF). Due to the complex shape of the structure, the individual vibration modes do not exhibit purely translational motions, but generally a coupled transversal, longitudinal and rotational motion. Thus individual Frequency Response Functions (FRF) have peaks corresponding to several modes. In one hand this enables to cross-check the measured frequencies but in the other hand closely spaced frequencies are difficult to identify.
The first few lower frequencies were identified (Table 1) and representative FRF curves are shown in Figs. 5 and 6. The continuous lines represent the average curves and the dashed lines are the limits of standard deviations.

Table 1. Natural frequencies and corresponding damping ratios.

Mode	*Frequency* [Hz]	*Direction*	*Damping* [%]
1	2.45	Longitudinal	1.05
2	2.70	Torsional	1.34
3	2.90	Transversal	1.05
4	3.35	Transversal	1.42
5	3.50	Longitudinal	1.88
6	4.25	Longitudinal	1.97
7	5.30	Longitudinal	2.21

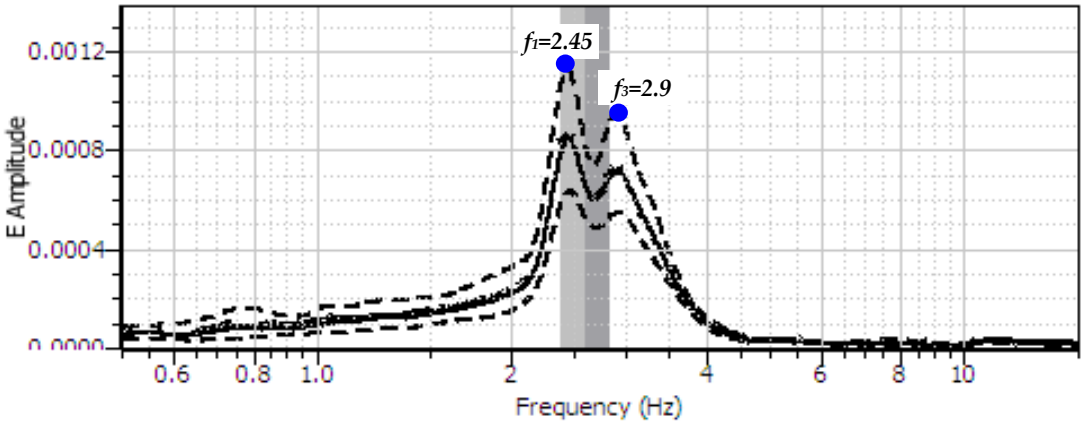

Figure 5. FRF curve recorded on point 2.

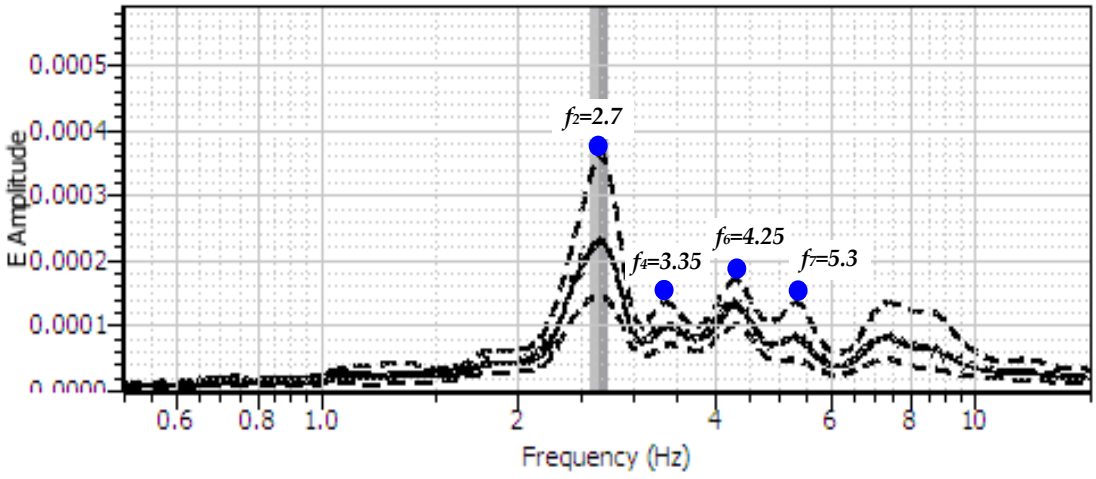

Figure 6. FRF curve recorded on point 5.

4 MODAL AND SEISMIC ANALYSES

In order to portrayed the elastic seismic behaviour of the building a three-dimensional analytical model was developed using SAP2000 [CSI 2004]. The model included the entire peripheral masonry wall system, the floor and roof diaphragms, and the steel framing (Fig. 7). A modal analysis was first carried out to validate the model. A minor adjustment of the elastic modulus of the masonry achieved reasonable correlation with the experimental results.

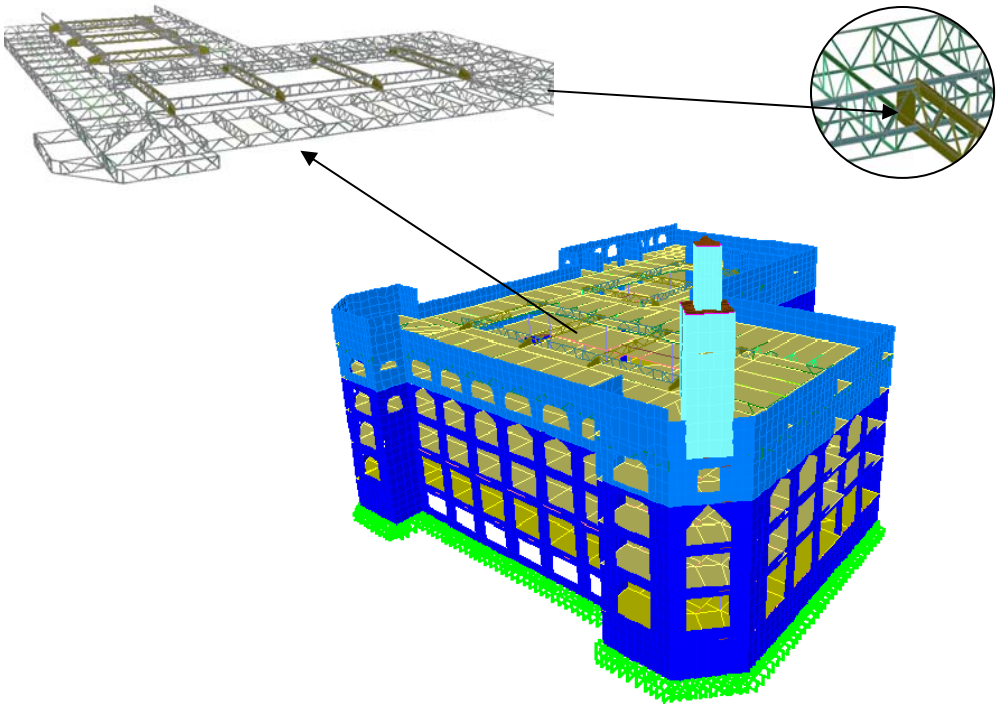

Figure 7. Three-dimensional analytical model.

A spectrum response analysis was performed by applying an acceleration spectra derived from the RPA99v2003 (Algerian seismic code). The seismic response of the building was studied in details to understand the vulnerability of each structural element particularly the masonry walls.
Figure 8 shows the stress distribution in the masonry walls where we can notice that the masonry around openings is subjected to substantially greater stress demand. On the basis of these results, several critical zones were identified for strengthening.

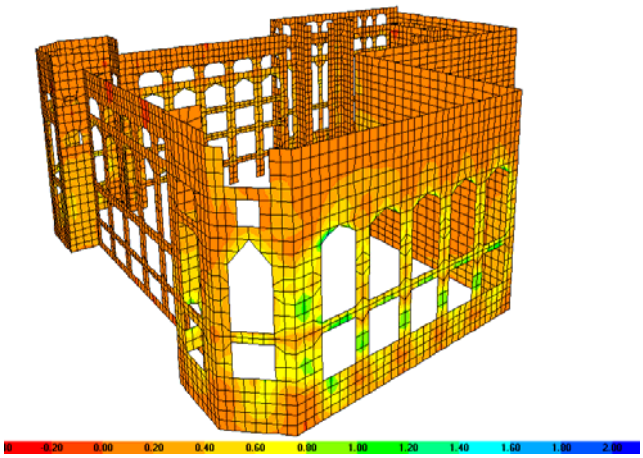

Figure 8. Stress distribution in the perimeter masonry walls.

5 STRUCTURAL STRENGTHENING

As outlined earlier, critical components are localised in the vicinity of the lower openings of the masonry walls. Considering the different strengthening schemes of masonry walls to enhance their in plane strength capacity, it was decided to use the technique based on the fibre-reinforced polymers

which is most suitable in this case because of the high demand to capacity ratio. Fibre reinforced polymers (FRPs) can be adhered to the surface of a masonry wall with epoxy to provide strength across potentially weak planes. Because of the high tensile strength of FRP materials, a fairly thin sheet can provide substantial strength and confinement to the masonry. Though lateral strength of masonry wall can be enhanced several fold using FRP sheets, inelastic deformation capacity may be limited as a result of debonding of the sheets which occurs suddenly with little ductility. Thus, FRP materials should be placed strategically on those piers that are likely to attract damage first so that alternate, and more ductile, mechanisms can occur. The locations and directions of the FRP sheets are indicated on Figure 9 according to the results obtained from the dynamic analysis. In order to relieve the high stresses around the lower openings on the wall, a reinforced concrete rings are provided as shown on Figure 10.

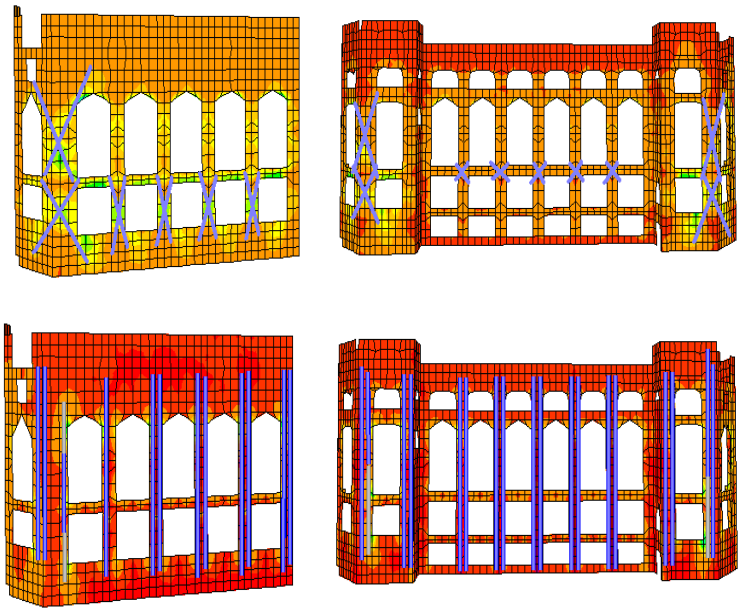

Figure 9. Fibre reinforced polymer locations.

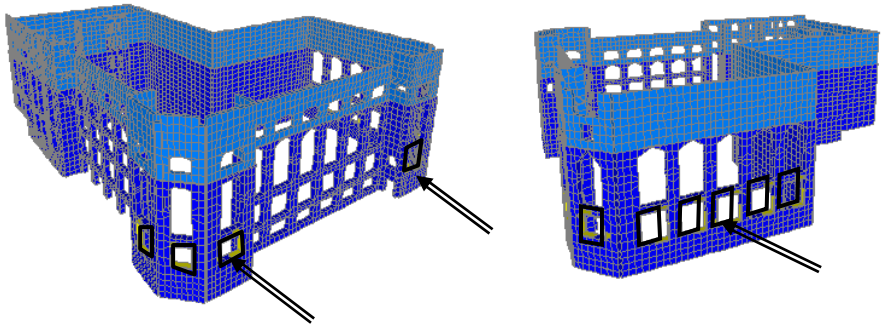

Figure 10. Reinforced concrete windows frames.

6 CONCLUSION

Ancient masonry bearing walls are reputed to be vulnerable to seismic loading. The old masonry becomes even weaker because of the effect of degrading agents which alter the strength and energy dissipation capacity that are distinctive characteristics to resist earthquakes. To rehabilitate such buildings, it is of paramount importance to evaluate their actual resistance capacity. In addition to

conventional material testing, the use of ambient vibration testing is efficient to determine the overall dynamic characteristics of the building. Based on simple dynamic analysis it is possible to determine the critical or deficient zones. Strengthening techniques based on fibre reinforced polymers is appropriately used for the particular cases of high demand to capacity ratio that had been detected in many locations of the perimeter walls. In addition, the high stress concentration around the big openings was relieved by using reinforced concrete rings. The combined upgrading technique offers an acceptable stability and strength increase and preserves the architectural aspect of the building.

Evaluation of Ceramic Tiles Frost Resistance Using Frequency Inspection Method

Marta Korenska [1]

T 21

ABSTRACT

The frequency inspection method is based on the physics of elastic stress wave propagation in bodies. An exciting impulse, being realized, for example, by a mechanical impact on the specimen surface, gives rise to low-frequency stress waves to propagate within the structure and reflect on cracks and the specimen surface. The specimen response to the exciting impulse is picked up on the surface by means of a sensor and transmitted to a computer for frequency analysis. The predominant frequencies may be associated with multiple reflections within the structure, carrying information on the structure integrity and defect localization.

The present paper deals with an experimental study of the frequency inspection method applicability to assess the long frost resistance of ceramic tiles. In order to verify the frequency inspection results and examine their application to the ceramic tile frost resistance assessment, we have also analysed some of the tiles' other properties, such as, porosity, the modulus of elasticity and deformability.

1 PASSIVE ACOUSTIC EMISSION

1.1 Introduction

The analysis was applied sets of ceramic tiles, which had been fabricated in HOB in year 2002. To assess the long frost resistance, the ceramic tiles were subject to 300 freezing - thawing tests to EN ISO 10545-12 [EN ISO 10545-12,1998].

1.2 Test Method

Prior to the tests, the ceramic tiles were immersed into a vessel containing water whose temperature was t_1 = 5°C. After having been pulled out from water, the specimen was wiped with a wet rag. Immediately after the removal from water, the ceramic tiles were placed in a refrigerating chamber. The tiles being frozen, the refrigerating chamber temperature was maintained at t_2 = -5°C for 15 minutes.

The freezing cycle being completed, the tiles were immersed into water for 1 to 2 hours in order to thaw out. The ceramic tiles were left lying in water till the test continuation.

A check measurement was carried out prior to stress cycle start and, subsequently, after the completion
of 50, 100, 150, 200 and 300 cycles.

A metal hammer of a mass of 169 g, which was hinged in a fixture ensuring a constant release level, h=2 cm [Plšková 2004], was used to hit the tile. The tile response to the exciting impulse was picked up by means of a piezoelectric sensor of Sedlák S7 type, whose operating frequencies range from 100 Hz to 50 kHz. The sensor was fitted to the tile surface at a point of coordinates x = 18 cm, y = 16,5 cm, i.e., in the maximum amplitude region [Martinek 2003, Plšková 2003].

The response voltage was fed into the input of a Yokogawa DL1540CL digital oscilloscope and further processed by means of a special signal-analysis software package. Fig. 1 shows the measuring apparatus.

2 MODULUS OF ELASTICITY AND DEFORMABILITY

2.1 Introduction

We have studied the variations in the modulus of elasticity and deformability using the bending test, and, furthermore, the flexural tensile strength values for ceramic tiles. Ceramic tiles had been fabricated in HOB in year 2002.

For the measurements to be practicable on a measuring apparatus complying with ČSN 736174 [ČSN 736174 1994], the ceramic tiles were cut longitudinally by means of a diamond saw, thus producing flat strips of a thickness of 100 mm. In this way, two test specimens arose from each ceramic tile. The first specimen was subject to the flexural tensile strength measurement, the second, to the determination of the modulus of elasticity and deformability from the bending test. Once the bending strength is known, the various loading steps can be specified. Table 1. presents the ceramic tiles.

Table 1. Description of ceramic tiles.

Type of ceramic tyles (Year of production)	*Specification of ceramic tyles*	*Number of freeze - thaw cycles to [EN ISO 10545-12,1998]*	*Dimension of ceramic tyles [mm]*	*Average value of water absorption [%]*	*Surfacing of ceramic tyles*
HOB (2002)	1, 2, 3	0	330 x 330 x 8	0,4	glaze
	4, 5, 6	150			
	7, 8, 9	300			

2.2 Test Method

The test specimen is loaded stepwise by forces F_1 through F_n, generating mechanical tension, which are growing up in steps of 10% of the flexural tensile strength, R_1. The load application and release is performed continuously at a rate of 250 Ns^{-1}. Let the transverse deflection corresponding to F_1 be $S_{tot,1}$. Then the load is increased to $F_2 = 2F_1$ and the total transverse deflection is $S_{tot,2}$. Subsequently, the load is reduced to F_1 and an elastic transverse deflection, $S_{t,2}$, is determined.

The total transverse deflection at the specimen span centre corresponding to F_n is calculated from the following equation:

$$f_{tot,n} = \frac{1}{2}(S_{tot,n} - 2S_{tot,1} + S_{tot,2}), \tag{1}$$

The elastic transverse deflection at the beam span centre corresponding to F_n is calculated from:

$$f_{e,n} = \frac{1}{2}(S_{tot,n} - S_{t,n} + S_{tot,2} - S_{t,2}) \tag{2}$$

Finally, the modulus of elasticity, E, and the modulus of deformability, E_n, are calculated from following equations:

$$E = \frac{F \,.\, l}{f_e \, b \,.\, h}\left[0{,}213\,\frac{l^2}{h^2} + 0{,}46\right] \tag{3}$$

$$E_o = \frac{F \,.\, l}{f_{tot} \,.\, b \,.\, h}\left[0{,}213\,\frac{l^2}{h^2} + 0{,}46\right] \tag{4}$$

where F denotes the specimen load in N, f_e is the elastic transverse deflection in mm, f_{tot} is the total transverse deflection in mm, b is the specimen width in mm, h and l are the respective specimen height and length in mm.

The flexural tensile strength, $R_{f,max}$, can be calculated from the following equation:

$$R_{f,\max} = \frac{M}{w}, \tag{5}$$

where M is the maximum flexural modulus in v N.mm and w is the section modulus in mm^3 with respect to the bottom filaments at the failure point.

The load was applied to the specimen via hard rubber bands. Two identical weights were applied at the 1st and 2nd thirds of the specimen span l. The maximum bending moment is calculated from the formula

$$M = \frac{F.l}{6}, \tag{6}$$

where F is the fracture load in N and l is the support distance in mm.

2.3 Experiment Results and Discussion

A HACKERT/FP2 100/1 pressing machine was employed for the measurements. To measure the transverse deflection, a dial gauge to 0,001 mm was used. The specimen dimensions were as follows: length L = 330 mm, width b = 100 mm, and height h = 8 mm. Fig. 7 presents a diagram showing the test specimen loading with a force F.

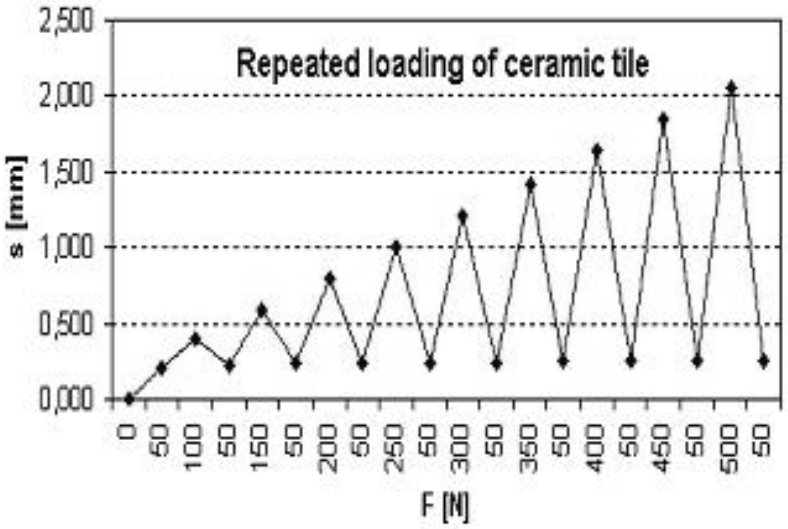

Figure 7. Repeated loading of ceramic tile.

The ceramic tiles, which have not been subject to the freeze-thaw cycles, exhibit an average flexural tensile strength of about 28 MPa. After the ceramic tile had been subject to 150 freeze-thaw cycles the above-mentioned quantity dropped to 27 MPa, i.e., 95.5 % of the initial value; and after 300 cycles, to 25 MPa, which is about 89 % of the initial value. Fig. 8 presents a value of modulus of elasticity and deformability of ceramic tiles. Fig. 9 shows a value of tensile strength of ceramic tiles.

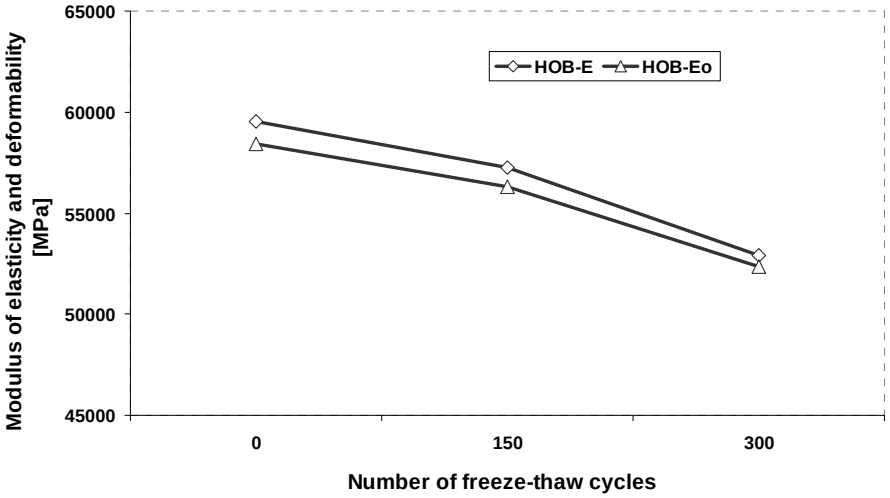

Figure 8. Modulus of elasticity and deformability of ceramic tiles.

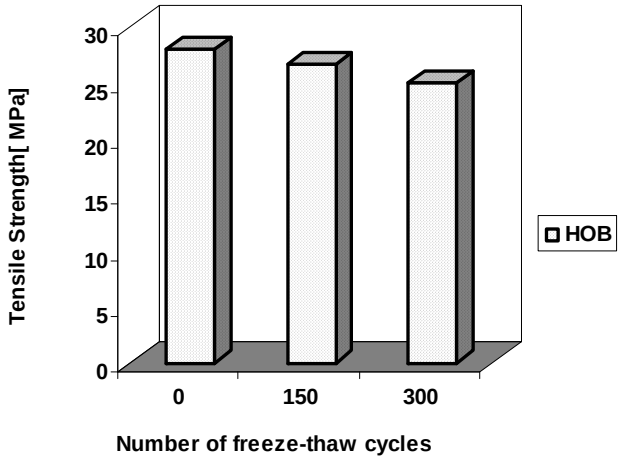

Figure 9. Tensile Strength of ceramic tiles.

3. CONCLUSIONS

The analysis was applied a sets of ceramic tiles, of a plain tile type, which had been fabricated in HOB in 2002. To assess the long frost resistance, the ceramic tiles were subject to 300 freezing - thawing tests.

With the exception of a single ceramic tile, only insignificant resonance frequency changes. Average values of changes of resonance frequency were 313 Hz by type HOB in the course of the freezing and thawing cycles. This gives evidence of a very good quality as well as frost resistance of this ceramic tiles types, from which a long service life may therefore be predicted.

From the results we can also see that the frequency inspection method is a useful non-destructive testing method being applicable to the evaluation of the ceramic tile structure condition and allowing predicting of the frost resistance and service life of these products.

An experimental study designed to determine the modulus of elasticity and deformability for ceramic tiles loaded by freeze-thaw cycles has been carried out. It is apparent that the ceramic tiles under test exhibited a very high flexural tensile strength and a surprisingly high modulus of elasticity.

With an increasing number of the freeze-thaw cycles applied, the flexural tensile strength goes down gradually. Fortunately, this decrease is rather moderate. After the ceramic tiles HOB undergo 150 freeze-thaw cycles, the strength decrease amounts to some 4.5% and after 300 freeze-thaw cycles the strength decrease to 11%. Thus giving evidence of a very good frost resistance of these products.

Influence of the Mix Proportion of Mortars and Paint Formulation on the Behaviour of the Mortar/coating system in Water Transport Phenomena

Kai L. Uemoto [1]
Neide M. N. Sato [2]
Vanderley John [3]

T21

ABSTRACT

The development of biological microorganisms on external walls of buildings painted with acrylic latex or PVA latex paints (emulsion paints) is frequent, generating unexpected building maintenance expenses. Inspections in painted façades identified stained areas due to biological growth of organisms such as fungus, while structural parts of the wall, in concrete, exhibit the original colour, indicating that the characteristics of the substrate are fundamental factors in the growth of these organisms.

The aim of this paper is to show the influence of the mix proportion of mortars and the paint formulation on the behaviour of the mortar/coating system in relation to water absorption and evaporation. The study was conducted with different painting systems: two acrylic latex, matt-finish and mid sheen-finish (semi-gloss), and one PVA latex, matt finish, were applied on mortars, with two different mix proportions, 1:0:3 and 1:2:9 in volume. Water absorption and evaporation were measured during one week and the water vapour transmission of paint films was also measured.

The experimental data showed that all coating systems, when applied on a porous substrate, are permeable to water to different extents. These substrates, when exposed to water, present high water absorption and the absorbed water is eliminated slowly.

1 INTRODUCTION

Absorbed water is the main deterioration factor of external wall surfaces [Uemoto et al 2001]. In order to prevent water penetration, the walls are protected by paints that provide a barrier on the surfaces and thus reduce the volume of absorbed water. The rate at which water moves in a material is determined by its permeability, which is strongly affected by the nature of the pores, both in terms of their size and the extent to which they are interconnected [Chew & Ping 2003] [Uemoto et al 2001].
Microbial growth in external painted façades is considered to be one of the most important maintenance problems throughout the world, especially in sub-tropical and tropical regions [Sato et al 1995]; [Chew & Ping 2003]. This problem is quite common in typical façades of Brazilian buildings (Figs. 1 and 2), as well as in other areas of the world [Sedlbauer 2001, 2002]; [Becker & Putterman 2002].

Figure 1. Dark stains caused by biological growth

Figure 2. Areas with dark stains caused by rainwater, on the façade of the building

The presence of biological microorganisms is the most significant factor in the performance of paints when the aesthetic function is desired. These organisms do not usually cause significant damage to the paint film or mortar, but they do produce disfiguring stains on wall surfaces. Different mortars and paints present different characteristics such as permeability, vapour diffusion and water absorption, resulting basically from the differences in the mix proportion of the mortars and the paint formulation.
If a painted façade presents high water absorption and has difficulty in diffusing the absorbed water due to the characteristics of the wall, like the presence of hollow blocks, the rainwater accumulated inside the wall can facilitate the development of biological microorganisms.
Paints are complex materials, formulated by combining a binder (resin), pigments, fillers, stabilizers, surfactants, solvents and thickeners. The proportion of raw materials defines the paint film performance. For example, the pigment-binder ratio (P/B), usually calculated on a weight basis, controls paint film gloss – a consequence of surface gloss and permeability to water and vapour. Gloss decreases and permeability increases as the pigment-binder ratio increases. However there is no linear relationship between these two factors, since changes are normally most rapid in the range from 0.9:1 to 1.1:1 [Tyssal 1964]. The relation between pigment and resin is internationally known as Pigment Volume Content (PVC), which is the volume of pigment (and filler) in the dry film divided by the volume of the whole dry film, and it is expressed as a percentage. This expression is often used by the paint industry and sometimes it is also referred to as Pigment Weight Content (PWC).

$$PVC = 100\left(\frac{V_p}{(V_p + V_v)}\right) \quad (1)$$

Where: Vp is the pigment (and filler) volume and Vv is the binder (resin) volume
PVC is a factor that directly influences the porosity of the paint, thus resulting in differences in permeability, adhesion, gloss, degree of protection to the substrate, mechanical properties like tensile

strength and elongation, etc. Table 1 shows the typical gloss and permeability obtained for different PVC values.

Table 1. Paint formulations associated with gloss levels.

PVC (%)	*Gloss*	*Permeability*
10 to 15	High gloss	Low
15 to 30	Semi-gloss	Medium
30 to 35	Sheen or "silk"	-
35 to 45	Low sheen or "matt"	High

Most of the published data measures the influence of paint formulation on vapour permeability by using a paint film. However, the paint substrate also affects the paint film performance in terms of mass transfer. This can be caused by variation in paint film characteristics and also due to the suction of liquid paint by substrate porosity. In practical terms, the paint and the substrate work as a system: both parameters control the surface mass transport phenomena. This fact is not well documented in the literature.

German standards establish limits of water vapour permeability and water absorption (DIN 18550-1; DIN 4108-3), based on Künzel's studies [1977 apud Wagner, 2000], to limit the effects of driving rain and condensation on building constructions in such a way that damage (e.g. fungus growth, corrosion) is avoided. However, these limits are climate dependent and have not been adapted to the Brazilian climate. Therefore further studies need to be developed in order to establish performance criteria for building constructions, including painting systems.

This paper examines the water absorption and loss of water by evaporation of mortars, with two mix proportions, painted with different water-based systems (latex sealer and latex paints). All products are commercially available.

2 EXPERIMENTAL PROGRAM

To evaluate the performance of different painting systems in inhibiting the infiltration of water in the substrate as well as to understand the water transport mechanism through latex paints, three latex paints with different resin compositions and pigment/binder ratios were collected from the consumer market, and two mortar substrates with different mix proportions were prepared. The evaluation method is based on the comparison of the water absorption and evaporation over a period of time in painted and unpainted mortar substrates.

2.1 Materials

2.1.1 Basic composition of the paint samples

In the study, one acrylic sealer, one PVAc latex (matt finish) and two acrylic latex (matt and semi-gloss finishes) were collected from the consumer market in the city of São Paulo. The products were characterized according to ASTM D3723-05 Standard Test Method for Pigment Content of Water-Emulsion Paints by Low-Temperature Ashing. The non-volatile content was determined by drying the sample at 105oC, and the pigment content, by drying at 450oC. The resin content was estimated through the difference between non-volatile content and pigment content. Table 2 shows the main characteristics of the products and the pigment/binder ratio (g/g).

2.1.2 Mortar specimen (substrate)

For a better simulation of in-service conditions, mortar specimens, measuring approximately 20cm x 10cm x 3 cm, were prepared and cured during 28 days. They were prepared with Portland cement, lime and sand, with the mix proportions most commonly used in Brazil: 1:0:3 and 1:2:9 (cement: lime: sand, by volume). After casting, the mortar specimens were kept for seven days in a wet

chamber with 95% relative humidity (RH) and then stored for over 30 days in a laboratory environment at (25 ± 2) oC and (50 ± 5) % RH.

Table 2. Basic composition of the paints.

Tests	*Acrylic Semi-gloss*	*Acrylic Matt*	*PVAc Matt*	*Acrylic sealer*
Volatile content (%)	53.1	47.9	51.7	34.0
Pigment content (%)	22.7	33.2	32.9	54.1
Binder (resin) content (%)	24.2	18.9	15.4	11.9
Pigment/binder ratio (g/g)	0.94	1.76	2.14	4.55

2.1.3 Specimen preparation

After the curing period of the mortar, one coat of sealer and two coats of latex paint were applied on the mortar specimens, with a nylon brush, according to the manufacturers' instructions. A set of unpainted specimens was used as control. All specimens (painted and unpainted) were sealed with a silicone sealant in the 10 x 3cm faces.

2.1.4 Film preparation

Liquid paint was applied to a PVC substrate (plate) with a drawdown bar (film applicator), with a nominal wet thickness of 150μm. The liquid paint films were dried at ambient temperature for seven days and, after this period, were separated from the plate. The "free" film was used to determine water vapour permeability through the paint films.

3 TEST METHODS

The effect of the latex paint samples on the relative change of water content in mortar substrates was determined by measuring water absorption and evaporation of the specimens and permeability of paint films according to the following methods.

3.1 Water Absorption

The test was based on BS 6477-92 Specification for water repellents for masonry surfaces. One of the 20cm x 10cm faces of both sets, painted and unpainted specimens, was immersed in deionised water, with the painted face down, to measure uni-directional water absorption. Water depth was maintained at 1/3 of the height of the specimens during the test. Water gain was determined by weighing the specimens at predetermined time intervals. The measurements were performed until the set of unpainted specimens, used as control, reached complete saturation. The tests were carried out in an environment at 25oC and 50-60% RH. The relative water absorption of unpainted and painted specimens is shown in Fig. 3. The results were expressed in terms of mass change as a function of time. The mean values of the results obtained from five determinations were expressed in kg/m2.

3.2 Loss of Water

The same specimens previously used in the water absorption test were displayed face up for drying in a controlled environment. In this test the faces that had not been exposed to water in the water absorption test were sealed with aluminium foil, and the face previously exposed to water was kept unsealed so that the loss of water occurred only through this surface. The loss of water was measured by weighing the test specimen at predetermined time intervals, until a constant weight was reached. The mean values of the results obtained from five determinations were expressed in kg/m2.

3.3 Permeability of Water Vapour through Paint Films

The rate of water vapour transmission through the paint film was determined without the influence of the mortar. Film permeability was measured according to ASTM D1653-03 Standard Test Methods for Water Vapour Transmission of Organic Coating Films, Dry Cup Method. The "free" films are fixed on top of a glass recipient containing an amount of anhydrous calcium chloride (desiccant). The whole set (recipient with the film) is weighed and placed in a climatic chamber, in a controlled environment, with temperature of 25oC and relative humidity of 50%. The sets are weighed at predetermined time intervals. The increase in weight is due to vapour passing through the paint film. The difference in weight was a measure of the permeability of the latex films. The medium results obtained from three determinations were expressed in ng/(Pa.s.m).

4 RESULTS

Table 3 presents the water absorption by capillarity (mean values of five specimens and standard deviation, Sd), after 24 hours of exposure, of unpainted mortar specimens with mix proportions of 1:0:3 and 1:2:9. Table 4 shows the results of water vapour transmission (mean values of three specimens and standard deviation, Sd) through the sealer paint films.

Table 3. Water absorption by capillarity (24h) of unpainted mortar specimens.

Mix proportion (volume)	*Water absorption (kg/m^2)*	*Sd*
1:2:9	4.63	0.21
1:0:3	3.04	0.10

Table 4. Water vapour transmission.

Samples	*Permeability (ng/(Pa.s.m)*	*Sd*
Acrylic sealer	0.330	0.0100
PVAc paint	0.067	0.0188
Acrylic paint (matt)	0.012	0.0004
Acrylic paint (semi-gloss)	0.011	0.0004

Figures 3 and 4 show the results of water absorption of the mortar specimens, unpainted and painted with PVAc latex (matt finish) and acrylic latex (semi-gloss and matt finish). Figures 5 and 6 show the results of loss of water of the mortar specimens, unpainted and painted with PVAc latex and acrylic latex.

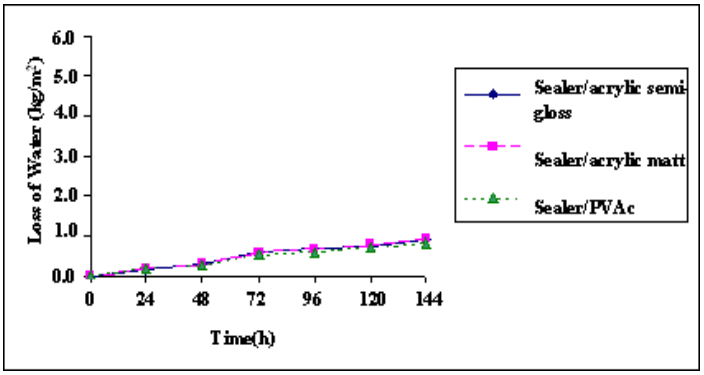

Figure 6. Loss of water of 1: 0: 3 mortar specimens, unpainted and painted.

5 DISCUSSION

5.1 Permeability of Water Vapour through Paint Films

According to Table 1, PVAc (matt) and acrylic (matt and semi-gloss) paints have different resin contents. According to the first author's studies [Uemoto 1998], the higher the resin content, the lower the water permeability. In this study the two acrylic paints did not show a significant difference in water vapour permeability: 0.012 (ng/(Pa.s.m) for matt finish and 0.011 (ng/(Pa.s.m) for semi-gloss finish. In the case of PVAc latex a more significant difference (0.067 ng/(Pa.s.m)) was observed, resulting from the higher difference in P/B and also from the difference in resin composition.

5.2 Water Absorption

According to Table 2, mortars with different mix proportions (1:2:9 and 1:0:3) present differences in water absorption capacities. Figs. 3 and 4 show that the paint formulation also affects the performance

of the mortar; the level of protection against water penetration varies according to the PVC and resin composition of the paint. The influence of the paint is more significant on more porous mortars, with a mix proportion of 1:2:9 (Fig. 3).

According to Figs. 3 and 4, the acrylic latex paint, semi-gloss finish, has the highest level of protection against water absorption, and the PVAc latex has the lowest level of protection. The water absorption rate shows a sudden decrease after 48 hours; longer exposure periods do not affect the moisture content of the specimens very significantly. Both unpainted mortars (1:2:9 and 1:0:3) reached saturation in 24 hours.

5.3 Loss of Water

Figure 5 shows that the evaporation (loss of water) process in porous mortar, mix proportion 1:2:9 (cement : lime : aggregate), is affected by the paint formulation. Paints such as acrylic latex, semi-gloss finish, greatly reduce the water evaporation rate, while more permeable paints such as acrylic latex or PVAc latex, both with matt finishes, allow faster loss of water. Also, the difference between the two acrylic paints is significant, despite the fact that their films present almost the same water vapour permeability, which suggests an interaction between the paint and the substrate.

Figure 6 shows that the evaporation (loss of water) process in less porous mortar, mix proportion of 1:0:3 (cement:aggregate; without lime), is independent of the paint composition. In such formulation, the paint had no influence on the loss of water, which is governed by the porosity of the mortar.

The rate of loss of water is always much lower than that of water absorption. In more porous mortar, mix proportion of 1:2:9 (cement: lime: aggregate), the paint's water vapour permeability is important to control the drying process. On denser substrates, like 1:0:3 mortar and concrete, the paint formulation does not seem to affect the drying process significantly.

5.4 Final Discussion

All the systems studied (mortar/sealer/paint) are permeable to water to different extents and the time necessary to eliminate the absorbed water is much longer than the absorption time. The water vapour permeability results (Table 3) of "free" films did not have any correlation with the evaporation results of painted mortar (Figs. 5 and 6). The permeability of the system is not only determined by the paint film, but also affected by the mortar characteristics; in the water evaporation process the phenomenon is very clear.

In more permeable mortar (1:2:9) it could be seen that the acrylic semi-gloss paint (low PVC) provides greater protection against water and probably other potentially harmful substances present in the environment. The acrylic matt paint (high PVC), with P/B of 1.76, as determined in the characterization test, does not protect the mortar against water penetration as well as paints with low PVC, with P/B of 0.94. In this case, the paint has only decorative but not protective purposes. In less porous mortar (1:0:3), the effect of acrylic paints with different P/B is observed mainly in the first 24 hours of water exposure. After this period the effect of different PVC is not as visible.

The application of paint is an efficient protection practice only in more porous mortar. For low porosity mortar the protection provided by the paint is of minor importance, once the substrate itself already presents low permeability. A less permeable paint such as acrylic semi-gloss reduces water absorption of the mortars; however, the loss of the absorbed water is also impeded by this paint. The water accumulated inside the wall can facilitate the development of microorganisms. Ideal "paintwork" needs to have low water absorption, such as acrylic latex, semi-gloss finish, and simultaneously allow the evaporation of the absorbed water, such as PVAc latex.

6 CONCLUSIONS

This study allows the conclusion that both paint formulation and mortar substrate mix proportion influence water absorption kinetics. In general, paints can reduce the water absorption rate in both substrates tested. The lower the pigment ratio, the higher the absorption reduction. On the other hand, paint formulation did affect water evaporation on the more porous 1:2:9 mortar. On the denser 1:0:3 mortar the porosity was the single factor which controlled evaporation.

The Maintenance of Colour on Finishing Coats

Pietro Zennaro [1]
Katia Gasparini [2]

T21

ABSTRACT

The maintenance of finishing coats is usually thought of as an activity relating to how the outermost surfaces of buildings affects the quality of the environment, today considered a matter of strategic importance. Appearance has gained in importance in its relation to substance, and this new way of reading the streetscape has meant that colour planning is an increasingly important activity. In many new constructions, particularly in non-residential buildings once banished to chromatic empiricism, more and more attention is being paid to choosing the colour of the external surfaces. However, if we are witnessing a new renaissance in the colour of buildings, the same cannot be said about the maintenance of these colours. The finishing coat is considered to be either strictly dependent on the behaviour of the underlying layers or completely independent of them. In the first case the skin is considered independently of the colour, in the second the inverse: the hue of the finishing layer is the most important aspect, independent of the behaviour of the support. It should be remembered that there is a long-standing tradition in which the finishing layer is considered a 'sacrifice layer' that does not require maintenance. The common idea of maintaining coloured layers involves the removal of the old layer and/or the application of a new one. If this method of maintaining the skins of buildings was acceptable in the past, the introduction of new products for the creation of thicker outer layers or products made from particular materials means that a new approach must be developed for the maintenance of entire blocks of layers. It would seem that durability, or persistency, is no longer considered to be an essential factor. Hue, lightness and saturation are no longer aspects that need to be conserved. The maintenance of colour finishing coats is considered of fundamental importance only in the restoration of historical buildings. On a hypothetical scale of priorities, where should colour maintenance lie today?

1 INTRODUCTION

The perception of material reality occurs through the detection of the outer layer of entities, apart from when they are transparent. Of course, no architectural product can avoid this rule. Both on the outside and the inside of configured spaces only the periphery of architectures is perceived: the last material threshold that is visible (or tangible, or that can be tasted, smelt or heard). This skin-like layer is that which, to a greater extent than other material aspects, is able to determine the quality of spaces, a quality strictly related to appearance. If this outer layer is visible it is bound to be coloured.

In fact a number of characteristics of materials contribute to the quality of the environment, the most important being the chromatic aspect of physical bodies and places. Visual perception occurs thanks to the variable presence of light that determines the chromatic sensation for each object. Colour is a psycho-physical sensation generated by the perception of a number of luminous frequencies emitted directly – or reflected – by physical bodies. The absence of light or the inability of the ocular-cerebral system to perceive certain frequencies produces a colour interpreted by the brain as black, black being the result of the inability of an object to reflect light in the range of visible frequencies (an object might reflect infrared or ultraviolet rays, but these cannot be perceived by the human eye).

The frequencies of the visible spectrum range from 4×10^{14} to 7.5×10^{14} Hz approximately; the simultaneous confluence of all the visible frequencies is perceived as white. A vast number of colours can be perceived between these two frequencies which, for convenience, are divided into six bands of tones (as defined by the CIE, Commission Internationale de l'Eclairage): violet, blue, green, yellow, orange and red.

The entire, complex set of materials and techniques used in the field of architecture relies on the thin layer of visible surfaces to stimulate our emotions. And if spatial configuration appears to be one of the fundamental concerns of architecture, it should be remembered that this is perceived – at least in visual terms – as chromatic variations which are dependent on a multiplicity of conditions (intensity and variation of the incident and/or reflected light, changes in the environmental conditions due to climate, season, humidity, changes in the colours of the surroundings, differences between the viewers, subjective and cultural interpretations, psychosomatic conditioning, defects in eyesight, etc.).

The outer layer of architecture, especially (but not exclusively) when covering the external surfaces of buildings, has always performed the function of representation to the public. In fact all buildings are seen more frequently from the outside by an indefinite number of people, many more than those who normally occupy its spaces. The external walls are also those that hardly ever display the same, constant colour due to variations in daylight caused by the rising and the setting of the sun, the changing seasons, the reflections of traffic, and many other external factors. These walls are also those that suffer most from decay as they are constantly exposed to the elements and to aggressive pollutants.

Apart from a few exceptions, the surfaces of the internal walls of buildings undergo a much less incisive chromatic variation than the external surfaces (thanks to artificial lighting, control of lighting obtained via curtains, blinds, windows with solar filters and other systems), and fewer variations caused by the reflections of the activity or movement of people and objects.

When external surfaces survive the filter of time then the whole building, or some of its parts, become historical because it constitutes a cultural inheritance left by past epochs, an aspect considered fundamental in the material evolution of mankind. Even if many of the architectures of past epochs are today completely stripped of their original colours and given different colours to those they had in the past, in turn becoming more or less illicitly part of history (for example the stones, marble and bricks stripped of their original plaster or of their intense colour or repainted with more recent materials), they can convey new images, the result of a fascination derived from a glorious, hypothetical, dreamlike past. This need to hypothesise a dreamlike past is the fruit of an idea conceived after the

events. All hypotheses, whether they concern the past or the future, seem to be forcedly adapted to the present.

The present era, in particular, refuses to accept the decaying of organic bodies or of man-made works. "Decaying and putrefied bodies" are repudiated in history as a method of contrasting the obscene… "Death is tolerated only when the bones are white: if architects are unable in their studies of 'healthy and robust, active and useful, ethical and happy peoples and homes' (Le Corbusier in *Vers une architecture*), they can at least find themselves at ease in front of the white ruins of the Parthenon. A young life and a decorous death, this was the motto of architecture" [Tschumi 1996] until almost the end of the XX century. Today life must be perennially young and any sign of yielding duly smothered using any method able to gloss over the signs of ageing, both in people and in buildings.

What we know in the field of the culture of materials is a story of external surfaces, a story subject to interpretation which can misrepresent the original as it is based on the reality of the present where plaster is perfectly smoothed, covered in flashy colours whose intensity is influenced by cinema or television where advertising promotes the increase in the level of tones and their chromatic saturation. Because nuances are no longer appreciated, an unprecedented violence is transferred to the walls of buildings, even in historic centres and even where so-called 'colour regulation plans' have been adopted.

In reality, the methods used to plaster and paint walls in the past led to the creation of rugged surfaces, covered with protrusions, planar irregularities, colours spread unevenly in several coats to the extent that they would break off in flakes or would be scraped away so that they could be seasonally 'refreshed', a new coat of paint being applied over the existing one. This is what maintenance consisted of. Today, from the point of view of the maintenance of finishing coats, especially where the choice of materials such as paint and lime has been imposed (materials which are inherently susceptible to decay), one must deal with a specific set of maintenance proposals.

2 MAINTENANCE

If, on one hand, the greater respect for places and an awareness of local cultures has led to the necessity to regulate the chromatic aspect of architecture of longstanding historical importance, on the other hand for new buildings – and for the renovation of relatively recent constructions or emblematic buildings – colour continues to be a 'surplus': a feature that is not considered necessary, applied following vague parameters. The final decision on the choice of colour is usually left to the amateur skills of the client and the contractors who are more used to addressing economic problems than those of environmental quality.

Furthermore, the considerable advance obtained with the introduction of materials and techniques by manufacturers means that there are very few limitations in the choice of possible colours. In the past the application of the colour blue (for example) on surfaces directly exposed to the sun's radiation was not considered suitable because it faded rapidly, today this problem has been sufficiently overcome by means of the production of materials that, exposed to ultraviolet rays, are altered to a much lesser extent than their predecessors. The choice of colours, no longer limited by the duration of the materials and the specificity of their application, is blatantly influenced by advertising. Tones and saturations reach levels never seen before in the field of construction.

Added to these developments in materials is the availability of a vast range of colours. Accustomed to hearing of printers or video screens that can produce millions of colours, it is easy to think that such a broad choice could be made available for the finishing coats of buildings. However, a standard observer is unable to distinguish between more than 100,000 colours. So what is the point of offering a range of hundreds of millions of colours? Of course this is a marketing technique that results in the disorientation and confusion of the users: chromatic background noise with no real utility whatsoever.

Also the materials used are no longer dedicated to a particular use. There is no material for the colouring, painting, tinting of surfaces and decoration in general that does not contain a percentage of polymers. Even the basic colours of lime, imposed by a number of town councils for the facades of historic centres, contain a significant quantity of polymeric substances introduced in the materials to reduce the effects of being washed out by rain. Adopting these non-traditional products allows the colour to remain constant for a much greater length of time than when traditional lime-based tints with no additives are used.

Many products used for finishing can be applied to any kind of supporting layer as long as the support is pre-treated. To be more precise: as well as the adequate treatment of the support, the basic colouring product is the same and the variation occurs only by means of additives, a small percentage compared to the final quantity of product applied. This procedure is considered an innovation in which more know-how and less material is incorporated. In effect, this is the result of the optimization in production and storage of the materials.

To the external membrane, then, are attributed functions (thermal protection, salubrity, interactivity, etc.) that often cannot be supported by the layer of paint except for brief periods of time as they have to be, in the first case, useful for the protection of the underlying layers and, at the same time, representative. This tendency, of using any kind of supporting layer, seems to cry out to those who attempt to penetrate into the world of products for the construction industry the logic of specialization of the functional layers: one external membrane dedicated and specialized according to the context in which it is applied. Surely the approach to the maintenance of these layers, made with the materials referred to above, presents problems that are not easy to resolve, as this involves trying to identify the 'ingredients' of the materials, details of which are hardly ever revealed by the companies that produce them.

It is possible to obtain, as well as extemporaneous tones and saturations, materials with equally extemporaneous finishes, introducing a new representation of the external spaces. An emblematic case, in some situations in Italy, is the spread of the plaster or polished finishes in the external walls of buildings, as well as an unprecedented increase in the use of the same finishes for internal walls. The polished plaster finish, typical of certain interiors built in past epochs, when used externally will certainly present problems of lack of durability and accelerated decay, even if the materials have been specially produced for exteriors. Early crazing, microcracking or cracks that are more or less visible are the order of the day in these circumstances. The lack of elasticity and the low level of porosity lead to a condition of accelerated decrease in reliability of the surface finish. What form of maintenance should be adopted in these cases? Once the finish has started to deteriorate and depending on the result that needs to be obtained, one can:

1. substitute the previous layer with another of the same or different type, after having removed the old layer;
2. apply a protective layer of another type;
3. patch up the finish by re-plastering only the areas that have been damaged.

This is the procedure that is usually followed every time that an external surface needs to be repaired. Perhaps it should be remembered that "The purpose of colouring of walls is as much for the conservation of buildings as for the improvement of their appearance" [Donghi 1920]. The colouring or painting of buildings, and other structures, is the technique that – by means of the deposit of a very thin layer of material, carried out in various ways – is able to improve the appearance and increase the durability of the building. Usually this means mechanically depositing substances onto the surface of the bodies using tools such as brushes, rollers, pads, spatulas, etc. or with spray guns. A similar effect is produced chemically or electrochemically. In this case one can no longer refer to it as mechanical application, but rather as coating or surface treatment. The most suitable techniques are chosen

according to the materials that make up the support on which the protective or expressive layer (colour) is deposited.

In constructions the supporting layer, usually treated so as to best receive these deposits, is extremely varied: from plaster to walls consisting of various materials (bricks, concrete, plasterboard, etc.), metallic surfaces, woods, glass, plastic, and new composite materials. Thus the building sector offers a range of possibilities of chromatic coating that is so vast that it seems to be difficult to find a single way of approaching the problem of maintenance. Carrying out maintenance work on buildings treated with a plaster finish or with an anodized finish is clearly not the same thing. Specific methods are required to return the finishing coat to the desired degree of quality. Once the colouring product has been applied to a support, it provides performance levels derived from its composition, from the method used for its application, from the behaviour of the supporting layer and from the external actions that it undergoes, being subjected to chemical, physical, mechanical and biological actions and actions related to the building's use. The intensity and duration of these actions contribute to determining its durability 'in the field'. Any kind of maintenance work has the task of prolonging the useful life of the building and guaranteeing levels of performance congruent with the potential that a painting product applied to a building can provide.

Carrying out maintenance is useful only if it never stops. But what is the point of discussing maintenance of finishing coats when these no longer exist? This is the case, for example, with finishes that are thick or with the insertion of pigment materials within plaster, the latter solution becoming operative in order to eliminate a phase of work: painting. Pigments are added to the mixture of the last layer of plaster so as to form a coloured finishing mortar. But while this requires a certain amount of technical know-how and suitable equipment for its application, in the application of plaster the workmanship is expressed by the plasterers. The figure of the painter is eliminated both for the exterior and the interior of buildings, with the use of white mortar and plaster finishing. Another professional figure is thus disappearing from the building site, caused by the desire to economise, the constant loss of professionalism and fact that technical and practical know-how is no longer passed on.

A practice that is becoming more and more accepted in the creation of surface finishes relies heavily on the need for continual mutation and the elimination of the need to carry out maintenance work (for example, the self-cleaning or pollutant-resistant glass or paints already widely used in infrastructures such as tunnels, road constructions, etc.). In a society used to instant change, the restoration of facades is of little interest because they should be frequently and easily modified. The buildings that make the skin a qualifying element of variation are significant, and the glossy architectural magazines are full of them. Maintenance seems to be considered a 'poor' activity, going against the idea of staying eternally young, beautiful and efficient. A comparison with cosmetic surgery, however, can remind us that to be in line with what is required by the rules of beauty one needs botox crèmes, injections of silicone and anything else that can modify one's image. The idea is not so much to maintain the efficiency of the skin but to obtain an appearance that can satisfy current fashions, even if the end result can appear monstrous. Thus in architecture it seems unnecessary for skins to perform their given function, as long as they appear congruent and can adapt to new styles. In this way even the action of maintenance becomes an action that modifies the pre-existing state with the aim of conforming to fashions, and the resulting 'new image' can be more or less different in relation to the preceding one, whether or not this change is useful or functional. The important thing is to *appear* adequate, despite not being adequate at all.

3 CONCLUSIONS

The change in the ways we perceive man-made environments, in particular man-made structures, has given rise to a number of changes that – in certain respects – can be considered epoch making, at least in the sector of coloured finishes. The application of colour on the walls of buildings is currently considered an operation of little interest from the point of view of the behaviour of the materials. It is

considered a cosmetic option having a lower priority than other processes; it follows the fashion of the moment and a subculture of the building sector.

Despite being considered strategic in terms of the image projected by a building (in a society in which image is decisive for the market), the outermost surface is normally thought of as unnecessary either for the improvement of the efficiency of the building system or for the layers to which it is applied. The decline in interest in this aspect is the result of a number of questions that have decreed its obsolescence. The first of these is the cost of labour.

A process such as applying colour to the walls of buildings has always required qualified and sensitive – and therefore expensive – skilled labour. To succeed in eliminating the need for this, or to reduce the time and number of methods needed for the application of colour, has required the availability of special materials that can be used on any kind of support. Thus the sector of painting products, or rather pigmenting products, has worked to create products that can have an almost infinite chromatic range and degrees of saturation that were previously unimaginable in the building sector. The drive to raise the level of saturation comes from the world of the media and of the need to make buildings emerge from their surroundings, the opposite of the historical assumption that buildings should be integrated with the landscape.

This has brought about an epoch-making change in the use of materials; these are no longer developed within the building sector but in that of polymers and chemicals in general, as well as the in the field of nanotechnologies. Methods and techniques have been studied to obviate the need for the stratum of colour to protect the underlying layer. The materials employed today are indifferent to the substrate, being able to adhere to nearly all types of building material. This has given rise to a radical change in the way maintenance is carried out. If in the past it was necessary to protect the last coloured layer, but above all the underlying layers, now – when the choice of materials and their behaviours is no longer restricted – the coloured layer serves a purely aesthetic function. The approach to maintenance has become specific, or rather specialized. Also the inclusion in the colouring material of substances that repel dirt and pollution has given the coup de grace even to operations of normal cleaning. In short, we have arrived at the threshold at which products can be used that repair themselves, clean themselves and regenerate themselves. Probably everything that approaches the level of nanotechnology is showing a potential similar to that of human skin whenever it suffers minor damage. And the layer of colour, exactly for this connotation of thin coating film, is heading in this direction, where maintenance can only be carried out following sophisticated, specialized and dedicated technologies, a long way from the historical repainting or 'patching up'. The other layers are left to their destiny, denied the precious protection that has always completed most works of architecture.

Investigation of Physical and Mechanical Properties of Clay Bounded Plasters Applied on Kerpic Buildings from Diyarbakir

Şefika Ergin Oruç [1]
Bilge Işık [2]

T 21

ABSTRACT

Earthen material is preferred all over the world due to its easily workability, economical and ecological concern. Both on rural and urban areas some of the earthen structures can be considered as architectural heritage of the country. For that reason investigation must be carried for maintenance, restoration as well as for new buildings.

Earthen material is mostly used in wall (Kerpic), floor and plaster applications. The wall surfaces can be plastered or not. In case of wall plastering, the physical and mechanical properties of earthen wall should be taken into consideration. Clay bounded plaster is widely used on earthen wall surfaces. Clay affects the durability of plaster in terms of resistance against external impact. Therefore, plaster properties should be investigated in detail for determining their durability. The study can run on new test sample program or test can be carried out on existing walls or plasters.

This is a study on clay bounded plaster on existing earthen wall in rural areas of Diyarbakir. In the study, physical properties of the plasters have been examined on the samples that were taken from Yuvacik village, Diyarbakir/Turkey. Experimental results have showed that the material does not deteriorate due to water absorption and vapor permeability properties are determined as suitable.

1 INTRODUCTION

Earthen material (Kerpic) is mostly used in wall, floor and plaster applications. The wall surfaces can be plastered or not. In case of wall plastering, the physical and mechanical properties of earthen wall should be taken into consideration. Clay bounded plaster is widely used on earthen wall surfaces. Clay affects the durability of plaster in terms of resistance against external impact. Therefore, plaster properties should be investigated in detail for determining their durability. The study can run on new test sample program [1] or test can be carried out on existing walls or plasters.

This is a study on clay bounded plaster on existing earthen wall in rural areas of Diyarbakir. In the study, physical properties of the plasters have been examined on the samples that were taken from Yuvacik village, Diyarbakir/Turkey. Experimental results have showed that the material does not deteriorate due to water absorption and vapor permeability properties are determined as suitable.

2 ADOBE WALL SURFACES

Structural walls can be constructed with various earthen materials. Earthen walls and their surface **perform** according to the properties of the main material and the additives. The wall surfaces are exposed to different environmental conditions. To reduce damages from environmental conditions, plaster can be applied to the surfaces of the walls. If so, the plaster should possess some properties considering the required durability.

Environmental **impact** leads to damages at external wall surfaces throughout the time. These effects could be physical, chemical and mechanical damages on the wall or plaster.

3 CLAY BOUNDED PLASTERS

Clay bounded plasters are vulnerable to water. Erosion can occur due to water exposure. Such cases new plaster can be applied for renovation. The study will contribute to the new plaster decision.

The properties of plasters that can be used on to earthen wall vary in respect to origin and amount of binders, aggregates and additives. The most used binders are clay-cement, clay-gypsum, clay-lime, hybrid and straw fiber [2]. Straw added into clay based plaster prevent cracks due to shrinkage after applied to the wall [3]. Whitewashing on plasters contributes to durability of the envelope while decreasing the water permeability. Lime plastering could be also applied to external plasters.

Clay-cement bounded plasters have high strength and low elasticity. These plasters are sensitive against mechanical and thermal movements and can easily crack. Such plaster types should not be used as indoor plaster or external plaster over light-wall-materials (wall materials having unit weight less than 1000 kg/m^3) [4] which have low strength and part of building that any structural movement were expected [5] [6]. Therefore, their application is limited to buildings. They can be used externally on basement walls (stone or concrete) and reinforced concrete ceiling of buildings which are exposed to external conditions. Clay-cement bounded plasters are used in structure where continuous high humidity ratios and high abrasion exist. Usually shrinkage cracks occurred if the plaster is smoothed with trowel. Drying duration of the plaster is very closely related with atmospheric conditions. Flowering on the surface of the plaster can occur if soluble salts are in the soil.

Clay-gypsum mixed plaster type has low strength and elastic behavior. Gypsum in the clay undergoes reaction with clay minerals during hydration and the plaster gains durability. Plaster deterioration is low when compared with unstabilized clay bounded plaster. Clay particle in unstabilized plaster extends when exposed to water. Clay-gypsum shows a balancing behavior to heat and humidity [7]. They have smooth surface and dust production does not develop.

Clay-lime bounded plasters have low strength. They have good binding property and are less affected by water and humidity. These plasters can be easily applied to indoor and outdoor surface of the building. Clay-lime bounded plaster types should be preferred in applications on low strength and light structural materials and also active parts of a building. Its abrasion strength is low. Clay-lime plaster should be applied in two layers. In the first layer middle size sand and in the second layer fine sand should be used. Lime-composite has long duration for hardening process so, the second layer should not be applied immediately.

Hybrid plaster is composed of more than one binder; like lime and gypsum or lime and cement. Gypsum and lime bounded plasters should be applied to elastic surfaces with low strength. Cement and lime bounded plasters can be applied on heavy duty surfaces, both indoors and outdoors [8].

Cracking of earthen material or clay material is frequently encountered; therefore this deficiency should be resolved. The best solution for this problem is adding fibers like straw, linen, cotton stem and similar organic fibers into it. Straw is generally added to plasters for increasing its tensile properties [8].

4 EXPERIMENTAL STUDY

In this study, physical and mechanical properties of external plasters bounded with clay from existing wall were examined.

A structure built in 1967 at Yuvacik village of Bismil county, Diyarbakir province was chosen in order to conduct experimental study (Figure.1). Straw added earthen (Kerpiç) blocks were used in the structure and for plastering.

The samples for experimental study were taken from external plaster of the building and categorized as east (D1), north (K1) and south (G1).

Figure 1. The structure where samples were taken from.

4.1 Sieving Analysis

Sieving analysis of the samples was performed to determine particle size distribution and physical properties of the material according to TS 130 standard [9].

The results of sieving analysis are given in Table 1.

Table 1. Results of Sieving Analysis.

Sieve size (mm)	Over sieve weight (gr)	Sample percentage (%)
2	6,55	2,183
1	23,2	7,733
0,5	24,75	8,25
0,25	47,38	15,793
0,125	94,54	31,513
0,63	62,56	20,853
Under Sieve	41,02	13,673

4.2 Unit Weight, Composite-Porosity, Specific Weight

The experimental studies were conducted according to the Code TS EN 1936 in order to determine Unit Weight, Composite-Porosity, and Specific Weight of the material [10]. The results are given in Table.2.

Table 2. Results of the experiments.

Sample	Size (cm)	Weight (gr)	Unit Weight gr/cm^3	Composite %	Porosity %	Specific Weight gr/ cm^3
D1	1,53×2,23×2,91	9,98	1,01	41.06	58.94	2,46
G1	1,63×2,50×3,68	16,48	1,10	42.95	57.05	2,56
K1	1,28×1,28×3,32	6,24	1,15	44.75	55.25	2,57

4.3 Water Absorption Capacity due to Capillary Effect

The experiment for determination of water absorption capacity was carried out in compliance with TS EN 1925 standard [11]. Three samples were prepared as regular geometrical shapes and named as G1, K1, and D1 (Figure 2).

Figure 2. G1, K1, and D1 Samples Preparation.

The samples G1, K1, and D1 were completely wet in 25, 81 and 154 minutes respectively and the first one dissolved in 169 minutes, the second one dissolved in 121 minutes and the third one did not dissolve.

D1 sample was illustrated in Figure 3.

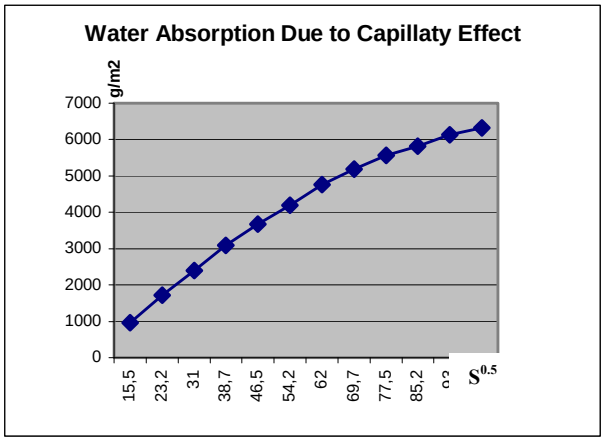

Figure.3 Water Absorption of the Samples D1 Due to Capillary Effect.

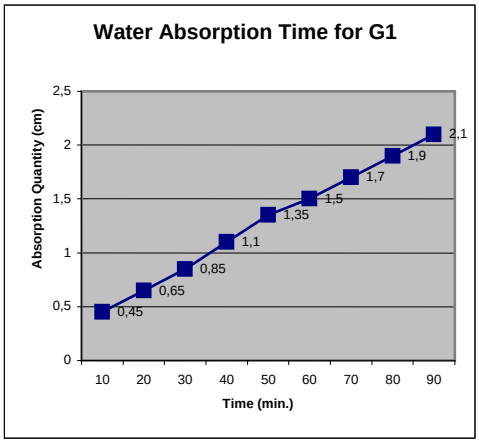

Figure.4 Water Absorption Time for G1.

4.4. Water Absorption Time

Water Absorption Time experiments for G1, K1, D1 samples were conducted according to TS EN 1936 standard [10]. Figure 4-6 represents water absorption times of the samples. The sample procedure is illustrated in Figure 7.

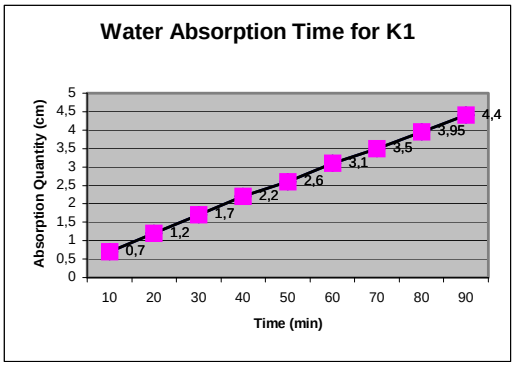

Figure.5 Water Absorption Time for N1.

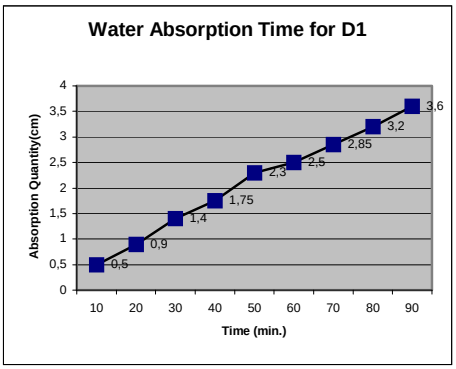

Figure.6 Water Absorption Time for E1.

Figure.7 Water Absorption Test.

Figure.8 Vapor Permeability Test.

4.5 Vapor Permeability

Vapor permeability experiments were performed according to TS 7847 standard [12] (Figure 8). The experiments were carried out for each sample and the results are given in Table 3.

Table 3. Results of Compressive Strength Experiments.

Sample	Dimensions (cm)	P_{max} Fracture Load (kg)	A Load Application Area of Samples (cm^2)	σ_k Compressive Strength (N/mm^2)
E1-1	2.58*2.89*5.15	450	7.46	6.03
E1-2	2.23*3.62*5.76	260	8.07	3,22
E1-Average				4,6

4.6 Compressive Strength

Compressive strength of the samples was determined according to TS 2514 standard [13] (Figure 9). The samples were cut as rectangular prism and the experimental results of two samples pertaining to E1 are given in Table 4.

Figure 9. Compressive Strength Experiments.

5 RESULTS

Properties of the materials used for structures are crucial for long duration and healthy buildings. Durability of envelope can be achieved through paints, plasters etc. The aim of the study is to determine performance of the clay binder plaster on earthen walls.

The samples for experimental studies were taken from external plaster of a house built in 1967 at Yuvacik Village of Bismil County, in Diyarbakir. Straw was added into plaster for better bounding in local technique. Damage at the external plaster was very low. Mechanical and physical properties of the samples were examined and the results are as follows:

Water absorption due to capillary effects of a sample according to TS 2514 standard states that a sample should not be dissolved before 45 minutes. In this study the G1 sample dissolved at 169th minute, K1 sample dissolved at 121st minute and D1 sample did not dissolve during the experimental period, which was 169 minutes. The results of this experiment show that the samples are resistant enough against deterioration.

Water absorption from 14mm tube measured is 3.6, 2.1 and 4.4 cm for E1, S3 and N3, respectively.

Water vapor permeability according to TS 7847 standard should be at least (1/μ.d) 0,5 m^{-1}. In this study these values are 5,13 m^{-1} 4,89 m^{-1}, and 5,33 m^{-1} for E1-, S1- and N1-, respectively. These results show the validity of the sample for vapor permeability period

TS 2514 standard for compressive strength on earthen block is minimum 0.8 N/mm^2 and the average of all samples should not be less than 1 N/mm^2. In the study these values were 6.03 N/mm^2 for E1-1, 3.22 N/mm^2 for E1-2 and the average was 4.63 N/mm^2. The results show that the samples are appropriate according to the TS 2514 standard.

Mechanical Behaviour of Non-bearing Brick Masonry Facades

Ignacio Oteiza [1]

Juan R. Rey [1]

T21

ABSTRACT

The non-bearing, fair-face brick masonry wall is one of the most commonly used enclosure systems in Spanish building, applied in over 80% of new construction. This system is a descendant of the bearing wall facades used ever since the Middle Ages. The solution initially adopted with the routine implementation of two-way concrete structures in the mid-twentieth century, consisting in a one-foot outer wythe, soon gave way (in the nineteen sixties) to a ½-foot outer wythe of fair-faced brick, a non-ventilated (insulated or otherwise) chamber and an inner stretcher bond wythe made of four-cm face brick laid on edge. This system poses mechanical, damp, thermal and on site construction issues that may lead to a series of pathologies, including facade collapse in some extreme cases.

The study presented forms a part of a research project (PROFIT) funded by the Ministry of Industry and Trade in conjunction with a number of contractors, the Spanish association of brick and tile manufacturers (Hispalyt), quality control organizations, the Polytechnic University of Madrid and the Eduardo Torroja Institute (IETcc). The paper discusses the results of structural trials conducted at the IETcc in connection with the mechanical behaviour of walls and their constituent materials. The results of these trials are compared to the mathematical models under evaluation at the Polytechnic University of Madrid to determine the form, recommendable dimensions and the use or otherwise of ancillary elements in non-bearing brick masonry facades.

1 INTRODUCTION

Brick masonry, one of the elements most profusely used throughout the history of western construction, continues to be the most common housing enclosure typology to be found in Spain. And yet design and construction records often contain very little information on this unit of work, a circumstance that is particularly significant against the backdrop of the recent entry into effect of Spain's new Technical Building Code. In the early twentieth century, masonry walls which since the Middle Ages had been designed to bear structural weight adopted a new function, with the attendant thinning of their dimensions from the prior 1 ½' to the present ½ foot. This reduction has posed mechanical, damp, thermal and on site construction issues that need to be explored and analyzed to prevent their degeneration into a series of pathologies associated with masonry exposure to the elements and on site construction conditions, which may in some cases lead to collapse of the building enclosure.

Recent studies on damage detected in masonry in-fill show that mechanical erosion is still routinely found in the form of scaling, cracks and fissures. This justifies an experimental study to substantiate present solutions, improve their implementation and attempt to eliminate the most common causes underlying such pathology.

2 DAMAGE IN WALLS

Generally speaking, damage may be classified into three main groups: physical, mechanical and chemical. Moreover, damage can rarely be attributed to a single cause. Mechanical damage may be **caused directly** by loading, overloads, thrust, impact or friction and **indirectly** as a result of faulty design, workmanship, materials or maintenance. Damage to masonry in-fill may be classified as mechanical, one of the most prominent causes being the disparities between portal frame and brick masonry stiffness values, which generate different degrees of tolerance to deformations; these, in turn, tend to appear at joints connecting the two elements.

2.1 Statistical Data and Trends

A number of surveys were conducted on the different types of damage detected in brick masonry in-fill and possible causes, from which the following trends were identified:

- Mechanical damage was found in at least 42% and in some cases nearly 50% of all the brick masonry in-fill surveyed.
- Mechanical stress was the direct cause of such damage in at least 18% of the cases.
- Inappropriate design was the source of at least 40% of the damage, presently accounting for 47%.
- Although in blank walls the percentage of damage per construction unit has declined slightly, it continues to be found in at least 25% of the total.

3 EXPERIMENTAL PROCEDURE

3.1 Characterization of Materials

In the first stage, research focused on characterizing the materials comprising brick masonry, via an experimental study performed at the Eduardo Torroja Institute for Construction Science (IETcc - CSIC, a Spanish National Research Council body). Six types of standard brick were analyzed. A photograph of perforated fair-face brick, the object of the research described below, is reproduced in Fig. 1. Its dimensions are: 240 mm x 115 mm x 49 mm. The mortars studied were all made from 42.5R CEMII/B-V type cement.

The characterizing of the components of walls built with conventional (designated type C) perforated fair face brick was conducted to the specifications laid down in Spanish and European standard UNE-EN 772-1 "Methods of tests for masonry units. Part 1: Determination of compressive strength"

Figure 1. Brick type C , Brick capping and Brick after testing

The results of the compression tests run on perforated brick (Figure 1) showed that the mean compressive strength of these units was 35.04 N/mm^2.

3.2 Standard-compliant Mechanical Testing on Small Walls

The primary aim of this part of the study was to analyze compressive and bending strength in brick masonry walls.

3.2.1. Compression tests on low perforation brick masonry walls, to Spanish and European standard UNE-EN 1052-1

Specimens measuring approximately 50 x 50 cm were prepared, each consisting of eight rows of perforated brick with one exposed face, received in a 16.6-MPa sand and cement mortar. One of the specimens is shown in Figure 2, both before testing, fitted with strain gauges on both sides, as well as during and after failure.

Figure 2. Test specimen before and after compression failure.

The specimens tested to a mean compressive strength of 12.55 N/mm^2. A second series of tests was conducted on three 50 x 50-cm specimens, made with 13.9 N/mm^2 mortar. In this case, the mean compressive strength recorded was 10.04 N/mm^2 and the modulus of elasticity was found to be 13092.63 N/mm^2, although the values of the latter parameter showed a wide scatter. The instantaneous stress-strain ratio, E, specified in the SpanishTechnical Building Code for masonry, is 1000·f_k. Applied to the mean strength obtained in the tests, this would call for a value of between 10000 and 12500 N/mm^2, i.e., generally lower than the mean values found with the standard tests.

3.2.1 Bending tests on low perforation brick masonry walls, to Spanish and European standard UNE-EN 1052-2, Part 2 (2000)

The object of this standard is the determination of the bending strength of clay-based brick and cement mortar walls. The standard envisages two different situations: where the failure plane is parallel and

where it is perpendicular to the bed or horizontal joints. Figure 3 shows walls tested for bending strength along a plane parallel to the horizontal joints. The specimens tested to a mean bending strength of 0.80 N/mm^2.

Figure 3. Failure parallel to bed joints.

Figure 4. Failure perpendicular to bed joints.

The mean bending strength found for walls tested along a plane perpendicular to the horizontal joints (Fig. 4) was f_{x2} = 2.19 N/mm^2.

3.3 Bending Tests in Full Size Walls

Two 5-m wide specimens, 2.5 and 3 m high, respectively, were tested. This test was run on walls ½ foot thick, supported at the top and bottom but not on the sides. The intention was to simulate the conditions prevailing in actual brick facades. A testing frame was built with rolled steel shapes, to be able to apply both vertical loads and horizontal loads perpendicular to the plane of the wall.

The first specimen measured 5 x 3 m. Figure 5 shows the wall after it was built, on the compression side, A (left) and side B (right), prepared for testing. The failure sequence is depicted in Fig. 6.

Figure 5. View of 5 x 3-m wall, side A (left) and side B (right).

A 6-kN/m (30 kN total) linear vertical pre-load was first applied to the top of the wall. This was followed by a five-minute stabilization period before the horizontal load was applied to the steel shapes used to distribute the load. The shapes were positioned one quarter and three quarters up the wall, generating two uniform horizontal load lines. A displacement gauge was positioned at the centre of the

wall to measure its horizontal movement. Deformation was measured with strain gauges placed on both sides of the wall. Three gauges were positioned along the centreline (1.50 m from the top) on both sides, one in the centre and the other two at 1.50 m from each edge of the wall. Data were recorded on a Solartron IMP datalogger connected to a PC.

Figure 6. Bending failure sequence for a 3 x 5-m wall.

The graph in Fig. 7 depicts the load – horizontal displacement curve at the centre of the wall, from the time the horizontal load was applied. A slight change was observed in the slope of the curve at between 12 and 13 kN due to the appearance of cracks in the masonry. At a load of about 18 kN, which prompted a 2-mm displacement, the slope changed abruptly due to cracking in the failure section, located around the upper horizontal load line in the wall. Failure occurred at a load of 24.42 kN and displacement of 6.90 mm.

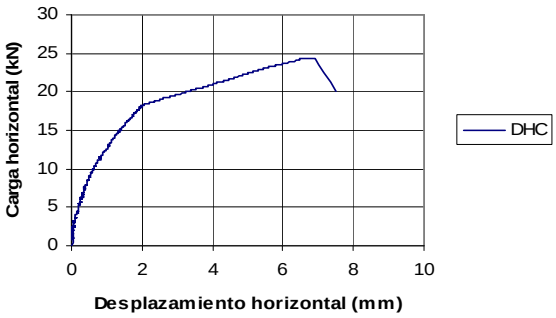

Figure 7. Load – horizontal displacement at centre of wall

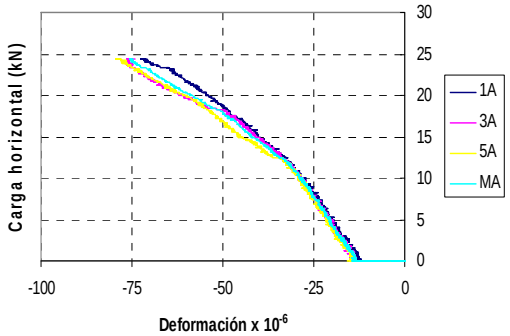

Figure 8.
Load – deformation on side A of the wall.

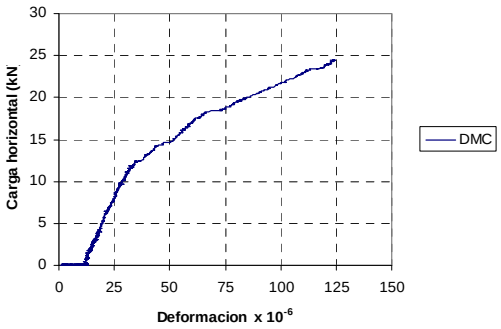

Figure 9.
Load – deformation on side B of the wall.

The graph in Fig. 8 shows the deformation at the centreline of side A of the wall, the side subjected to compression stress, recorded by gauges 1A, 3A and 5A when the horizontal load was applied. The curve labelled MA represents the mean of the measurements recorded by the three gauges. The initial deformation shown on the graph was due to the vertical pre-loading that preceded horizontal loading. This pre-loading generated bending stress due to load eccentricities (the eccentricities generated when

the load was applied to the shape positioned on the wall for this purpose cannot be determined exactly) and flawed construction, namely lack of plumb with the concomitant deviations in wall verticality or flatness.

The graph in Fig. 9 shows the mean deformation generated along the centreline on side B of the wall. Wall behaviour was approximately elastic and linear up to a horizontal load of between 12 and 13 kN. Up to this loading, the measurements recorded by the tensile side gauges were similar to the data logged by the gauges on the compression side. At higher loads, the wall began to crack, stiffness declined and buckling became more intense.

The failure load obtained was found to be 24.42 kN, or 12.21 kN per load line, while the surface load was 1.628 kN/m^2. The peak ultimate horizontal moment, disregarding both additional vertical pre-loading and second order eccentricities, as well as initial construction errors, was 0.75 x 12.21 = 9.157 kNm across the entire 5-m wide section (9.157/5 = 1.831 kNm/m).

For the central section of the wall, the vertical pre-loading-induced second order moment at failure due to horizontal deformation was 2.2% of the first order moment, i.e., practically negligible. Based on the initial deformation values obtained, the initial moment generated by vertical pre-load eccentricity plus eccentricity due to flawed construction may be estimated to be around 20% of the moment generated by the horizontal load. While hardly negligible, in engineering standards this load is taken into account as part of the additional eccentricities generated by construction errors, slenderness and lack of precision in the point where the vertical load is applied.

The second test was conducted on a wall measuring 5 x 2.5 m. The three snapshots in Figs 10 to 12 depict the failure sequence and the failure line generated.

Figures 10 to 12. Failure sequence, 5 x 2.5-m wall.

The wall was first subjected to a 30-kN/m (150 kN in all) linear vertical pre-load from the top down. This was followed by a stabilization period, after which the horizontal load was applied

The graph in Fig. 13 depicts the load – horizontal displacement curve at the centre of the wall, from the time the horizontal load was applied. The initial deformation or displacement recorded was due to the eccentricity induced by the vertical pre-load as well as other additional eccentricities occasioned by construction errors, namely lack of plumb and the resulting imperfect verticality.

At a load of approximately 15.54 kN, the wall cracked longitudinally at the lower horizontal load line, where the displacement recorded was 3.11 mm. The ensuing deformation to 10.63 mm was so abrupt that the testing machine was unable to maintain the thrust, resulting in a decline in both pressure and load. After this first failure stabilized, the horizontal load process continued until the peak test load was reached. Failure occurred at a load of 31.68 kN, when displacement was 13.02 mm.

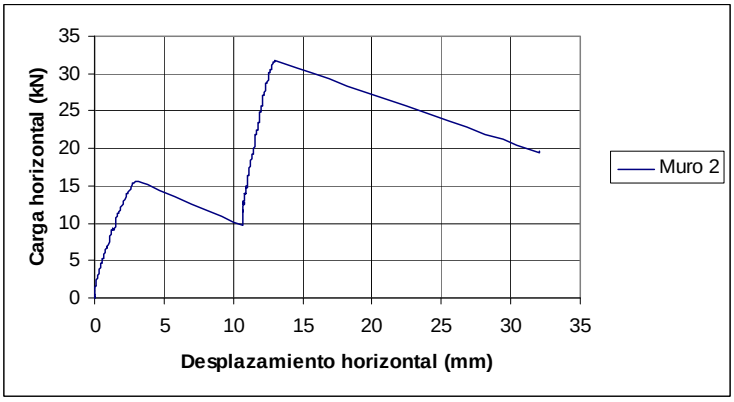

Figure 13. Load – horizontal displacement at centre of wall

The graph in Fig. 14 shows the deformation at the centreline on side A of the wall, the side subjected to compression stress, recorded by central gauge 3A when the horizontal load was applied. The initial deformation observed on the graph was due to the vertical pre-loading that preceded horizontal loading.

The graph in Fig. 15 shows the mean deformation generated along the centreline on side B of the wall, as recorded by gauges 3B and 5B. The graph shows the abrupt rise logged at a load of 15.54 kN.

The ultimate load found was 31.68 kN, or 15.84 kN per load line applied, for a surface load of 2.53 kN/m^2.

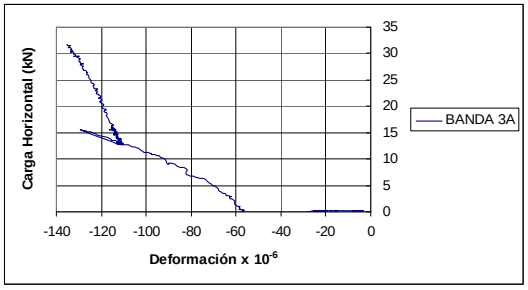

Figure 14. Load – deformation on side A.

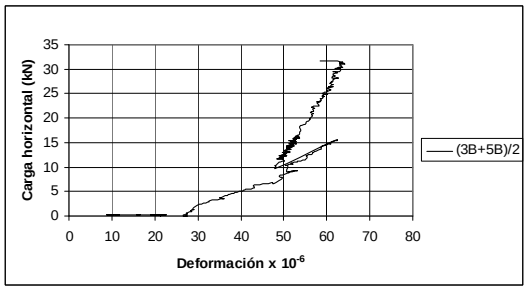

Figure 15. Load – deformation on side B.

4 CONCLUSIONS

Some of the results of a research project relating to the mechanical behaviour of walls and their component materials are discussed in the present paper. Compressive strength and modulus of elasticity were found for low perforation brick masonry walls with brick and mortar combinations used in standard construction. The values found for compressive strength ranged from 10 to 12.5 N/mm^2, while the modulus of elasticity varied widely, from 13000 to 24000 N/mm^2. Bending strength was also determined along the planes parallel and perpendicular to the bed joints, with the former showing mean strengths of from 0.8 to 1 N/mm^2 and the latter mean values on the order of 2.2 N/mm^2.

In addition, two full size walls one half-foot (11.5-cm) thick were tested to failure under horizontal loads. For the first wall, vertically pre-loaded at 6 kN/m (30 kN in all), the uniform surface failure load was 1.628 kN/m^2, with a deformation of 6.90 mm at the centre of the wall. For the second, vertically pre-loaded at 30 kN/m (150 kN in all), the uniform surface failure load was 2.53 kN/m^2. These values may serve as a reference for wind action calculations in wall enclosure design.

Durability of Highly-Insulated Timber-Frame Flat Roofs

Christoph Buxbaum [1]
Oskar Pankratz [2]

T 22

ABSTRACT

European roof structures in industrial and commercial construction (warehouses, etc.) are usually carried out in prefabricated reinforced concrete or with metal sandwich-panels. Due to the increasing requirements for the thermal protection of the building envelope, highly-insulated timber-frame flat roof constructions have become an alternative energy efficient method of construction.

The aim of the present study is the analysis and comparision of the hygrothermal performance and furthermore durability of non-ventilated light-weight flat roofs. The main focus is the assessment of potential risks of mold and especially wood decay funghi growth due to moisture accumulation inside constructions, if they are smooth-surfaced (i.e., without aggregate surfacing), or covered with gravel aggregate. Within the investigations, several numerical simulations were done. In particular, the effect of the selected modeled constructions (i.e., the interaction of different types of vapor retarders and membrane systems) on moisture behavior was estimated.

1 INTRODUCTION

This paper presents initial results of a study concerning the durability performance of non-ventilated, highly-insulated timber-frame low-slope roofs in the climate of Central Europe. The primary aim was to investigate the possible interaction of varying roof membranes and vapor retarders on the hygrothermal conditions of the chosen constructions. The calculations were performed for partially-attached systems with smooth-surfaced roof membranes and alternatively for gravel-surfaced membranes, which are often required due to fire regulations, protection from ultra violet (UV) radiation, against wind uplift forces, or simply demanded due to architectural aspects. The basic approach was to analyze the drying potential of unvented low-sloped roofs when different roof membranes and varying code-approved or modern vapor retarders are alternately used. It is important to note, that usally in Austria, according to code OENORM B8110-2, the protection against condensation is evaluated by using the dew-point- method (Glaser scheme). However this method only considers steady-state and very simplified boundary conditions. Neither realistic influences like solar radiation, wetting processes, etc., nor hygroscopic sorption or liquid transport are taken into account. The scope of this study is therefore to predict the long-term and therefore especially durability performance as realistically as possible by using transient hygrothermal calculations.

2 DESCRIPTION OF CASES

In frame of the research, prefabricated low-sloped roof timber constructions, which are uusally used in Austria, were analyzed with regard to their drying potential. These roof structures are typically constructed of a simple static structure consisting of timber beams 300mm (12´´), which are faced with bracing oriented strand boards on both sides. The space between the beams is assumed to be filled with mineral wool insulation. Based on this standard case, 10 different systems with varying roof membranes (having varying permeance and color) and vapor retarders were analyzed.

Table 1. Description of the investigated roof assemblies cases 1 to 10.

R 1	Vapor Retarder, Permeance = 0.0252perm (s_d- Value = 130m)
R 2	Humidity-Adaptive Vapor Retarder; Permeance = 13.12/0.328perm (s_d- Value = 0.25/10m)

As stated, the primary aim of this paper is to demonstrate the impact of different roof membranes with and without gravel surfacing and varying vapor retarders on the hygrothermal and durability performance of highly-insulated timber-frame low-sloped roof constructions. Thus, two types of vapor retarders were included; specifically those meeting Austrian standards and code-approved, as well as modern, humidity-adaptive products. Regarding surfacing, the chosen simulations were calculated without gravel and with gravel surfacings to investigate whether reduced surface temperatures might decrease the inward drying.

It is noted that the analyses were conducted under the assumption that the roof structures had good air tightness and insulation installation, and thus without convective vapor flow affecting moisture build-up.

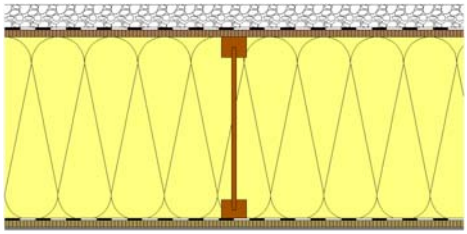

Figure 1. Schematic draft of standard case.

3 DESCRIPTION OF CALCULATION

The simulations were carried out by using the software WUFI®. (Wärme und Feuchte instationär – Transient Heat and Moisture), which was developed at the Fraunhofer Institute for Building Physics (Kuenzel 1994) in Holzkirchen / Germany and validated using data from outdoor and laboratory tests.

3.1 Default Program Settings

The heat transfer coefficient at the exterior surface was 19 W/(m²K), while that at the interior was 8 W/(m²K). For cases without gravel surfacing, short-wave solar radiation absorptivities of 0,5 and 0,9 were chosen for the grey-colored plastic membrane and for the black-colored rubber membrane, respectively. The slope of the roof was 2° northwards. Hourly weather data measured in 1995 in Holzkirchen / Germany represented the outdoor climatic conditions. The room climate varied as a sine curve between 20 °C and 30 % relative humidity in winter and 22 °C and 60 % relative humidity in summer. The initial conditions of the materials were chosen with a temperature of 20 °C and a higher initial RH. of 80 % (Karagiozis 1998). It`s noted that such a higher moisture content (i.e., 80 %) may be possible due to rain wetting during transport, erection work of large roofs structures or even flank diffusion over adjacent masonry (Kuenzel 1996). The material parameters required for each material were taken from the WUFI® material data base. The hygrothermal behaviour was simulated over a period of seven years.

4 SIMULATION RESULTS

This paper focuses on the “generally” hygric behaviour of the chosen roof assemblies. As is commonly recognized, the control of moisture is a critical part in the design of building envelopes. Hence the total water content and results concerning moisture accumulation in the “assumedly critical” exterior oriented strand boards were taken as the indicators of drying potential and risk of mold or even wood decay fungi growth.

A high intitial humidity of 80 % which is equivalent to ~ 16 % by mass in case of the oriented strand boards. These higher moisture conditions were chosen due to the fact that a non-regular dampening (i.e., wetting) of construction materials can always be possible due to rain penetration. Moreover for the evaluation undertaken in this paper, higher initial moisture conditions are quite useful in estimating the "real" drying potential of the materials (WTA, 2002).

4.1 Roof Systems without Gravel Surfacing:

Total Water Content (TWC)

First, simulations using roof systems (i.e. cases) 1 to 4 without gravel surfacings were carried out. Figure 2 shows the trend of the total water content (TWC) of these cases during the seven year period. It is clearly seen that all cases are showing a constant drying performance over the course of the seven years. It is also determinable that the humidity-adaptive vapor retarders, applied in cases 2 and 4, are having an significant effect on the moisture accumulation within these constructions. In these cases, the drying inwards is relatively fast; hence, it is not limited due to a vapor-tighter vapor retarder. The humidity-adaptive retarders have reduced vapor restistance at higher relative humidity levels and the vapor flow inwards is therefore not reduced. The total water content (TWC) of case 2 is leveling off at a seasonal maximum of ~ 2.25 kg/m² after about 4 years. In addition to that, the black coloring of the rubber in case 4 affords a higher drying rate. Higher temperatures at the exterior due to a higher radiation absorptivity of the membrane generates increased vapor pressure inwards and optimizes therefore the drying rate. So it is is clear to see that the capacity of inward drying should be considered as an important design factor (Powell and Robinson, 1971, Straube, 2001, Desjarlais, 1995).

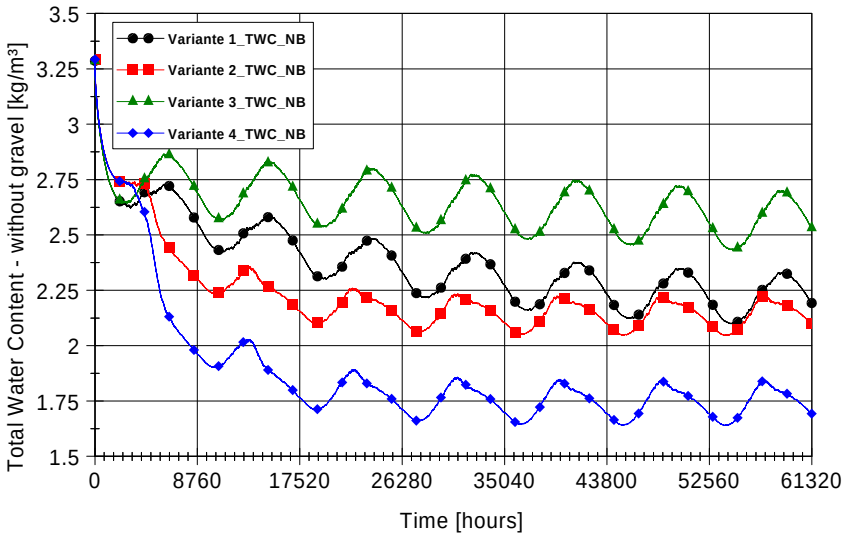

Figure 2. Total Water Content (TWC) of Cases 1 to 4, without gravel surfacing.

Water Content (WC) Exterior OSB Decking

The next step in this parametric study was to predict the moisture response of the wooden components and especially the exterior OSB decking. One can observe in Figure 3 that the moisture content of the OSB for cases 1 through 4 is decreasing over the years. In cases 1 and 2 it levels off at about ~ 13 % by mass, and in case 4 at ~ 9.5 % by mass. Only the moisture content of the exterior OSB in case 3 remains at a high humidity level for the whole period, decreasing from 18 % by mass to only ~ 16.8 % by mass. This effect is quite crucial for practical application, since the unscheduled moisture within the construction will be trapped between the vapor-tight exterior rubber and the interior vapor-tight conventional retarder for a longer time. This potential higher humidity level during long periods would endanger the risk of mold or even decay funghi growth and hence a potentially premature constuction failure.

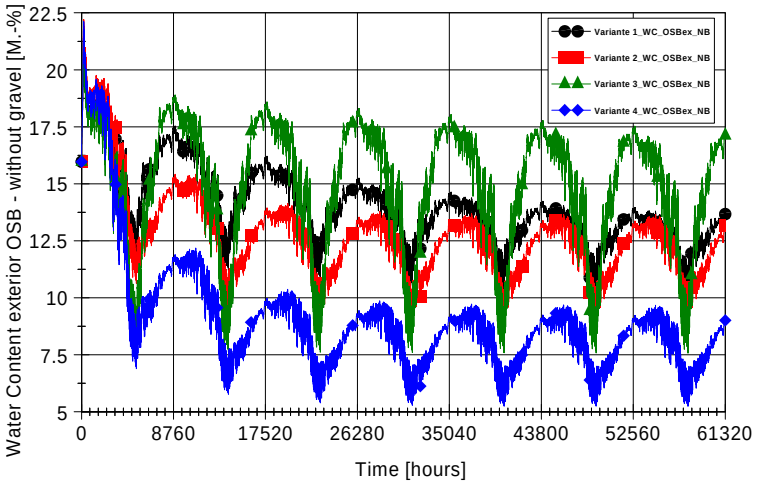

Figure 3. Moisture content (by mass) of the exterior oriented strand boards for cases 1 to 4, without gravel surfacing.

4.2 Roof Systems with Gravel Surfacing:

Total Water Content (TWC)

Next the previously discussed roof assemblies were again subjected to simulated modeling with a 5cm gravel surfacing above the membrane layers. Figure 4 depicts the TWC for cases 5 to 10. Starting again with initial moisture conditions of 80 %, it is now observeable that cases 5 and 7, which contain vapor-tight, code-approved vapor retarders, are showing a constant moisture accumulation. Especially the TWC of case 5 with the less vapor tight exterior plastic membrane increases rapidly. That would suggest that the lower vapor resistance of the exterior membrane is influencing the moisture uptake in a very special way. This affect is due to the high relative humidity level within the gravel layer during most time from spring to fall. Higher vapor pressures above the membrane are generating vapor flows from the outside, through the membrane, to the exterior OSB. That means that a vapor-tight membrane in cases with gravel surfacing would reduce the risk of an extraordinary moisture impact due to vapor flow from the exterior. Combined with vapor-adaptive retarders at the interior, the constructions are able to dry out.

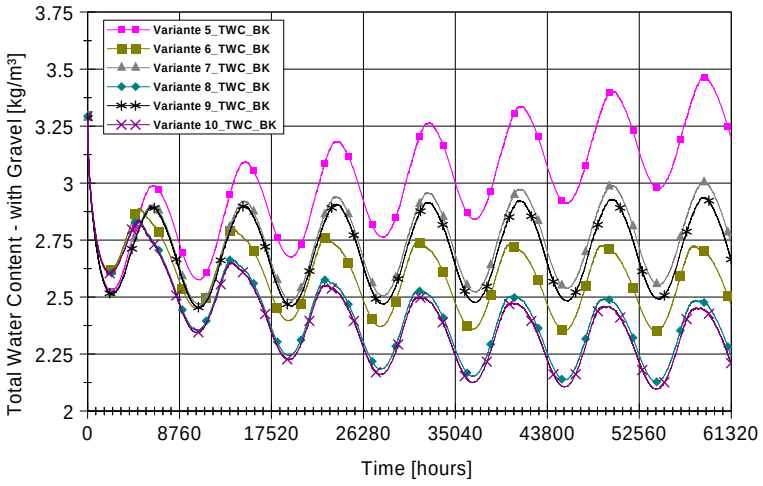

Figure 4. Total Water Content (TWC) of Cases 5 to 10, with gravel surfacing.

These effects are observable for roof assemblies 6 and 8, which include humidity-adaptive vapor retarders and therefore dry out over the course of the years. Tis is especially true for case 8 with the vapor-tight rubber membrane, which is showing an optimized moisture performance. It is also clearly evident that roof assemblies 9 and 10, which contain similar vapor-tight plastic membranes show comparable behavior to those cases with the exterior rubber membrane.

Water Content (WC) Exterior OSB Decking

The increased total water content ratios accentuate the need for a detailed investigation concerning the moisture contents in the exterior OSB. Note that according to the literature (Weiß et. al., 2000), wood decay funghi growth is normally possible at higher moisture contents, i.e., > 20 % by mass. The temperature tolerance varies between +3 °C and +40 °C with an optimum depending on fungi species lying at about +18 °C to +20 °C, but usually in building constructions a critical limit of about > 5 °C should be considered. The calculated results diplayed in Figure 5 indicate that the moisture content of the exterior OSB in roof assembly 5 after the 3rd year remains over 20 % and rises up to ~ 26 % during the simulation period. This wetting process, combined with favorable temperatures, dramatically assists the possibility of mold and wood funghi growth within a few years.

In addition to that, even the OSB in case 7, which includes a rubber membrane, tends to a slightly increasing moisture gradient over the course of the years. The moisture content per mass goes up from 18 % at the start to ~ 20 % in the 7th year. Hence moisture related problems like mold growth, but sooner or later even wood rot is likely to occure.

In contrast, the OSB WC of Case 9 is showing a steady state performance throughout the calculation period, apart from seasonal fluctuations, and remains under 20 % by mass. Anyway it is clearly observed that the drying potential is also limited, which means that unforeseen wetting processes will keep higher moisture levels over a longer period – a certain amount of risk can therefore also not be excluded.

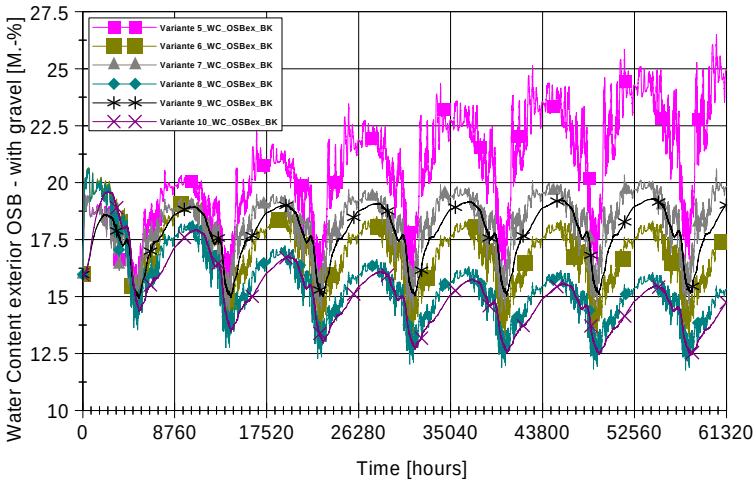

Figure 5. Moisture Content per mass of the exterior oriented strand boards in Cases 5 to 10, with gravel surfacing.

Only in cases 6, 8 and 10, where humidity-adaptive vapor retarders were applied, can it be observed that the assemblies are showing a drying performance and hence the risk of moisture related problems is limited.

6 CONCLUSIONS

This paper presents initial theoretical results concerning the hygrothermal behavior of non-ventilated, highly-insulated timber-frame flat roofs in the climate of Central Europe. The investigations indicated that the interaction of membrane systems and vapor retarders are strongly influencing the moisture migration and accumulation and therefore durability performance of low-sloped roofs in such timber constructions. Darker membranes are increasing the temperatures in the exterior part of the roof assemblies and therefore optimizing the solar-driven diffusion to the interior. Combined with humidity-adaptive vapor retarders at the inside, the drying process can rapidly be improved.

Timber-based roof structures covered with gravel surfacing are, as a matter of principles, more vulnerable. A sufficient drying rate is only found to be realizable if humidity-adaptive vapor retarders are incoporated in the system. For avoiding moisture build-up due to diffusion from the exterior, rather vapor-tight membrane systems should be used.

Refurbishing the Roof: Possibilities, Consequences and Policies in Building Rehabilitation

Ana-Maria Dabija [1]

T 22

ABSTRACT

There are some well-known axioms in regards to roofs:

- the roof is an important part of the building envelope and therefore it should fulfill the performance needs of the envelope, and in particular those associated with specific functions related to it's position in the building.
- the roof is the fifth façade of a building (many architects know this, from their own experience).
- the roof is one of the very important subsystems of the building that costs about 6 – 10% of the building and yet investors think it costs too much. (This is usually a statement of the roof builders.)

The roof is a component of the building that fulfills more than one major function – protection against incoming rain, snow, and wind. In different architectural cultures, the space below it accomplishes the task of storage, of drying room, smoke house, or of regular rooms, with the same hygrothermal performances as the rest of the house. According to the geographic location, the roof may be traditionally low-sloped or pitched. During the Art Nouveau and the Modernist Architecture period – and up to the present day – low-sloped roofs were designed in parts of the world where traditionally pitched roofs were used.

This paper presents some possible interventions for renovating roofs and problems the designer may have to deal with when refurbishing a building, and changing the geometry or the function of a roof.

KEYWORDS

Roof, Building refurbishment, Mansard-roof, Garden-roof, Renovation

1 INTRODUCTION

As everybody knows, the envelope of the building is a system that separates two different environments: the exterior one from the interior one. Therefore its contribution to achieving and maintaining a constant, comfortable (appropriate for the specific use) microclimate is very important.

Equipment (i.e., HVAC systems) is of course very important as well but the first barrier that receives the input from the exterior or interior environment is composed by three elements that "close" the building: walls, roof and the slab on the ground or over the cellar (or other type of cold basement). Both walls and roofs have the main task of protecting the building against weathering.

The main functions that an envelope should fulfill for the spaces it encloses are the following [Dabija, 2000]:

- protection against water (liquid and solid) intrusion
- hygrothermal protection
- acoustic protection
- fire and wind protection
- natural lighting and visual contact between these spaces and the environment exterior of the envelope
- natural ventilation

The roof, as a part of the envelope, has a role in fulfilling all these functions, but of course the performance needs of protection against rain, snow, wind are the ones that define traditionally this subassembly.

2 TYPES OF ROOFS

Historically, climatic conditions have generally dictated the type of the roof: low-sloped or pitched. Low-sloped roofs are often associated with warm European countries that experience little rain or snow; pitched roofs are common in countries where the quantities of rain and snow are significant. Of course, there are the modern high-rise buildings with low-sloped roof systems that have nothing to do with the traditional way of building. They represent another issue.

In Romania (and probably in other South-Eastern European countries as well), the attic was traditionally an auxiliary space (Figure 1) for preserving goods (sausages, for instance, were smoked there). In such instances due to the use of space, the roof was supposed to be cold and more ventilated. Thus, it was very much like a buffer space.

Figure 1. A traditional Romanian village house with smoke stains resulting from the "domestic" activity of preparing supplies for winter; smoke passes through the joints of the roof elements.

In many European countries (Central and Western Europe) the space under the roof was traditionally used for living. In these cases, the structural system of the roof as well as the corresponding walls were designed based on this hypothesis.

Today, contemporary houses in Romania normally consider the attic as a possibility for increasing the living area of the dwelling, so most of them have mansards (warm attics) under the roofs (Figure 2).

Figure 2. A newly built pension in Sinaia, Romania (courtesy, arch. Cristina Sandulescu).

Nowadays, when undertaking renovation, modernization or general repair projects, owners increase the living area of their houses by transforming the attic into comfortable dwellings.

The low-sloped roof is, in Romania as well as in other northern European countries, a consequence of the intensive, vertical development of the built environment. It is highly improbable that a high rise building (more than 5-6 levels) would have a pitched roof. The higher is the building, the more severe are the measures taken for ensuring it against wind and not only water and snow.

Taking advantage of general repair, the owners – or the designers – aim to improve the functionality or the performances of their buildings. Usually in such situations or in general repair, the existing waterproofing membrane is replaced - maybe (i.e., hopefully) - by another waterproofing system that would provide improved durability performance.

A frequent proposal for the renovation of the roof, that alters the functionality and adds to the modernisation of the entire building, is to add practically a condominium with a pitched roof that shelters a mansard. There are situations when such an approach is appropriate, but normally this step is presented in a too optimistic light, without mentioning the implications of such an action (see 3.2.3).

3 TYPES OF INTERVENTIONS

The paper focuses on appropriate and non-appropriate systems of renovations applied to existing buildings, and in particular the roof system. We will not address the most common types of repairs or current interventions.

3.1 Transforming an Existing Attic into a Mansard.

According to Romanian regulations [Athanasescu *et al* 2005], the attic is the space sheltered by the roof. It is not a warm space; thus, in other words, it is not a part of the envelope. The floor between the attic and the level below has to ensure the necessary thermal protection of the envelope. The roof

represents the protection against weathering but the space beneath it is a ventilated space that provides sun and wind protection and a possibility for the air vapours to migrate to the exterior.

The mansard is a part of the envelope; it is an attic with the same hygrothermal conditions as the rest of the building. Another feature of the mansard is that at least a part of the ceiling has to be sloped, in other words the roof geometry has to be – more or less - emphasized. To transform the attic of a 1 – 2 storey building into a mansard is technically and theoretically not too difficult. Some steps have to be taken by each of the different specialists:

3.1.1 Architectural Considerations

- The entire space beneath the roof cannot be used. The steeper the slope, the more the space can be functional [Athanasescu *et al* 2005]. The living area can be defined only from the point where people can stand (the minimum free height of at least 1.90m), as presented in Figures 3 and 4.
- Evaluations should be made to ensure adequate functional circulation in these rooms (heights, distances etc) as well as appropriate placement of the furniture and equipment (see Figure 3).

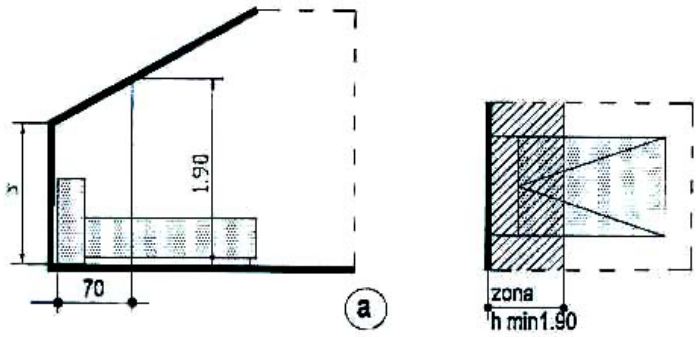

Figure 3. Recommended placement of the bed in a bedroom; the height of the room at 0.70m from the mansard wall should allow an adult to stand comfortably.

- special care should be taken for co-ordinating the architecture design with the other sections of the building and its given spaces (in particular with sanitation; for example, the placement of the sanitary objects determines the particular line for the pipes). The placement of such objects has to allow their use in normal conditions.

Observation: Not only the plans are important in this situation, but also needed is very careful evaluation of the height where the different objects are to be placed and – more than that – the relation between the user and the position of these objects so that the user may actually be able to reach to them (Figure 4).

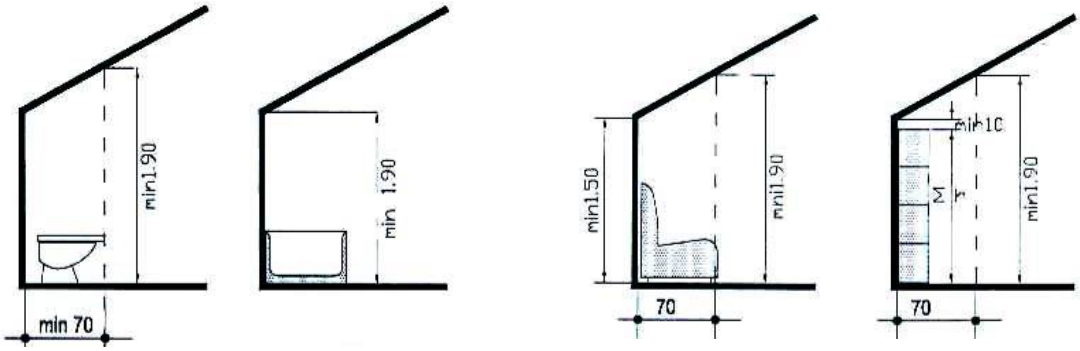

Figure 4: Recommended placement of sanitary facilities or living room furniture;
the height of the room at 0.70m from the mansard wall should allow an adult to stand comfortably.

- The building of an appropriate access to the attic is required in many situations but not in all cases because the space under the roof was already readily accessible. In many cases the access was provided through a trap door so stairs have to link these spaces with the rest of the house.

3.1.2. Structural Considerations

- an evaluation has to be made to ensure that the building can stand the extra load.
- the design of a new set of stairs may induce consequences on the structural system of the building that have to be taken into consideration.
- an evaluation has to be made to check if the existing roof structure can bear the extra load of roof tiles, which are in most situations considered necessary for ensuring improved waterproofing performance of the roof system.

3.1.3 Hygrothermal, Acoustic and Light Control Considerations

Installation of thermal wall insulation must be undertaken. (This step is necessary if improving the thermal performance of the walls is not taking place anyway. Many private houses are being insulated with mineral wool or expanded polystyrene to increase thermal behaviour of the envelope.) Accordingly, measures to protect the thermal insulation against vapour must occur.

- Thick thermal insulation of the roof must be provided with necessary action taken that protects against vapours (barriers, ventilated space above the thermal insulation, and the like). In many situations, due to the fact that the attic was only an auxiliary space, the thickness of the exterior walls of the attic is smaller and therefore, in order to achieve the same thermal performance, the thermal insulation thickness should be increased.
- Any thermal insulation between the attic and the floor beneath it should be removed, because this space becomes part of the warm interior environment.
- Satisfactory measures must be taken to prevent the roof from leaking, either due to poor protection against water intrusion, or from too tightly sealing this upper floor (circulation of air between the roof structure and the roof cladding elements (different types of shingles, metal sheets, etc).
- Acoustic protection should be provided (especially in the case of metal roofing) against the sound of rain or hail.
- Roof windows (i.e., skylights), used for a minimal ventilation of the original space, should be replaced with appropriate windows that ensure necessary daylighting and that also fulfill the performance needs for thermal, acoustic and sun protection comfort.

3.1.4 Installation Consideration

- Electric, heating, sanitary and ventilation components have to be ”lifted” to this new floor, sometimes with high costs.

3.2 Interventions for Low-Sloped Roofs of Existing Buildings

The difference of temperature extremes on low-sloped roof surfaces in Romania is around 100^0C. We can compare ourselves with some parts of the USA where substantial temperature differences can occur within 24 hours. In 2007 the air temperature went as high as 45^0C in Bucharest, while in the winter the temperature went sometimes as low as -20^0C in the same city). In foreign documentations [Parker&Barkaszi, 1994], [Bass&Baskaran 2003], we found references to temperature differences of 60^0C.

Normally, in Romania, the durability of a well protected, bituminous waterproof membrane can reach 25 years. If we have a traditional (bituminous) waterproof membrane, what is happening is that it absorbs thermal radiation during the day, heating the whole assembly including the space beneath the roof. During the night the heat is transmitted both to the inside and outside environment.

These temperature fluctuations can create strong thermal shocks and decrease the life-cycle of the membrane (not to mention the discomfort of the users of the space beneath it). A primary measure is to protect the membrane with a reflective coating.

Figure 5. Example of unprotected bituminous waterproof membrane (courtesy Prof. Alexandru Stan).

There are three possibilities for interventions on the low-sloped roofs of multi-storey buildings:

3.2.1 Replacement of the Roof Membrane System
Replacement of the roof membrane system with a similar one. This is performed without consequence to the functionality of the building. The implications on the environment are the same as before the intervention.

3.2.2 Replacement and Improvement of the Roof Membrane System
Replacement and improvement of the roof membrane system while increasing the energy savings of the building and preserving the natural environment;

As shown above, in Romania, the first measure of protection of the roof membrane, with repercussions also on the energy consumption is to provide a protective reflective coating. From a strictly thermal performance and energy-savings point of view such a measure reduces the use of air conditioning systems by about 10%.

Figure 6. Images of roof-gardens in Paris on the Montparnasse Railway station.

Another possibility for saving energy (and reducing heating costs) is the use of green (terrace) roofs. By using these systems, the state of the exterior environment is at least preserved, if not improved.

Creating spaces for parks, gardens and trees in the center of the cities is rather unlikely in these days. Some western countries (such as Germany, Austria, Switzerland, France, some parts of Canada and USA) have developed a strategy of creating "green space" on the top of new or existent buildings. [Bass & Baskaran]. Polluted areas might even be thus rehabilitated (as we note the case of Linz in Austria where the politics of the "green roof" helped to "de-pollute" this industrial city). Briefly, among the advantageous aspects of green (terrace) roof performance, we can mention [Dabija 2006]:

- retention of an important quantity of the rain water (vegetation acts like an absorbent sponge), thus reducing the pressure imposed on water collectors placed on the terrace.
- reduction of the noise level felt by users who live on the top floor. This is due to the additional mass represented by the soil and the plants. In general, persons living near noisy environments such as airports, discotheques, parking structures, and industrial areas are better protected against noise with a rather non-expensive means.
- protection against electromagnetic radiations [Parker&Barkaszi, 1994];
- achievement of a constant interior temperature with no heating peaks in the apartments situated on the top floor under the roof. This is due both to the additional thermal protection represented by the soil and plants as well as to the increased percentage of humidity produced by the breathing of the plants, that cool the air in the vicinity of the roof.
- preservation of the natural environment, as represented by these systems. As mentioned, in polluted industrial areas, the environment might be "healed" after the installation of green roof terraces (see the Linz case [Municipality of Linz, 2006]).

Unfortunately, in Romania, such approaches are rare, because these systems are still considered to be very expensive.

3.2.3 Building Condominiums on the Terraces of Existing Buildings

Currently in Romania the building activity f is extremely intense. Not only are new buildings from residential houses to high-rise offices appearing, but the need for renovating the old stock has become more acute, as the costs of utilities (heating, in particular) increase. On the other hand, like everywhere else in the world, the prices of houses in the centers of the cities are very high. In order to build in this expensive area, either one expects some buildings to be demolished (unlikely, unless catastrophes occur) or ways to be found to build condominiums (on top of the roofs of existing buildings).

The owners are presented the bright side of the problem: building a condominium, with a pitched roof, is an advantage, as it ensures
- better protection against water and snow (given strictly by the geometry of the traditional roof)
- a fairly rapid pay-off of the investment, once you rent the mansard that results.

The true colours are, however, not as radiant. Supposing the structure of the building allows the extra storey, there are legal problems as well as technical, design, structural, construction, economical other implications that are extremely complicated:

1. Legal, sociological, financial and juridical aspects: In multi-storey dwellings, where each apartment is owned by a different person, it is not a simple task to have everyone accept building a condominium. The nuisance (debris, dust, noise, shocks) of demolishing the roof system (waterproof membrane, thermal insulation, slope, concrete) to reach to the reinforced concrete floor is differently felt by persons on the different floors. Those under the roof are most exposed while those on the ground floor have almost no problems about it. Once the condominium is built, new problems appear: how and who gets the money, how is it spent, and so forth.

2. Structural and installation aspects: The new structure is different from the rest of the building. It has to be a light structure with light walls. This type of construction leads to a completely different regime of use of the installations, thus creating problems with the other occupants. It is easier (in terms of inter-human relations) to design and build an entirely new, autonomous utility system (heating, sanitation, electricity) exclusively for the mansard; it is however very expensive.

3. Functional, structural, equipment (and economical) aspects: The staircase has to be taken to the condominium, unless the condominium is a two-storey apartment. (Then other discussions appear: for example, why should everybody pay in terms of discomfort for somebody's wish of having extra space?) In the case of three storey buildings (that are not provided with elevators), the addition of the condominium necessitates providing an elevator for the transformed building, because the number of levels increases from 3 to 4, where an elevator is compulsory. The costs are very high and the possibilities to place such equipment inside the building are very reduced (if ever possible). To fulfill the requirements of the regulations, exterior, panoramic elevators should be provided. In the case of buildings that have elevators, the problem of taking the elevators to the top (newly built) floor also implies changing the existing elevator, if possible.

4. Construction aspects (technology): While working on the condominium, extra costs have to be taken into account for protecting the building. Once the roofing membrane has been ripped off, it be immediately replaced. There have been cases of buildings (at least one every year), when the rain destroyed from top to bottom all apartments and produced short-circuits, because the roof was not protected any more.

All these problems have sociological and economical implications, and to be sure are difficult to solve.

CONCLUSIONS

Interventions on the roof are not ever simple. However, there are some major directions for renovating roofs that have appeared in the last years. These interventions correlated with the needs to preserve and improve the environment. In the case of existing sloped (i.e., pitched) roofs, the possibility to renovate and refunctionalize the space of the attic is valid. In the case of low-sloped roofs of multi-owned, multi-storied dwellings, the apparent advantage of an extra level with pitched roof and mansard should, in our opinion, be reconsidered. The green terraces seem to be the answer to many requirements and the "legend" of the high costs that such systems incur should fade due to the important gains.

Durability of Clay Roofing Tiles: Assessing the Reliability of Prediction Models

Mariarosa Raimondo [1]
Michele Dondi [2]
Claudia Ceroni [3]
Guia Guarini [4]

T 22

ABSTRACT

The indirect prediction of frost resistance of construction materials has been widely investigated in recent years giving rise to several models based on pore size, open porosity, water absorption and/or capillary rise. This study is aimed at appraising these models on 13 industrially-manufactured roofing tiles with a different frost resistance determined by severe freeze/thaw testing (EN 539-2). Samples were characterised by measuring pore size distribution (MIP), pore specific surface (BET), open porosity and water absorption (ASTM C67 and C373), capillary rise (UNI 10859) and phase composition (Rietveld-XRPD). No model is able to foresee reliably the product frost resistance since all models exhibit a strong dependence on the data population and probably succeed only with a homogeneous sample in terms of both composition and manufacturing technology. Among them, the Arnott's model seems to be the most reliable to discriminate among scarcely (<100 freeze/thaw cycles) and highly frost resistant products (>250 cycles); however, a complete understanding of the excellent performance (>400 cycles) provided by some roofing tiles is still lacking. Looking at their phase composition, tiles with the best performance contain also abundant calcium-magnesium silicate phases formed during firing while products with a frost resistance lower than expected are characterised by large amounts of amorphous phase or residual mica-illite and quartz. This circumstance indicates new ways to achieve highly frost resistant products that is alternative to the conventional design imposing microstructural rearrangements (low porosity and coarse pore size) through drastic batch changes and/or firing at higher temperature.

1 INTRODUCTION

Nowadays clay roofing tiles are widely used as exterior masonry components and their durability, defined as the ability to withstand adverse climatic conditions, is one of the most important requirements to be considered in the structural design of modern buildings.

The deterioration of construction materials can be due to several factors; among them, design and construction techniques, material properties and environmental conditions, which may be, in most cases, considered more predominant than others. Particularly, in cold regions the service lifetime of masonry components is heavily affected by the frost action and salt crystallization.

Frost action is produced when the external temperature falls below 0°C and the water included in the porous structure starts freezing; the density change of the liquid-solid water transition involves the development of an internal pressure, leading to the formation of micro-cracks whose extent can overcome the strength resistance of the material and promote inescapable damage. The extent of these damages will be strictly dependent on the exposed surface area, the saturation degree of the material, as well as on the number and size of pores. Specifically, for pore dimensions greater than a critical value and/or for a low saturation degree, the developed pressure, and hence damage, will be negligible since the free space in the pores accommodates the expansion of the freezing water; in contrast, severe structural damage can occur. Owing to these circumstances, the material characteristics, which in turn depend on the raw material formulations, the forming process, and the firing cycle, become key factors in the evaluation of the deterioration risk.

Many papers in the field of civil engineering analyse the factors affecting the durability of construction materials going also through the elaboration of prediction models. In the last years, for example, Maage [Maage [1990], Arnott [Arnott [1990], Franke and Bentrup [Franke and Bentrup è1993], Koroth [Koroth *et al.* [1998], Robinson [Robinson *et al.* [1995] and Vincenzini [Vincenzini [1974] elaborated different models which basically relate to technological (i.e., water absorption in different experimental conditions, capillary coefficient) or microstructural (i.e., porosity amount, size, and internal specific surface of pores) properties, deriving then equations able to define the product durability on the basis of the calculated indices.

This study is aimed at appraising these models on industrially-manufactured roofing tiles with varying frost resistance, experimentally determined by severe freeze/thaw testing, assessing both their reliability and restrictions. The role played by phase composition on products durability has been also analysed.

2 MATERIALS AND METHODS

Thirteen (13) industrially-manufactured roofing tiles, obtained from different working plants, were selected. On the basis of different shape and colour, they have been classified as *Marseilles* (samples A, C, F, H and L), *Portuguese* (samples B, D, E, G, I, J and M) and *Coppo* (sample K) tiles. All were produced by extrusion and fired at a maximum temperature between 850 and 1150°C with a thermal cycle of 24-48 hours from cold -to -cold.

Products were characterized by the determination of phase composition, open, closed and total porosity, bulk density, pore size distribution and pore specific surface. Phase composition (Table 1) was determined by X-ray powder diffraction (Rigaku DIII, experimental conditions: monochromated $CuK_{1,2\ \alpha}$ radiation in the 5-80°2θ range, scan rate 0.02 °2θ, 2 sec per step) and quantitative analyses were performed by Rietveld method using the GSAS software; the relative error is ± 5%

Open porosity (OP) and bulk density (BD) were quantified according to ASTM C373; specific weight (SW) was measured by He pycnometry (Micromeritics MVP 1305) according to ASTM C329 and total porosity (TP) was calculated by the equation: TP = (1-BD/SW) ·100. In addition, the following

porosity-related properties were also measured: 24-hours (WA_{24h}) and 4-hours (WA_{4h}) cold water absorption, 5-hours boiling water absorption (WA_{5h}) according to UNI 8942/3; the ratio WA_{24h}/WA_{5h} being defined as the saturation coefficient C_s (Table 2).

The pore size distribution (in the 0.01 – 100 μm range) was determined by MIP (ThermoFinningan Pascal 140) with an experimental uncertainty of about 1% relative; the experimentally measured mercury - brick contact angle of 166.4° was inserted into the Washburn equation [34] and the porosimetric results corrected by a factor of 1.24. Data were expressed as medium pore diameter (MD), PV (cumulative volume of pores, cm^3/g), P3 (relative amount of pores having a diameter larger than 3 μm), Φ_{50} (median pore size, μm) and Φ_{90} (ninetieth percentile, μm); the pore specific surface analysis was performed by nitrogen absorption (Micromeritics FlowSorb II 2300) following the B.E.T. single point method (ASTM C1069) (Table 3).

Table 3. Medium pore diameter (MD), cumulative volume of pores (PV), relative amount of pores having a diameter larger than 3 μm (P3), Φ_{50} (median pore size), Φ_{90}, pore specific surface (BET) and capillary coefficient (K_s) of roofing tiles.

Sample	*MD* (μm)	*PV* (cm^3/g)	*P3* (%)	Φ_{50} (μm)	Φ_{90} (μm)	*BET* (m^2/g)	*Ks* ($g/cm^2\ s^{1/2}$)
A	1.88	0.146	56.0	1.8	4.5	0.728	5.8
B	0.52	0.134	3.3	0.5	1.2	1.712	2.2
C	0.41	0.189	0.7	0.4	0.8	1.808	5.2
D	0.34	0.161	1.6	0.4	0.7	1.613	2.6

The capillary absorption was determined according to UNI 10859 on small pieces of about 5 cm^3 obtained from each roofing tile. Plotting the specimen mass recorded after 10, 20, 30 and 60 minutes versus the square root of the elapsed time, a graph was obtained presenting an initial straight line, whose slope is the experimental capillary coefficient K_s (Table 3). Frost resistance was assessed by severe freeze/thaw testing (EN 539-2) on 10 samples for each industrially-manufactured product. Tests were carried out in a climatic cell at temperatures ranging from -15°C to +15°C performing 400 different freeze/thaw cycles; this number of cycles - much higher than those (150) scheduled by the reference standard - was chosen in order to simulate very extreme conditions.

Table 4. Frost resistance of roofing tiles determined according to EN 539-2.

Sample	*Number of freeze/thaw cycles*	*Overcame freeze/thaw cycles*	*Defects found after freeze/thaw testing*
A	400	400	Several chips on the back of the sample
B	400	375	Loss of interlocking ribs, hairline cracks
C	50	25	Large exfoliations on both sample sides
D	400	400	none
E	300	275	Several exfoliations on both sample faces
F	125	100	Loss of interlocking ribs, delaminations, flaking, hairline
G	125	100	Breaking of test sample into three pieces
H	400	400	Detachment of a sample projection
I	100	75	Exfoliations, hairline cracks
J	125	100	Delaminations, exfoliations, hairline cracks, loss of interlocking ribs
K	125	100	Surface cracks, delaminations, exfoliations, structural cracks, pits
L	300	275	Exfoliations, loss of interlocking ribs, hairline cracks
M	150	50	Loss of interlocking ribs, chips, hairline cracks, delaminations

The product durability was evaluated from the analysis of both the mass loss and the structural changes standing out during and after the test; the freeze/thaw resistance was expressed as the fraction of samples which are able to withstand test conditions (Table 4).

Both microstructural and porosity-related parameters were utilized to calculate durability indices according to the models proposed by Maage, Robinson, Vincenzini, Arnott, Franke and Bentrup and Koroth; the variables considered by the authors to elaborate their models and the resulting indices are summarized in Table 5 and 6, respectively.

Table 5. Prediction models and classification of frost behaviour as proposed by the authors**.**

Durability Factor (DF)	*Models*	*Frost resistant products*	*Non-frost resistant products*
Maage	3.2/PV + 2.4P3	DF > 70	DF < 70
Robinson	$[K_s/10(1-C_s)] + (WA_{24h} - 10)$	Low values of DF	-
Arnott	$9.2\ P3 - 0.5\ K_s + 423\ (WA_{5h}/WA) - 100\ K_s\ C_s - 84.5$	High values of DF	-
Vincenzini	Φ_{90}	$\Phi_{90} \geq 1.80$ µm	$\Phi_{90} \leq 1.80$ µm
Franke & Bentrup	Φ_{50}	$\Phi_{50} \geq 1.65$ µm	$\Phi_{50} \leq 0.60$ µm
Koroth	$450(2.94 + WA_{5h}) + 330\ (1-WA_{4h}/WA_{5h})$	DF > 85	DF < 70

Table 6. Calculated durability factors of roofing tiles.

M	47.9	-0.1	410	1.4	0.3	255

A statistical elaboration of data was performed by simple (linear binary correlation) and multivariate analysis techniques (factor and multiple regression analyses) using the StatSoft Statistica 6.0 software. Factor analysis was carried out on the main physical, compositional and microstructural variables extracting principal components (3 factors according to the scree test for eigenvalues). Multiple linear

regression was executed by the forward stepwise method, including intercept in the model and setting F = 1.00 to enter and F = 0.00 to remove.

3 RESULTS AND DISCUSSION

3.1 Reliability of Models

The durability factors of table 6 account for a quite different behaviour of samples in terms of their ability to overcome frost action. In order to verify the reliability and the validity range of the models, a comparison between the experimental results – in terms of number of freeze/thaw cycles – and the calculated indices haves been undertaken (Figure 1).

As shown in Fig. 1, the following considerations can be drawn out:

- Maage durability factor (Figure1A), although presents a positive relationship with the number of freeze/thaw cycles, is not able to discriminate among frost (DF >70) and non-frost resistant (DF<70) products, with sample A being the only one that can be considered as frost resistant; in addition, the model provides no reasons for the excellent performance (>400 cycles) of samples B, D and H. Looking in detail at the microstructure of sample A, it is clear that the Maage factor mainly accounts for its quite high percentage of pores having a diameter greater than 3 μm (P3 = 56%).
- Any statistical significant correlation was detected plotting the durability factor, calculated according to Robinson's model, and the experimental behaviour of samples (Figure 1B); however, the index seems to decrease when the behaviour of products becomes better.
- The model proposed by Arnott (Fig. 1C) seems to present a good agreement with the experimental performance of scarcely resistant (<100 cycles) and highly resistant (>250 cycles) products; the main exceptions are always represented by samples L, B, H and D having excellent durability. The insertion into the multiple regression analysis of different physical and technological parameters provides a model (Table 5) where the role of each variable is quantified by a statistical different weight: the amount of greater pores (P3) seems to be the most influent so that, accordingly, index values increases as the percentage of P3 increases.
- The limit value of Φ_{90} = 1.8 μm proposed by Vincenzini to discriminate among non-frost (Φ_{90} <1.8 μm) and frost (Φ_{90} >1.8 μm) resistant products revealed in this case not to be reliable. Specifically, examining Fig 1D, the correspondence between the experimental performance and the index can be validated only for samples A and E, while sample G, although presenting a Φ_{90} value as high as 3.5 μm, does not show an acceptable durability.
- The evaluation of the median pore size values Φ_{50}, as proposed by Franke and Bentrup (Figure 1E), presents more or less the same limitations of Maage factor. In fact, A and G are the only samples which could be considered as frost resistant, though the experimental results indicate that good (samples E and L) or excellent (samples B, D, H) performance belong to products having a reduced value of pore size (Φ_{50} <0.5-0.6 μm).
- Finally, according to Koroth's model (Figure 1F), all samples should be considered frost resistant since the durability factor calculated for each of them is much higher than the limit value of 85; however, any significant relationship between the calculated index and the experimental results occurs.

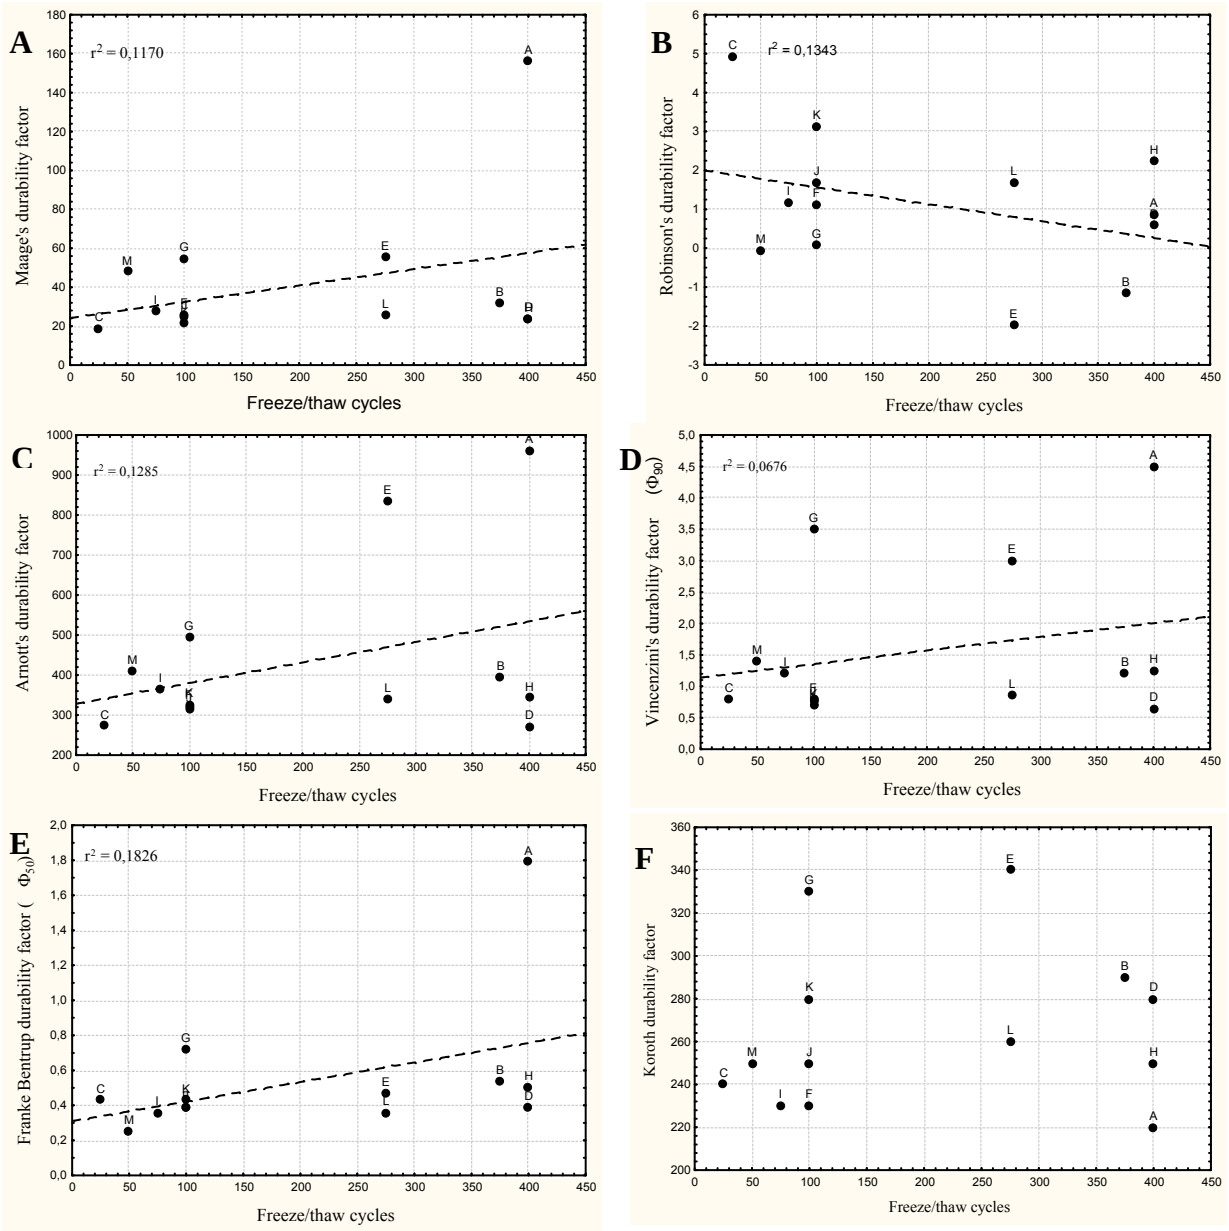

Figure 1. Experimental behaviour of roofing tiles (number of freeze/thaw cycles) vs durability factors of A) Maage; B) Robinson; C) Arnott; D) Vincenzini; E) Franke and Bentrup; F) Koroth.

3.2 Statistical Elaboration

Since simple binary correlations between the calculated indices and the experimental behaviour of roofing tiles were not satisfactory, a statistical elaboration of data (factor analysis and "stepwise" multiple regression analysis) was undertaken considering, besides the number of freeze/thaw cycles, physical (TP, BD, P3, BET, Φ_{50} and Φ_{90}) and compositional (amount of quartz, amorphous phase and Ca-silicates) properties of products as well.

- The extraction of the principal components (Table 7) highlights that, as expected, the frost resistance of products is correlated in a quite complex way with all the other variables so that the hypothesis that more than one parameter could simultaneously influence the materials real performance is in some way confirmed.

Table 7. Extraction of the principal components.

Variable	*Factorial weights*		
	Factor 1	Factor 2	Factor 3
Freeze/thaw cycles	0.535	-0.001	0.457
TP	0.545	-0.794	-0.123
P3	0.813	0.495	0.056
BET	-0.837	0.04	-0.438
BD	-0.542	0.794	0.127
Φ_{50}	0.864	0.381	0.115
Quartz	0.250	0.793	-0.528
Ca-silicates	0.457	-0.841	-0.008
Amorphous	-0.610	0.178	0.691
Φ_{90}	0.707	0.649	-0.042
Variance	4.132	3.446	1.214

Anyway, looking at the mutual relationships of figure 2, the following conclusions can be drawn out:

- a positive correlation exists between frost resistance and the amount of pores greater than 3 μm (P3), the median pore size (Φ_{50}) and Φ_{90} values;
- frost resistance is inversely related to the pore specific surface (BET) but also to the amount of amorphous phase, so that the highest its content, the lowest is the product performance;
- concerning the amount of quartz and Ca-silicates, their role on the frost resistance seems to be the opposite: a higher amount of new formed phases (such as Ca-silicates) increases the ability of products to withstand frost action, which in turn is decreased by the presence of high quartz amounts.

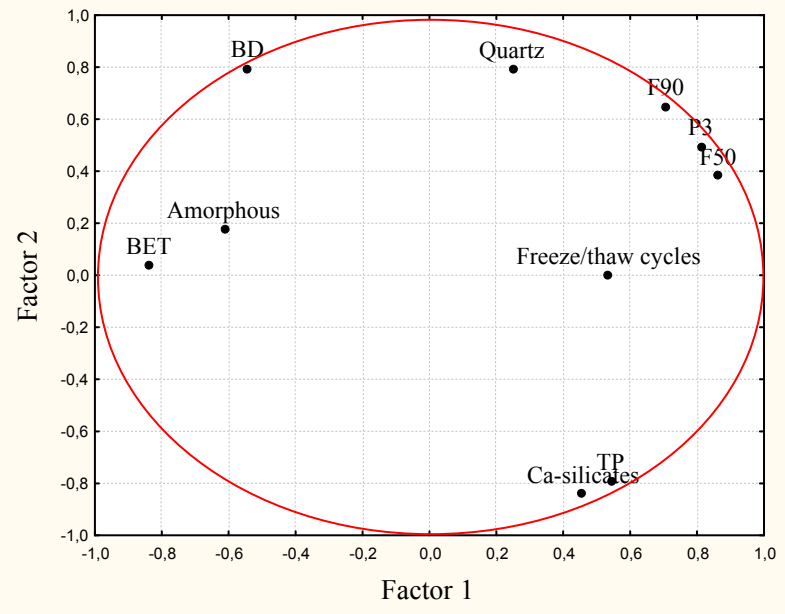

Figure 2. Extraction of the principal components: factor 1 vs factor 2.

The results of the multiple regression analysis (R^2= 0.94138, p<0.00184), taking into account the product frost resistance as dependent variable and the physical and compositional parameters as independent ones, made possible to confirm some of these indications (Table 8):

- according with the values of β factors, the statistical procedure selected the following as the most influent parameters: BD, quartz amount, BET, Ca-silicates amount, amorphous amount and Φ_{50};
- it is worth noting that the statistical weight (as expressed by β factors) of the mineralogical phases are quantitatively equivalent to that of BET and prevailing on the pore size represented by Φ_{50};
- concerning the positive or negative role played by each selected variable, it is confirmed that the amount of Ca-silicates, on one side, and that of quartz and amorphous, on the other side, work in the opposite way; a higher amount of new formed phases increases the frost resistance of products, while the presence of both quartz and amorphous potentially involves the risk of frost damage;
- the evaluation of the p-level corresponding to each selected parameters allows to assess the reliability of the results of the statistical procedure which can be considered satisfactory.

Table 8. Results of the multiple regression analysis.

Stepwise multiple regression analysis R = 0.970; R2 = 0.941; p-level < 0.002

N = 13	β	Std. Error	B	Std. Error	p-level
Intercept			-7063.22	1052.63	0.0005
BET	-0.821	0.201	-338.80	83.12	0.0065
Amorphous	-0.775	0.381	-9.20	4.53	0.0885
BD	1.857	0.231	4227.63	527.29	0.0002
Quartz	-0.882	0.368	-14.33	5.98	0.0054
Ca-silicates	0.779	0.223	7.34	3.99	0.0110
Φ_{50}	0.252	0.182	101.05	73.41	0.2180

Following these results, it can be pointed out that the production of roofing tiles with excellent frost resistance – which are able to overcome a number of freeze/thaw cycles much higher that those required by the current standard – involves the evaluation of both product and processing variables. As far as the composition of raw mixtures, their CaO content should be improved paying in the meantime great attention to the development of a highly porous microstructure and controlling the pore dimensions (to get lower BET values). Analogously, the amount of new formed Ca-silicates should be improved (≥ 40%), while the amount of amorphous phase reduced under about 20%. These requirements, together with the need to obtain a microstructure having a higher quantity of pores greater than 3 μm, can be satisfied through the modification of the firing process, i.e., increasing the maximum firing temperature.

4 CONCLUSIONS

This study has taken into account the frost behaviour of 13 industrially-manufactured roofing tiles which were assessed through a double approach: performing severe freeze/thaw testing (EN 539-2) and calculating the durability indices, according to some of the models present in the literature. The products microstructure, in terms of physical, technological and compositional parameters, was fully investigated and the results correlated with the frost resistance of roofing tiles.

Looking at the correlation between the experimental frost behaviour and the calculated durability factors, we can conclude that no model is able to foresee reliably the product performance since the models exhibit a strong dependence on the data population and probably succeed only with a homogeneous sample in terms of both composition and manufacturing technology.

Inserting into a statistical procedure all the microstructural and compositional variables, together with the experimental number of freeze/thaw cycles, new indications came out concerning the design and production of roofing tiles able to withstand adverse climatic conditions. Following these results, it can be pointed out that the production of roofing tiles with excellent frost resistance involves the evaluation of both product (i.e., raw materials composition, microstructure and phase composition of tiles) and processing (i.e., firing temperature) variables.

The Assessment of Durability of Discontinuous Roofing: An Experiment on Sandwich Panels

Giuseppe Alaimo [1]
Francesco Accurso [2]

T 22

ABSTRACT

The sustainable development of the construction trade requires a more rational use of the resources used. In light of this, the knowledge of building components and systems durability becomes fundamental in planning the service life of those components and to forestall unexpected deterioration and pathologies. Within the framework of more general research on the durability of building components, which involves various Italian universities, Palermo university has been concerned with discontinuous roofing. After the theoretical study on the reliability of a range of twenty-four technical solutions within the discontinuous roofing class, the sandwich panel, made up of two sides of metallic sheet with expanded polyurethane, was investigated. The research, carried out, in accordance with ISO 15686, concerns the behaviour in time of the sandwich panel, established through the monitoring of its performance characteristics (aspect, weight, colour, thermophysical and mechanical characteristics) when it is subjected to natural and artificial aging using an accelerated aging cycle in a climatic chamber. This was done for typical conditions of the Mediterranean climate. The tests on samples of different sizes, concerned the analysis of colour (light and dark), the measurement of conductivity, thermal resistance and resistance to tensile stress and bending moments. These were carried out on new samples, samples exposed externally and samples subjected to accelerated aging. The results allow the development of correlations between the variations of thermophysical and mechanical parameters and the deteriorations after the first two years of outdoor aging and the first sixty cycles of accelerated aging (rescaling). In such a study, particular attention should be given to the polyurethane interface sheet, in terms of criticality of thermophysical behaviour of the panel and the colour, appearance which compete to imply the quality of the whole building envelope.

1 INTRODUCTION

Durability deals with the maintenance of performances associated with a component at the beginning of its working life and the ways in which performance decays in time. Important aspects required to achieve building quality are maintenance planning and control of resources which will be used in all phases of the building process.

This paper presents the results of a research study on "Methodologies of planning and experimental evaluation of the durability of discontinuous roofing", within a national research program (P.R.I.N.) which involves the University of Palermo, the Polytechnics of Milano and Torino, the Universities of Brescia, Napoli and Catania. They constitute a network of research centres, where, in the last years they have developed experimental methodologies to evaluate the durability on different building components, for a range of environments. The results reached, until now, have been presented at Palermo's Conference on 15 September 2006, they furnish contribution to the international research of the CIB W80 RILEM 175 "Service Life Prediction Methodologies", e ISO TC 59/SC14 "Building Construction".

The roof has always been a fundamental component of the building envelope, and a determinant of the environmental quality of the indoors, because it contributes to controlling energy flows between the interior and exterior of the building. The roofs contribute to maintain the planned environmental conditions, with the control of technological functions of the technical elements of the class. That's why there's a need to make reference to the class of technical elements (classification UNI 8290) and to each technological performance level. Within the National Program, the Research Unit of Palermo is carrying out a study on pitched roofs, through a first phase of functional and technical analysis of a catalogue of technical solutions of the class by performing an assessment of natural reliability. We have chosen sandwich panels, used either as roof or wall elements, as the building components for our research, and of which Italy is a leading manufacturer in the world.

2 THE METHODOLOGY

Based on the latest national and international standards (UNI 11156-2006; ISO 15686), the methodology we have followed consists of evaluation using two distinct and complementary procedures for the two parameters of durability: reliability and service life [Maggi et al. 2000, 2001]. Reliability is estimated through a method that permits a qualitative evaluation following a comparative procedure involving the elements of a catalogue of technical solutions of the class, which is considered out of system and with no intended use [Rejna 1995]. Service life is estimated through experimental tests on samples of technical elements exposed to natural agents and accelerated aging test in the laboratory. The results must be compared to determine the time re-scaling of the performance decay of the component.

This methodology for the evaluation of service life results is in accordance with the approach designed by ISO 15686 "Building service life planning". The assessment of reliability proceeds through the evaluation of the four components of reliability:

Functional reliability which, through the functional analysis, individualizes the distribution of the functions inside the solution, on which the degree of fatigue of the element depends on its operation;

Executive reliability which, through the technical analysis, verifies the degree of executive correspondence in comparison to the design;

Inherent reliability which concerns possible dimensional changes of the component during the phases of the exercise due to the different thermal and humidity stress of the functional elements;

Critical reliability which considers physical-chemical compatibility between adjacent materials of a different nature, and which constitute the technical solution.

The global reliability expresses in qualitative and comparative terms the degree of probability that the technical solutions have to last in time, whereas its complementary to 1 expresses the risk of failure during the service life. The estimate qualitative of reliability, both in global terms and of its components, offers useful information on the choice of maintenance procedure. Allowing by means of comparison, assessment of technical solutions other than those studied, both to estimate the reliability of a solution data and to plan new solutions of data reliability. The method permit to express reliability on the basis of its components: functional, inherent and critical reliability refer to planning choices and their complement of 1 expresses the risk failure for errors in the planning phase; executive reliability concerning activity in the construction phase and its complement of one expresses the risk failure for errors committed in that phase.

3 THE RANGE OF TECHNICAL SOLUTIONS

A range of 24 technical solutions were evaluated, which also included representative solutions by local builders. As well, “innovative” solutions were studied and compared to "traditional" constructions. The technical solutions of the repertoire (some are illustrated in Figure 1), have been characterized by: type of seal element; nature of load bearing structure; presence of insulation and ventilation layers.

The type of seal element (in small or large elements) can be made of brick (plain roofing or channel tiles), cement, fibrous concrete, metal or sandwich panel. The load bearing seals can be mixed with brick and reinforced concrete, of prestressed concrete or with timber and metal. The innovative solutions are those which use sandwich or composite panels, insulated and ventilated. These are also used in residential building.

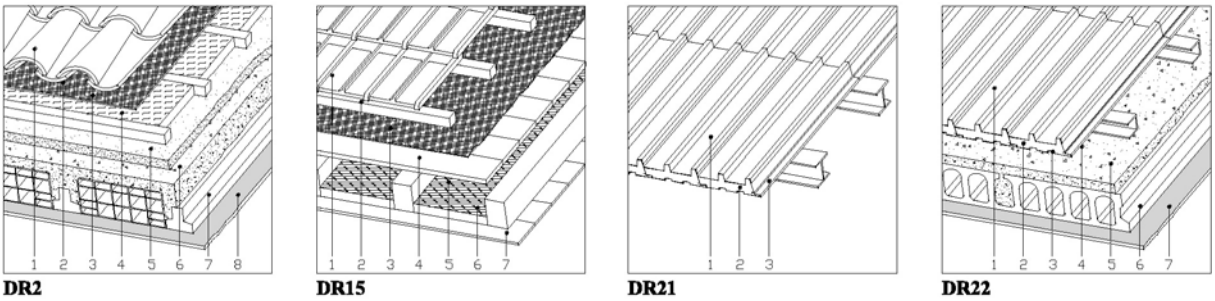

Figure 1. Some technical solutions of the repertoire.

4 THE EXPERIMENTS, SAMPLES AND PARAMETERS

The following parameters and properties were recorded for each sample: aspect; weight; colour; thermo-physical properties; mechanical properties. Such characteristics were determined for samples aged outdoors and in the laboratory using destructive and not-destructive tests, in the following manner:

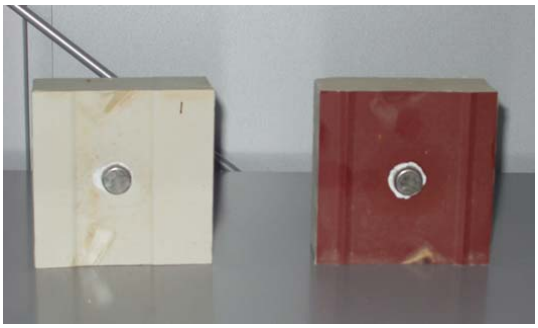
1) not-destructive tests: aspect (using visual and measurement methods); weight; difference of colour; measurement of thermal conductivity and thermal resistance on the whole sample.
2) destructive tests: mechanical characteristics (traction, shearing and bending); thermo-physical properties (thermal conductivity and thermal resistance on PUR sections).

The original panel was made of two pre-painted galvanized steel skin, with a thickness of 0.45 mm, and an insulated core of expanded polyurethane, with a thickness of 40 mm. The specimens cut from the panel were of sizes 100 x 100 mm, 100 x 250 mm and 100 x 1000 mm are differentiated by colour in bright (White-grey) and dark (Siena red).

5 NATURAL AGING

The samples were exposed outdoors, directed toward South and with slope of 30° (Figure 2a). Before the exposure, the edges of the specimens were protected with a special polyurethane paint. On some samples, we applied some programmable data-loggers (Figure 2b), in order to record the surface temperatures reached (exposed and shade side) during the exposure. The collected data, between March 2004 and March 2006, have been used to determine trends of the maximum, minimum and averages temperatures reached on the surface of the samples in Palermo with the different seasons of the year.

a



b

Figure 2. a: The samples exposed in outdoor; **b**: Temperature data-logger.

6 ACCELERATED AGING

The aging of samples was done inside a climatic chamber (Figure 3) that reproduces the principal climatic agents: rain, sunlight, high and low temperatures, variations of relative humidity. A necessary methodological preamble to the experimental phase included the definition of the range of weathering agents - actions - effects [Daniotti 2000] and corresponding deteriorations that can arise in the specimens. The artificial cycle (Figure 4a) has been developed on the basis of the specific climatic context of Palermo, and with the results of values measured outdoors, after initial calibration (Figure 4b).

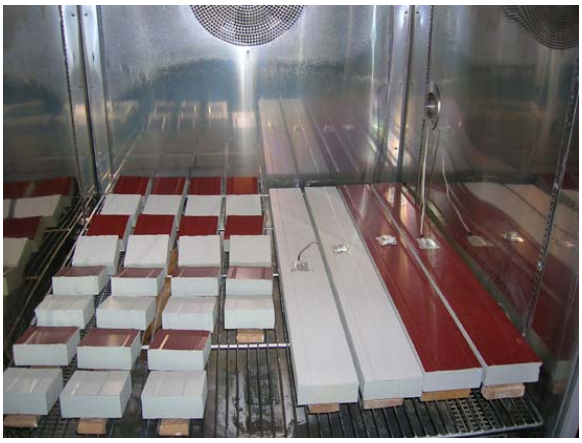


Figure 3. Samples inside of the Climatic chamber with temperature data-loggers.

The weathering accelerated cycle had a duration of 12 hours and consisted of the following phases:

Phase 1 - The samples were sprinkled with water at a temperature of about 20°C for 3 hours. In this phase the relative humidity inside the chamber was 95%;
Phase 2 - Temperature of the chamber was brought to 2°C for 1.5 hours;
Phase 3 - The samples were submitted to the action of warm dampness (T = 35°C, RH = 87%) for around 3.5 hours. This phase was preceded by a transition sub-phase of about 1.5 hours;
Phase 4 - In this phase the samples were exposed to the light produced by the UV lamp that together with the elevated temperature served to simulate the action of dry heat. The temperature was brought to around 80°C and the RH to 56% and maintained for about 2.5 hours.

The artificial aging has been conducted over 120 cycles corresponding to about 1500 hours of accelerated aging.

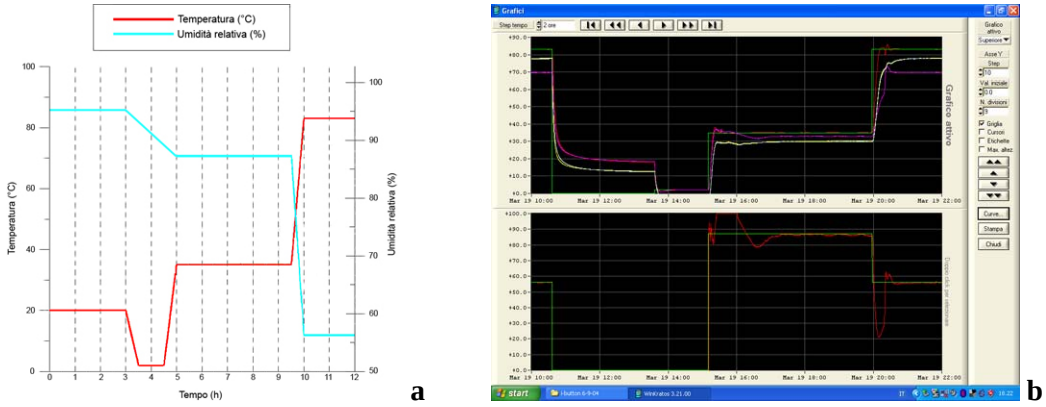

Figure 4. a: Theoretical accelerated aging cycle;
b: Experimental accelerated aging cycle (by Winkratos software).

The tests, destructive (thermal and mechanical properties) and non-destructive (aspect, colour, weight), were performed on the initial samples at time zero; the external aged samples after each year and after every 30 cycles for samples aged in laboratory.

7 RESULTS AND CONCLUSIONS

Surface Effects
Both with natural aging and accelerated aging, a slow evolution of degradation was observed. Initially, the phenomena of chromatic and yellowing alterations of the metallic surface were observed. Then the appearance of local oxidation marks, and with the increase of cycles, the formation of blisters and cavities in the foam, thus variations of shape at the interface foam-metal skin. After 120 cycles cracks on the interface appeared, which is certainly a critical point, both for thermo-physical and mechanical behaviour.

Tensile tests
The test has the purpose of evaluating the tensile strength of the polyurethane foam (Figure 5a,b) and its adhesion to the metallic support (ETAG 016-1, UNI EN 1607, EN 14509).

The specimen showed an improvement of the traction resistance up to 60 cycles, subsequently such tendency is reversed with the increase of cycles (Figure 6a).

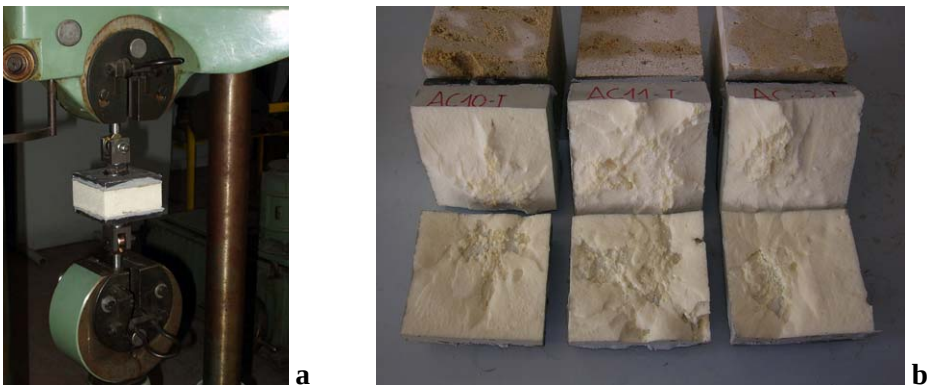

Figure 5. a: Tensile test; **b**: Type of failure (PUR).

It is important to underline the relationship found between the tensile strength, the percentage of uncovered metal skin (Figure 6b) and the length of the aging. The aging causes in fact an increase of the percentage uncovered after the failure. This effect was more accented in the dark samples. From comparison of the effects of the two types of aging in this type of tests, a correspondence can be noticed between the effects of 60 cycles and those of 2 years of natural exposure.

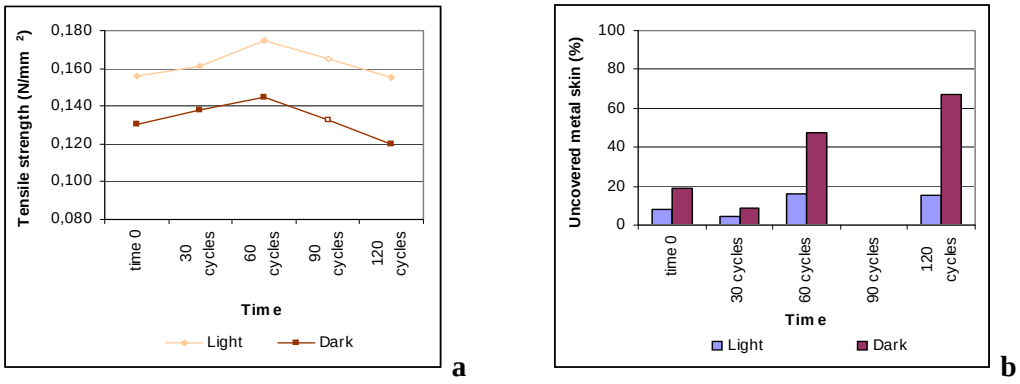

Figure 6. **a**: Tensile test; **b**: Metal skin after the failure (accelerated aging).

An analogue behaviour was observed, from a qualitative point of view, between the resistance to traction and thermal conductivity and thus a decrement of the characteristic up to 60 cycles and a successive reversal of the trend with an increasing number of cycles.

Thermal conductivity
Measurements have been conducted both on whole samples and on the polyurethane sections (extracted from the core of every samples two sections with a thickness of 10 mm) (Figure 7a), with the purpose to evaluate the influences of the external metallic elements and the interfaces with polyurethane.

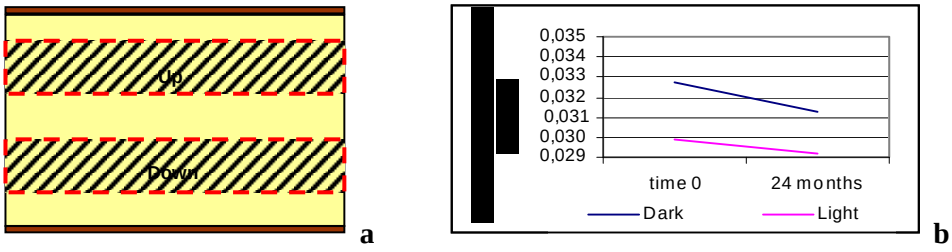

Figure 7. a: Sections of PUR; **b**: Change of conductivity (natural aging).

For up to 24 months of external exposure the conductivity of the samples remains substantially constant, both in the whole samples and in the sections of PUR (Figure 7b). In general the changes in thermal conductivity of the whole samples are greater than the changes in the PUR sections, because of the lower contact resistance due to the cover sheets glued to the PUR.

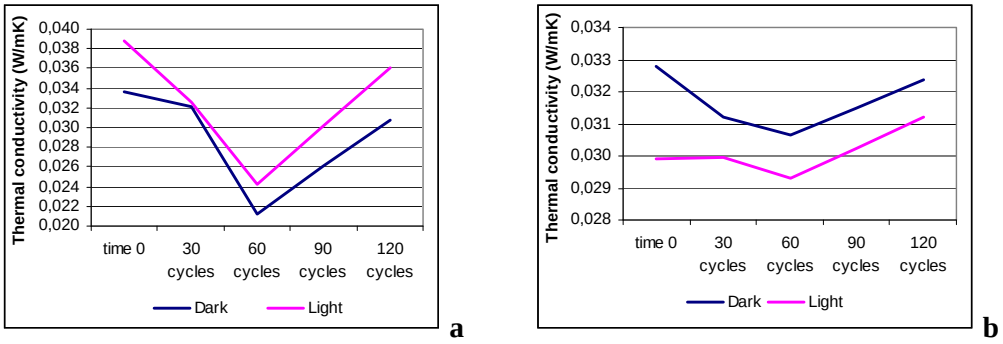

Figure 8. Change of conductivity – **a**: whole samples;
b: sections of PUR (light and dark samples -accelerated aging).

There is a substantial consistency among the measurements on the samples marked "Up" with those of the samples marked "Down". The results of the tests in the climatic chamber show an analogous behaviour from the qualitative point of view among the whole samples (Figure 8a) and the sections of PUR (Figure 8b) both for the samples White Grey and for those Siena Red.

Also in this type of tests after 60 cycles, an inverse relationship is observed with substantial consistency, involving the thermal conductivity both in the first year of natural aging, and in the first 30 cycles of accelerated aging. Definitively, the results show a significant qualitative relationship between variations of thermo-physical and mechanical parameters and a corresponding trend between the observed degradations after the first two years of external aging and the first 60 cycles of accelerated aging (re-scaling).

Colour
The results of the measurement of colour, in the CIEL*, a*, b* space, show:
• after about two years of natural aging, the light samples have been shown a significant variation of colour (ΔE) and a tendency to yellowing;
• in the samples that were artificially aged, we can see a difference of colour in two ways.

The light samples show a tendency to yellowing and a progressive variation of colour, the dark ones have a more significant variation after 30 cycles and a decrease in this difference with the increase of cycles. Results, for the light samples, are shown in Figure 9.

Between the different aspects investigated, the study of colour assumes particular value, both from an aesthetic and architectonic point of view, on the visible impression, on the individual psychological effects as the “Sick Building Syndrome”. Thus, the colour is able to reflect not only the quality of the building product, but also that of the existing environment.

Another important social aspect is the maintenance, in particular that carried out on the aesthetic appearance of buildings in the outskirts of the city, where social decadence is almost always accompanied by the lack of urban and building quality. Therefore, this is an aspect which requires adequate attention also from a normative point of view.

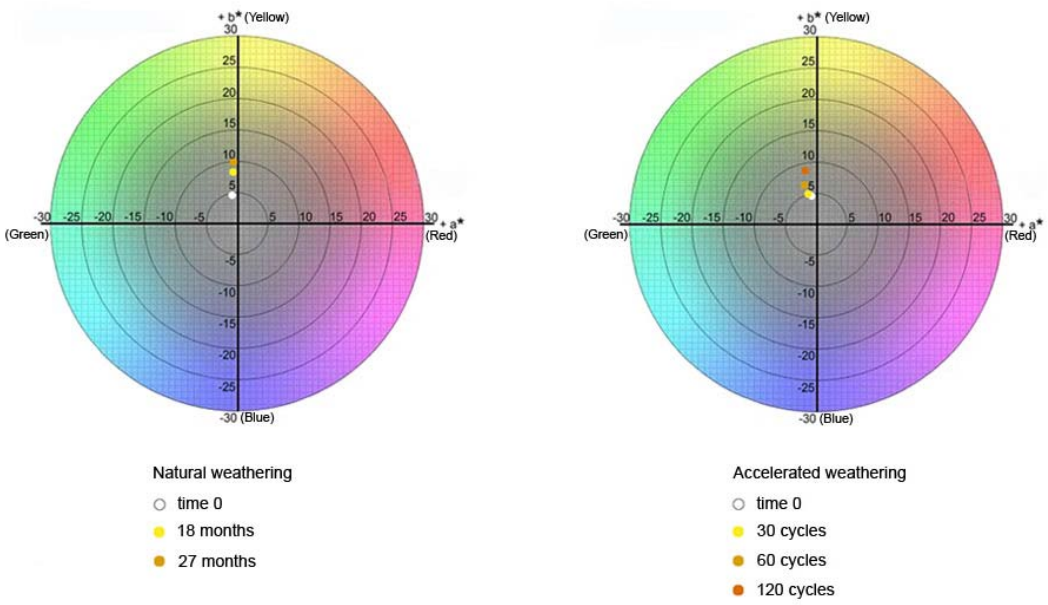

Figure 9. Chromatics diagrams a*, b* for the light samples.

It will be useful continue to check the course of the thermal conductivity of the samples exposed outdoors to shed new light on the role of the skin-core interface and on the variability of the insulating property. The study could establish properties of the aged polymer and the gas contained inside the cells to provide an explanation to the improvement of the characteristics (tensile strength, thermal conductivity) measured in the initial phase of the panel's aging.

Roof Management Program for Multiple Roof Systems

Steven P. Bentz [1]
Walter J. Rossiter, Jr. [2]

T 22

ABSTRACT

Roof management programs are intended to extend the service life of roofing systems, while maximizing the efficient use of available funding whenever repairs or replacements are performed. The requirements of an acceptable roof management program include: good roof design and installation using quality materials in applications where the materials are appropriate, satisfactory maintenance of the roof to acceptable standards, preventive maintenance before costly deficiencies occur or timely repairs immediately after deficiencies are found, and documentation of information regarding roof performance for utilization on future projects. This paper presents an overview of a roof management program developed to provide a methodology for performing these actions while understanding the limitations of time, manpower, and funding with which to do so.

Within this program, evaluations of roof systems are based on ten factors which are quantified (i.e., scored) and thus provide the basis for a prioritization schema. A key consideration is enabling the scoring by minimally trained personnel with little roofing experience. The ten factors to be scored for the roofing prioritization schema, in no particular order, are durability, age, roof criticality, susceptibility to damage, membrane condition, flashing condition, attachment, slope and drainage, constructability, and leak history. Each factor is ranked on a comparative scale from 1 to 10, with 1 being a low or poor score, and 10 being a good or high score. The individual scores for the ten factors are then added together to develop an overall score for the roof, which is then used to objectively develop a prioritization for the repairs or replacements. Representative evaluations at several large U.S. campus-type facilities have demonstrated the utility of this approach, and will be described in the paper as examples of using this program to extend roof service life.

1 INTRODUCTION

Roofing practitioners have long acknowledged that successful low-sloped roofing performance relies on a combination of four key elements namely; sound design, suitable materials, good workmanship, and proper and timely maintenance [1]. Historically, in spite of such acknowledgement, far too often little attention was paid to putting this tenet into practice, particularly with regards to maintenance. For example, almost 20 years ago, Firman chastised that in general the industry is geared towards new and re-roof construction, with very little emphasis given to maintenance needs [2]. He further stated that owners were mainly responsible for this because they were not demanding an emphasis on maintenance. The result, in his opinion, was that owners contributed to most roof leaks due to lack of maintenance. Reasons for this attitude have not been explored, but the present authors believe that it was associated with a short-sighted, outright unwillingness to allocate the funds necessary to perform the needed maintenance. Fortunately, as time elapsed, many practitioners awoke to realize that the roof represents a sizeable investment that needs to be protected, and began to promote roof maintenance management programs as a formal mechanism for doing so. Bradford evidenced this shift in attitude clearly and succinctly in 1996 when he called the need for roof maintenance indisputable [3]. To be sure, we can readily say in 2007 that widespread use of roof maintenance programs has been realized in the United States. Here we quote Bradford's 2004 writings that during the past several years, roofing contractors and roof consultants have seen substantial increases in requests for roof preventive maintenance services [4]. He opined also that everyone in the roofing business-from manufacturers to consultants to contractors of every size—has seemingly developed a program, system, or department to address owners' roof system maintenance needs. Today, any building owner in the United States can search the World Wide Web for 'roof maintenance management' and find web sites for hundreds or more firms that offer such services ranging from limited inspections and repairs to full management.

The objective of a roof maintenance program is to extend the Expected Useful Life (EUL) of a roof system [5]. The elements comprising such a program are periodic inspections, routine maintenance and repair, and correct application of quality roofing products [5]. Historically, one of the first major organizations in the United States to adopt a formal roof maintenance management program was the U. S. Air Force (USAF) [6]. Although controversial because of some of its requirements, a generally accepted feature of the USAF program was the assignment of a quantitative rating of the condition of a roof as determined through its inspection. In turn, the individual ratings for a number of roofs at a facility were used for ranking their relative conditions to establish priorities for completing necessary repairs [1]. Such prioritization is particularly important in the case of multi-building complexes. Today many maintenance programs incorporate roof-condition ranking systems for determining the allocation of maintenance funds. In the United States, perhaps the most widely known maintenance management program is the ROOFER Program of the U.S. Army Corps of Engineers (USACOE) [7]. This program, which incorporates relative ratings of roof condition among its many features, is not only used at Army facilities but has also been adopted and adapted in the private sector. Such programs can be costly due to the amount of information needed to populate the database. Today's computer technology has aided in the development of maintenance programs but, at the same time, has increased the amount of information that is input. The cost to obtain the data is sometimes the governing factor, exceeding the cost of the software itself.

This paper presents an overview of a newly developed roof maintenance management program for use on multi-building complexes such as campus, military bases, and office parks. Examples of its features are given from limited practical experiences in the field. The goals of this program are to prioritize roofs, train on-site personnel, and simplify the process. One key feature of this program, consistent with those developed for example by the USAF and the USACOE, is the inclusion of a quantitative ranking of a roofs' conditions. Another key feature is the training of on-site personnel and the use of those trained personnel in conducting the inspections. Regarding this latter feature, we note with interest that Sinderman, in his web article discussing roof maintenance management, quoted a U.S. roofing consultant as saying that a lot of roof maintenance "is just having someone walk your roof who is competent, trained, and knows what to look for and how to evaluate repairs" [8].

2 ROOF PRIOTIZATION SCHEMA FACTORS

The foundation of the program presented here is the delineation of ten factors used in ranking the relative conditions of the roofs (entire buildings or roof sections at one building) inspected. These ten factors, referred to as the "Roof Prioritization Schema," are, in no particular order:

- **Age** (EUL of the existing roof system)
- **Importance Factor** (use of the building
- under the roof area)
- **Susceptibility to Damage** (roof traffic
- indicator)
- **Membrane Condition** (existing
- membrane)
- **Flashing Condition** (existing flashings)

Attachment (type of attachment)
Slope and Drainage (slope to drains and general roof slope, size/amount of drains, gutters, scuppers, etc. and functionality)
Constructability (difficulty of repairs/replacements)
Leak History (observed or reported leaks)
Durability (existing membrane toughness)

These factors are scored on a relative scale of 1 to 10, based on a ranking system developed for this program. In general a score of 1 for a factor is a poor rating and a score of 10 is a good rating, except as noted in the descriptions that follow.

The methodology behind the Prioritization Schema is to aid in development of recommendations and prioritization of maintenance needs and roof replacement scheduling. The documentation provided in AFI 32-1051 [5] can serve as a primer for evaluations performed with these factors in mind. The technical basis for each of the factors in the ranking system is as follows:

2.1 The Age Factor

While the age of a roof system may seem like a fair metric by which to measure a roof's performance, not all roof systems age the same. Therefore, having a multi-building complex with various different EPDM, single-ply, gravel-surfaced built-up roof (GSBUR), metal, and other types of roof systems of varying age presents the question of how old is too old? For the purpose of scoring roofs on the basis of age, roofs are rated on the expected useful life of the existing membrane as compared to the current age. For example, the expected useful life of an EPDM membrane roof system is approximately 12-15 years (Cash or Schneider Reference), therefore, an age of 6 years results in a score of 5, while an age of 1 year would result in a score of 9. A built-up roof has an expected life of about 25-30 years; therefore an age of 12 years would result in a score of 5, while an age of 24 years would result in a score of 1.

Based on the Author's experience a minimal percentage of roofs fail extremely prematurely, within 1 to 2 years. Conversely, we have seen a similar minimal percentage of roofs to fail after an extremely long service life of maybe 30 years. The largest majority of failures seen in practice tend to occur within one standard deviation of the average failure age. Using EPDM as an example, and taking the average failure age to be 12-years with a three year standard deviation, approximately 60% of EPDM roofs might be expected to fail within 9 to 15 years. Similar predictions based upon our experiences have been established for the other types of roofs.

However, with the longer service lives for many roof types, the range of the statistical failure point (standard deviations) increases, resulting in larger ranges for the expected failures.

Table 1 summarizes the expected useful life of some typical roof systems based on the Author's field experiences and complimented with data from roofing literature.

2.2 The Importance Factor

This ranking prioritizes roofs based upon the function of the building use or occupancy. That is, the level of importance is rated by how important the roof integrity is to the operation of the space below and how the occupants would be impacted by roofing damage or failure.

For example, a building housing sensitive electronic gear would score a 1 (i.e. failure is worse here) while a building housing spare machine parts would score a 10 (i.e. failure results in little damage).

Table 1. Expected useful life scoring.

Roofing System	Surface Type	EUL*	Score for 10-year old Roof
Built-up (3 or 4-ply)	Gravel	25-30 years	7=((30-10)/30) x 10
Modified Bitumen (2-ply)	Granules	20-25 years	6=((25-10)/25) x 10
Single-ply (TPO, PVC – heat-welded)	Un-surfaced/Exposed Membrane	15-20 years	5=((20-10)/20) x 10
Single-ply (EPDM – adhered)	Un-surfaced/Exposed Membrane	10-15 years	3=((15-10)/15) x 10
Metal (standing-seam)	Fluoropolymer Paint	40 years	8=((40-10)/40) x 10

*Note: The EUL shown assumes a minimal roof slope of ¼" per foot.
Formula Explanation: Ranking Factor = ((Upper End of EUL-Age)/Upper End of EUL)*10

2.3 Susceptibility to Damage

This factor addresses the probability of damage due to concerns such as foot traffic and surrounding conditions (overhanging trees, runways, taxiways, adjacent buildings, etc.). Are there multiple mechanical units on the roof that require access? Are there pavers or walkpads to protect the roof ?

Are traffic paths clearly identified? Each of these different types of traffic can cause undue stress on the roof system. Table 2 is a general rating system of the resistance of a roof surface relative to roof traffic and a general guide to scoring roofs with respect to this factor. Note that the metal roof system is scored based on the possibility of paint scraping, denting of panels, the possibility of seams being bent, etc.

Table 2. Resistance to roof traffic.

			Relative score					
			FT		SC		Access	
Roof System	**Surfacing**	**Traffic Resistance**	**Low**	**High**	**Low**	**High**	**Low**	**High**
Built-up (3 or 4-ply)	Gravel	High	10	8	10	8	10	8
	Smooth Surfaced	Moderate to High	9	6	9	6	9	6
Modified Bitumen (2-ply)	Gravel	High	10	8	10	8	10	8
	Granular Surface	Moderate to High	9	7	9	7	9	7
	Smooth Surfaced	Moderate to High	9	6	9	6	9	6
Single-ply	Exposed Membrane	Low to Moderate	7	5	7	5	7	5
	Ballasted	Low to Moderate	7	4	7	6	7	4
Metal	Fluoropolymer Paint	Low to Moderate	8	6	8	6	8	5
PMA	Ballasted	High	10	9	10	9	10	9

FT = Foot Traffic; SC = Surrounding Conditions; Access = Ability and/or need to access the roof.

2.4 Membrane Condition

This is a subjective view of the membrane based on the inspection of each roof for defects. The number, type, and extent of defects are included in the rating.

Table 3 summarizes some typical defects for roof systems.

Table 3. Typical roof membrane defects.

Roof System	Typical Defects
Built-up (3 or 4-ply)	Exposed felts, wind scour, blisters, asphalt migration (down slope), ply slippage (down slope), exposed embedded metal, inadequately filled pitch pockets, splits, or tears
Modified Bitumen (2-ply)	Open seams, inadequate bleed-out, exposed bleed-out, blisters, fish mouths, wrinkles, exposed reinforcing scrim, loss of granules, inadequately filled pitch pockets, punctures, tears, or splits.
Single-ply (heat-welded polymer)	Open lap seams, short lap seams, fish mouths, wrinkles, inadequately filled pitch pockets, punctures, tears, or splits.
Single-ply (adhered rubber)	Open lap seams, short lap seams, fish mouths, wrinkles, inadequately filled pitch pockets, punctures, tears, or splits.
Metal (standing-seam)	Open seams at standing-seams, missing or backed-out fasteners, buckling of pans, scratches, dents, or corrosion.

A membrane in good condition could be a 10, even if the membrane is 30 years old. A membrane in poor condition would be a 1, even if it is relatively new. The key in this factor is not to take extensive time to document each deficiency, but rather to use the general visual inspection to provide a relative magnitude of the defects. In our experience, with training most facilities personnel can subjectively rate a membrane condition to a reasonable degree to consistency.

2.5 Flashing Condition

In general, the assessment of flashings is similar to the assessment of the membrane in so far as the number, type, and extent of defects are included in the rating. Two important concerns not associated with membranes but included in flashings are the vertical attachment method and the counterflashing. Vertical flashings should be attached with continuous terminations. Counterflashings should be provided. The lack of either of these may necessitate the issuance of a lower value in this category. Flashings that do not appear to be performing well are to be rated lower than those that appear to be water tight and performing well.

2.6 Attachment

Attachment provides resistance to wind loads, and most design codes have very specific requirements for wind uplift resistance. Attachment methods are at times compromised by force-fitting a particular attachment method to a roofing deck that does not readily lend itself to the method. Figure 1 shows the three most commonly used roof attachment methods. The fourth method shown, the Protected Membrane Assembly, is a hybrid of the basic attachments in that the roof membrane may or may not be fully adhered, but the insulation clearly requires the ballast to keep it in place.

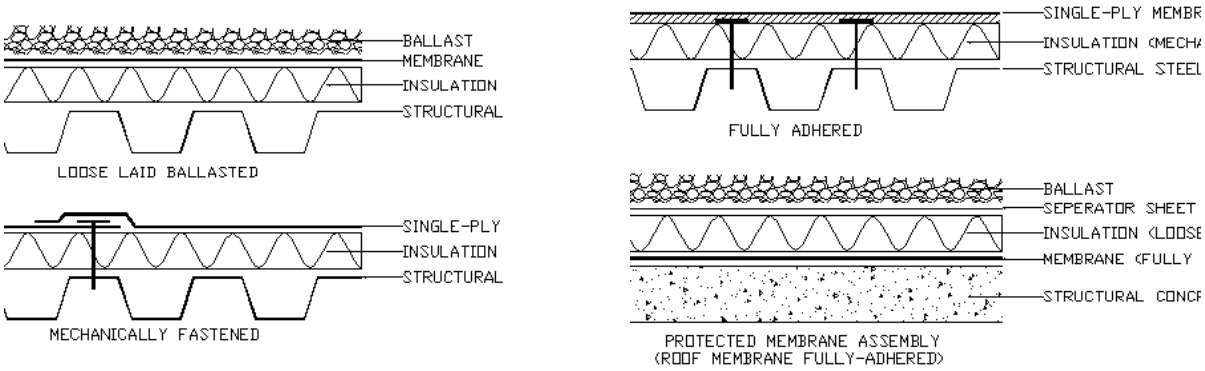

Figure 1. Attachment methods.

Deficiencies in attachment are a cause of roofing failures. Membrane blow-off causes failure of the weatherproofing system at the very least, and can be accompanied by structural failure of the roof

under certain circumstances. Another example is failure of the attachments causing failure of the waterproofing membrane. Examples include fasteners backing out through the membrane, or fasteners penetrating the roof deck and causing condensation and water issues in the spaces below. Either deficiency can have significant adverse effects on the long term use of the existing roofing installation. Evaluating the appropriateness of the attachment method for the specific type of roof deck and evaluating the condition of the attachment devices is critical to the long term performance of the deck. Attachment is evaluated by comparing an appropriately attached roof system with no apparent failures (score a 10) with an inadequately fastened, but functioning well roof system (score of 5) with fastener back out puncturing the membrane (score of 1). Typically fastener defects are difficult to detect in a surface visual review of the roof system. For this reason, it becomes important that the personnel performing the rankings also perform review of the construction documents, looking for fastening requirements and also access the interior of the building to attempt to verify fastening type and pattern from the underside of the roof deck. IN our experience, this factor is likely to be evaluated as either a 10, a 5, or a 1 by most assessors.

2.7 Slope and Drainage

Slope is an important factor in the proper function of a roof system. Adequate slope can compensate for inferior materials and construction quality; therefore, a roof with positive slope to drain (greater than ¼ inch per foot) should receive higher score than one with less slope. The waterproofing ability of the membrane is less likely to be compromised by draining water quickly away from the roof surface. Roof drainage and slope are two distinctly different parameters. An adequately sloped roof can have inadequate drainage, and a flat roof deck can have adequate drainage. Inadequate drainage on a well-sloped roof can lead to slower water runoff, taxing the roofs' flashing systems and potentially leading to leaks. A relatively flat roof system can have adequate drainage, which becomes a requirement when designing protected membrane assemblies. Well sloped roofs with minimal or no indications of ponding should score a 10, while no slope roofs with extensive ponding score a 1. Drainage is an important factor in the proper functioning of a roof system. Drainage refers to the ability of the roof system to carry water away from the roof and the building. The building code usually dictates the minimum level of drainage required for a roof system. Conventional roof design calls for at least four drains for larger roofs, a minimum of two drains for roofs under 10,000 square feet, and a maximum spacing of drains in any direction of 75 feet. Roofs that meet these criteria should receive a higher score; those not meeting the requirement should be scored lower. In addition, drainage also covers the adequacy and function of the existing roof drains. Roof drains that are clogged, that inadequately carry water away from the roof and building, or that overflow during severe events, should be scored appropriately lower when evaluating drainage. Roofs with good drainage, adequate for the flow of water, well placed to divert water from the roof and building score a 10, while roofs with minimal drainage that retain water score a 1. Scoring within the slope and drainage category should be an average of the 1 to 10 recorded for Slope and the 1 to 10 recorded for Drainage.

2.8 Constructability

This factor is associated with the human element of postponing needed repair or renovation of failed roof systems only because they are difficult to access. In our experience with multi-building complexes, the more difficult it is to reach a roof, the longer the replacement is avoided. To overcome this tendency toward procrastination, we rank relatively inaccessible roofs with lower values than those that are readily accessible. Constructability refers to the construction factors involved in maintaining or replacing a particular roof, taking into account building location, height, type, roof location and number, use, and occupancy. Roofs on taller buildings are more difficult to access than those on lower buildings. A building located in cramped conditions with inaccessible roof edges will be more difficult to replace. Roofs that can be easily and readily replaced or repaired due to their location, height, use, etc. should be scored a 10. Roofs that will be difficult to replace due to inaccessible locations or extensive restrictions should be scored a 1.

2.9 Leak History

Leak history can be quickly determined based upon interviews with building occupants or visual inspection of the interiors. A roof that leaks extensively each time it rains scores a 1. A roof that never leaks would be scored a 10. Scores between 1 and 10 are based on a count of the number of leaks and a comparison of the total number of leaks at each building across the complex. It should be noted that the leaks need to be considered purely on number, not on what is damaged. Additionally, the determination of leak history scoring could be augmented with knowledge gained from Non-Destructive Evaluation (NDE) such as infrared or nuclear moisture scanning, if performed; however, NDE is not necessarily a requirement for completion of the ranking system.

2.10 Durability

Material durability refers to the roof system's ability to resist weathering and natural or man-made impact without breaking down. Membrane type, thickness and surface treatment have a significant effect on roof system durability. The roof membrane and surfacing must have the capability to expand and contract to prevent splits and tears from extreme temperature changes. This capability must be present when a roof is constructed, and remain at adequate levels throughout the EUL of the roof. Thus, in order for a roof system to perform adequately, it must have adequate material durability when it's constructed and not have a tendency to lose those characteristics as it ages. For the most part, roof membrane materials today possess the material durability to resist weathering and building-related movement. However, some roofing materials may not be suitable for the climatic conditions of the site. A relatively thin, single-ply membrane that is suitable for a sunny, mostly dry climate with no foot traffic in the southwestern United States is likely inadequate for a mid-Atlantic U.S. environment where large seasonal swings in temperature are experienced. A particular membrane assembly that is used in environments where insulation is not needed or used may not be appropriate in a heavily insulated assembly. Many manufacturers have multiple membrane products for numerous surfacing configurations. Table 4 provides a summary of the author's durability scoring methodology used in this prioritization schema. These scores are based on the author's experience and relate similarly to the age scoring EUL as shown above. It should be noted that scoring the age factor is purely based on the numerical age of the roof compared to its EUL, while scoring the durability factor is more related to the relative durability of one material to another.

Table 4. Durability scoring.

Roofing System	Surface Type	Relative Durability	Score
Built-up (3 or 4-ply)	Gravel	High	10
Modified Bitumen (2-ply)	Granules	Moderate to High	9
Single-ply (TPO, PVC – heat-welded)	Un-surfaced/Exposed Membrane	Low to Moderate	8
Single-ply (EPDM – adhered)	Un-surfaced/Exposed Membrane	Low to Moderate	7
Metal (standing-seam)	Fluoropolymer Paint	High	10

3 USING THE FACTORS

Based upon the evaluations performed at a multi-building complex in the Northeastern Atlantic Region each roof was given a ranking score in the 10 categories as defined above. The scores were determined by minimally trained field personnel and compared to the opinions of two Registered Roof Professionals who had also accessed each roof. Table 5 summarizes the scores for selected buildings at the complex to provide an idea of how the system works. Table 6 summarizes the resultant score for the selected roofs and ranks them in order of priority. It should be noted that the complex surveyed consisted of approximately 130 buildings, with a total gross building area of approximately 1.4 million square feet. In this phase of the work, 30 buildings were surveyed totaling approximately 512,000 square feet in area, or an approximate 33% sampling. Typically, scores below 60 would be considered a priority for replacement, while scores above 80 would indicate roofs that

were recently installed, or were in good condition. As can be seen from this ranking, the complex has many roofing systems that rank between 50 and 70, indicating a great need at the facility both for roofing maintenance activities to keep the roofs from deteriorating further and for funding to begin to replace those roofs with scores below 50 indicating a roofing system that is on the verge of failure.

Table 5. Sample Individual Roof Ranking Scores.

Bldg. Letter	Age	Crit.	Mem.	Flash.	Attach.	Slope/ Drainage	Const.	Leaks	Suscep.	Dura.
A	1	3	1	3	8	10	8	6	10	10
B	5	3	8	8	9	8	8	4	10	7
C	1	4	5	5	6	10	10	9	10	10
D	1	4	5	4	6	10	9	7	10	10

Note: Generic buildings considered, to show how rankings would be tallied, does not match those in Table 6.

Table 6. Roof Prioritization.

Fair Condition

4 SUMMARY

In summary, these 10 items can be subjectively rated by minimally trained individuals to obtain a roof rating. This roof rating can then be tracked in a database to obtain information on the relative degradation of the roof, and from this information, projected deterioration rates and replacement time frames determined. In addition, the rating can be used to rank multiple roofs across one or more multi-building complex in order to more efficiently spend the limited budgets.

ABSTRACT

The area of rooftop gardens has increased in Japan. As for waterproofing membranes used for rooftop gardens, the resistance to penetration by root systems such as roots or rhizomes of plants is needed in addition to the fundamental performance of waterproofing. Evaluation of root resistance of a membrane in advance is therefore required for actual roof application. The test method where trees or grass are planted in a container inside of which a test membrane was applied, and is then inspected for root penetration, has been widely adopted. However, the method takes a long time to obtain a result, and the development of a simple test method is needed for both users and manufacturers. It is well known from our experiences that rhizomes of bamboo grass are very hazardous for waterproof membranes. We therefore measured actual penetration force of the tip of a bamboo rhizome and observed the penetrating force of 9.8N. A new test method such as a needle penetrating method was developed on the basis of the results. The three penetrating needles of 0.1 mm, 0.3 mm and 0.5 mm in tip diameter were first prepared on the basis of the shapes of bamboo grass and lawn grass tips. Penetrating loads by the needles were then measured for various waterproofing membranes: five PVC sheets, five polyurethane membranes and five EPDM sheets. As for root resistance tests using actual plants, bamboo grass and lawn grass were also planted in containers, inside of which the same kinds of waterproofing membranes were applied. After the 1 year, the membranes were inspected, and the two results from the needle penetrating test and the container test were compared. It was found that the maximum strength in the needle penetrating tests and the strength at 1 mm penetration correponded well with the results of the container test. The proposed needle penetrating test and the two values as indices were considered to be useful for estimating the resistance of waterproofing membranes to root penetration.

1 INTRODUCTION

Rooftop gardens have been rapidly spreading in recent years. Unlike conventional systems having a heavy layer of concrete to protect the waterproofing membrane, soil for planting is directly placed on the waterproofing membrane without a concrete protective layer. In such a case, the tips of roots and rhizomes can come into direct contact with the membrane or even penetrate it if it is not strong enough. Such penetration by roots and rhizomes can lead to critical damage to the system directly leading to water leakage.

For this reason, waterproofing membranes for rooftop gardens are required to be root-resistant. However, root resistance has not been regarded as an evaluation item for conventional waterproofing membranes. At the present time, penetration resistance of waterproofing membranes has had to be judged solely by actually planting, waiting for the plant to grow, and observing if its roots or rhizomes have penetrated the membrane after a certain period. Though this method is realistic in that it uses actual plants, it requires a period of over a year to obtain the results, and above all, the results depend on the growth characteristics of the plants. If the plants are poorly growing, the forces of their roots are not strong enough to penetrate the waterproofing membranes, possibly leading to misjudgment of the root resistance of membranes. A mechanical test method for root resistance independent of the plant characteristics similar to other performance items for waterproofing membranes is desirable in order to evaluate root resistance of a membrane in an objective manner. With this as a background, the authors investigated a mechanical method of evaluating the root resistance of waterproofing membranes that is reproducible and simple.

In regard to past studies on this subject, methods have been standardized such as DIN 4062[1)] and the test method by FLL (the Landscaping and Landscape Development Research Society e.v.)[2)], in which actual plants are planted in containers applied inside by test membranes and the state of the membranes is investigated after intermittent observation over a period of several years. However, there have been few studies were found that evaluate the root resistance of waterproofing membranes using a mechanical apparatus instead of actual plants.

2 APPARATUS AND METHOD OF MEASURING PENETRATING LOAD

2.1 Shapes of Rhizome Tips

Whereas both roots and rhizomes can penetrate waterproofing membranes, severe damage to membranes is mostly caused by rhizomes. Therefore, in this study, the development of an apparatus for testing root resistance was intended for rhizomes. Since the shapes of rhizome tips were considered to produce a significant effect on the root resistance evaluation, the tips of bamboo grass and lawn grass were microscopically observed as representative rhizome tips.

Bamboo grass and lawn grass, both of which reportedly cause damage to membranes, are commonly used for Japanese style gardens and turf, respectively.

Typical shapes of their rhizome tips are shown in Figure 1. As these rather sharp shapes vary from one rhizome to another depending on the growth conditions, the tip shapes were approximated to hemispheres to examine their diameters.

The results, superimposed on the photo, are approximately in the range of 0.1 to 0.5 mm in diameter, though with differences depending on growth and time.

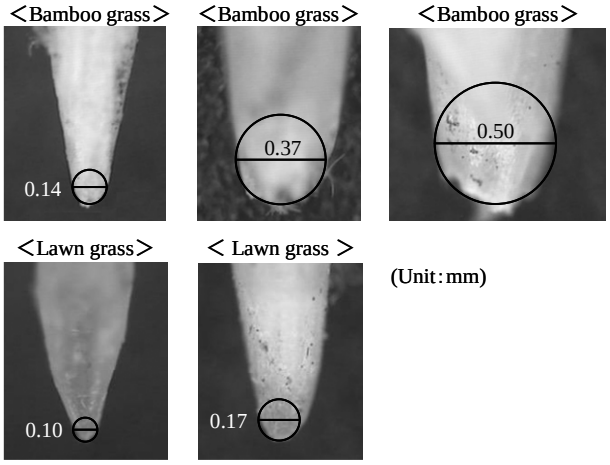

Figure 1. Tip of Rhizomes.

2.2 Simulated Needles

Needle-like tips simulating these rhizomes were fabricated based on the results of observation. The diameters of hemispherical tips were 0.1, 0.3, and 0.5 mm, with the axis diameter being 3 mm. Steel was selected as the material, as robust tips were required to test the root resistance of waterproofing membranes having a wide range of hardness.

2.3 Specimens

Specimens were prepared by sandwiching a membrane between two 8 mm-thick disks with a through hole in the center as shown in Figure 2. Since the diameter of the hole could affect the test results, tests were conducted using disks with the diameter of a hole of 2, 3, 5, and 10 mm to examine its effect. Figure 3 shows typical results. Whereas the stroke of the needle tip at puncture tended to increase as the diameter of the hole increased, the load at puncture remained nearly the same independent of the diameter of the hole. A hole diameter of 3 mm was therefore adopted for ease of measurement.

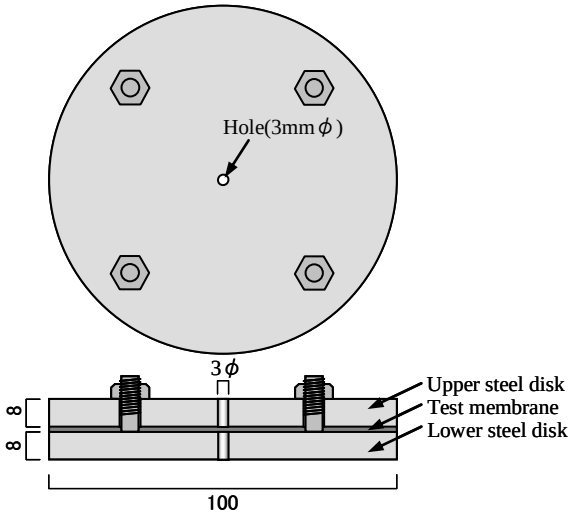

Figure 2. Membrane fixing disk (Unit:mm).

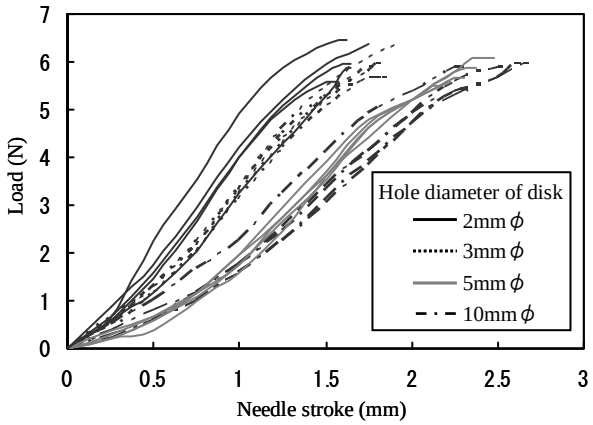

Figure 3. Relation between load and needle stroke at various diameter of disk in needle penetration test（PVC membrane: 0.5mm thick, Needle tip diameter: 0.3mm., Stroke rate: 1.0mm/min）

2.4 Test Procedure

As shown in Figure 4, the needle tip was pressed onto a waterproofing membrane, while measuring the load and the needle stroke. The penetrating speed of the needle was 1.0 mm/min for ease of testing. Also, as most waterproofing membranes are polymeric materials and are affected by temperature, tests were conducted partially at three levels, 10, 20, and 30 ℃, while the test temperature assuming the soil temperature was basically set at 20℃. Five specimens were tested for each type of waterproofing membrane.

3 MEASUREMENT OF PENETRATING LOAD

3.1 Tested Waterproofing Membranes

For the purpose of developing a test method, it is necessary to obtain data using, to the extent possible, a wide variety of waterproofing membranes having different mechanical properties. Tested membranes included the following: five mixes of elastic polyurethane rubber/urea resin fluid-applied membranes, five thicknesses of PVC sheet-applied membranes, and five types of EPDM sheet-applied membranes with and without reinforcement of different compositions. The types and mechanical properties of these membranes are listed in Table 1. Not all of these materials are available on the market. Some were specially manufactured as trial products for this study.

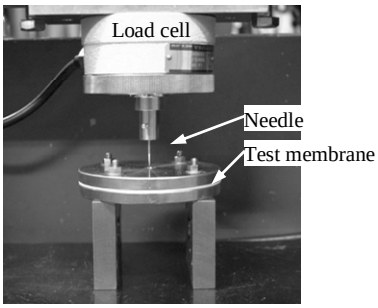

Figure 4. Test apparatus for measuring needle penetrating load.

Table 1. Test membrane.

Membrane	Sample Name	Thickness (mm)	Strength at peak*	Strength at break* (N/mm^2)	Elongation at break* (%)
Polyurethane fluid-applied membrane	PU-1	3.2	-	4.3	520
	PU-2	3.1	-	11.8	595
	PU-3	3.2	-	14.1	370
	PU-4	3.5	-	19.9	136
	PU-5	4.2	-	22.5	29
PVC sheet-applied membrane	PVC-1	0.1	-	22.0	232
	PVC-2	0.2	-	24.7	272
	PVC-3	0.5	-	12.0	223
	PVC-4	1.5	-	13.3	247
	PVC-5 (reinforced by glass fiber mesh)	1.5	101.8(N/mm)	82.9(N/mm)	232
EPDM sheet-applied membrane	EPDM-1	1.0	-	10.5	523
	EPDM-2	1.4	-	10.1	502
	EPDM-3 (reinforced by glass fiber mesh)	1.5	66.3(N/mm)	65.8(N/mm)	405
	EPDM-4 (reinforced by polyester fiber mesh)	1.4	122.0(N/mm)	51.0(N/mm)	453
	EPDM-5 (reinforced by polyester nonworen cloth)	1.5	-	55.7(N/mm)	374

* Date are shown as the averaged value of five specimens obtained from tensile test at 100mm/min.

3.2 Measurement Results

Figure 5 shows the measured penetrating load of simulated needles with a tip diameter of 0.1, 0.3, and 0.5 mm. Figure 6 shows the results at different test temperatures. Note that measurement was terminated when the needle tip punctured the membrane or when the load exceeded 50 N.

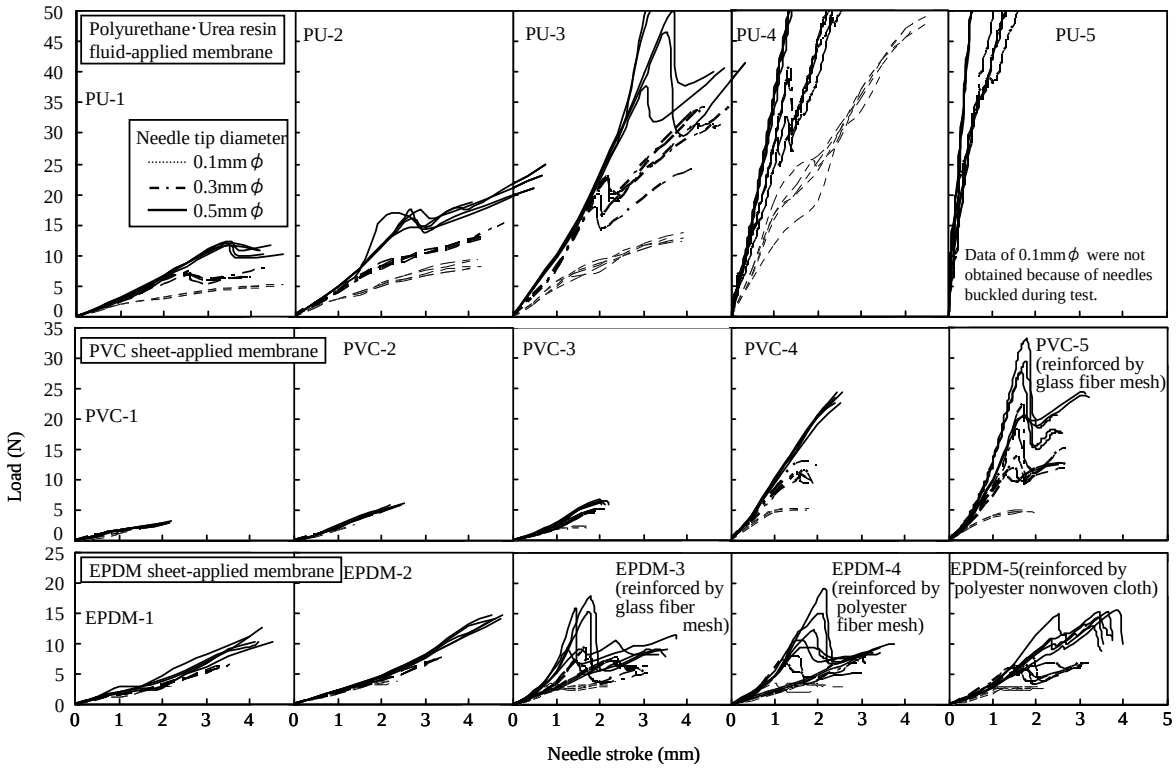

Figure 5.Load-needle stroke behavior at various needle tip diameters in needle penetration test.

3.2.1 Load-Stroke Relationship

The load increased as the needle penetrated into the waterproofing membrane. For most membranes, the load peaked when the needle tip pierced through the membrane and immediately decreased thereafter. The load behaviour tended to be complicated when the needle tip penetrated into thick membranes, such as urethane rubber/urea resin liquid-applied membranes, presumably because of the side surface of the needle coming into contact with the membrane. Also, for PVC and EPDM reinforced membranes, the load did not drop immediately after the peak but slowly decreased.

3.2.2 Effect of Needle Tip Diameter

In regard to the size of needle tips, which were worked into hemispheres, the peak load tended to increase as the needle tip diameter increased. However, the load behaviour of needle tips penetrating into reinforced membranes tended to be complicated presumably due to friction and interruption by reinforcement in membranes during penetration.

3.2.3 Effect of Temperature

Within the temperature range of this study, the load slightly tended to increase as the temperature decreased. However, no marked difference in the load was observed in the region of small strokes in which the penetration of actual roots and rhizomes causes problems.

This may be because the temperature range of 10 to 30℃ could not cause significant changes in the mechanical properties of membranes.

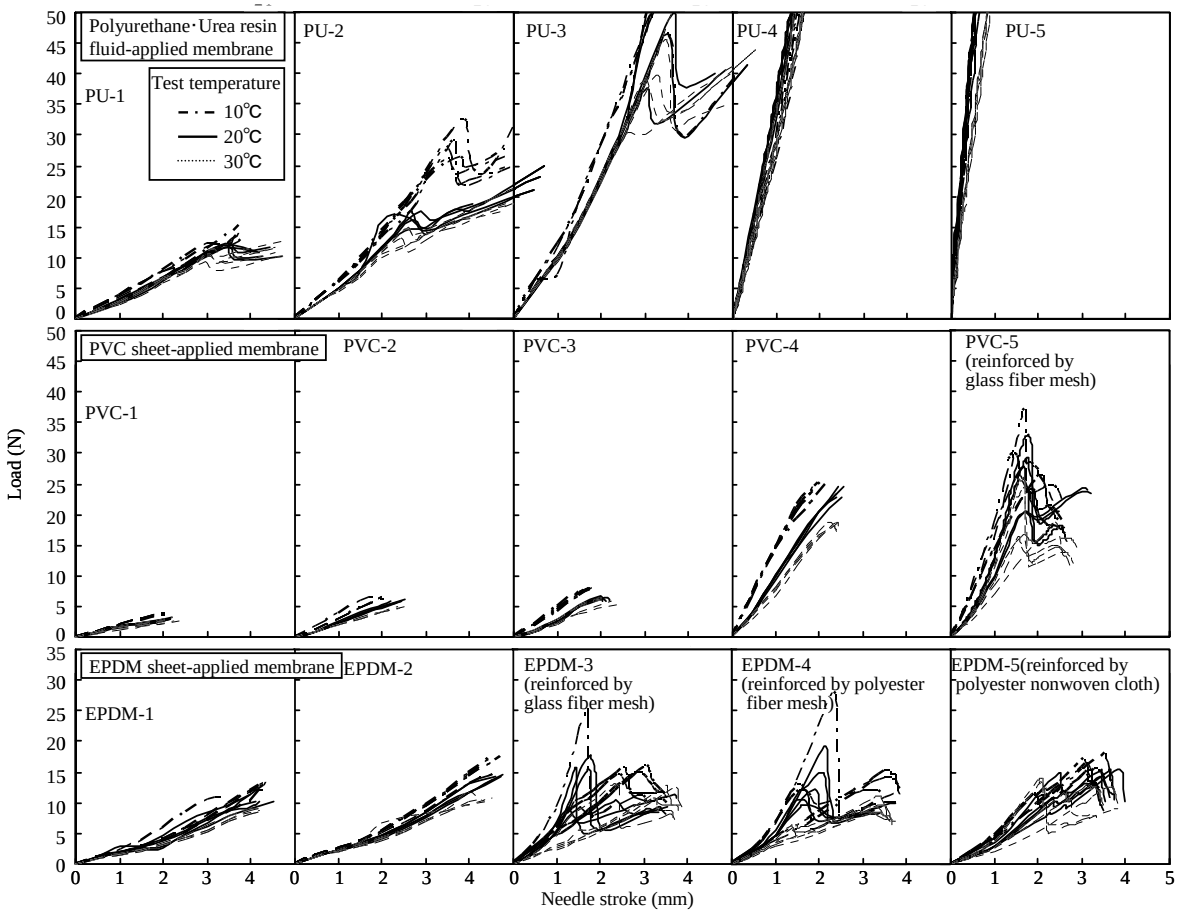

Figure 6. Load-needle stroke behavior at various temperature in needle penetration test.

4 ROOT RESISTANCE TESTS USING ACTUAL PLANTS

4.1 Test Plants

Bamboo grass and lawn grass were used again.

4.2 Specimens

A specimen consisted of an inner container, which was made of punched metal with many holes 20 mm in diameter, a test waterproofing membrane, and an outer container as shown in Figute 7. Soil was placed on the membrane to plant the grass, as well as between the inner and outer containers to let the roots and rhizomes that would penetrate through the membrane and holes grow out without being interrupted.

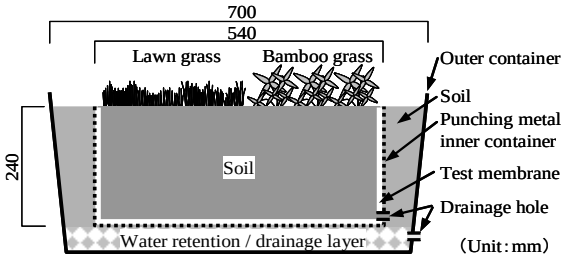

Figure 7. Test apparatus of investigateresistance.

4.3 Test Procedure

4.3.1 Specimen Preparation

A waterproofing membrane was laid on the inside of each inner container made of punched metal. As for the liquid-applied material, a box-shaped membrane was produced beforehand in a laboratory so as to fit into the inner container. Soil was then placed in the container, in which bamboo grass and lawn grass was planted. The inner container with the plants was then embedded in an outer container containing soil.

4.3.2 Growth Control of Plants

As shown in Figure 8, the specimens were placed in a greenhouse, which was not air-conditioned but was under rough temperature control by shading from the sunlight and ventilation, and watered according to the plant condition so as to let them grow well.

Figure 8. Specimens in greenhouse.

4.3.3 Observation of Specimens

During the test period, each inner container was periodically removed from the outer container to observe the state of root/rhizome penetration through the sides and bottom of the membrane. After observation, the container was fitted back into place to continue testing. Observation was carried out for a year from July 27, 2004 to July 27, 2005.

4.4 Test Results

Figures 9 and 10 show the test results. In the root systems of bamboo grass and lawn grass, which comprise rhizome portions and root portions, only the rhizome portions punctured some of the waterproofing membranes. Generally speaking, puncture by bamboo grass was observed at earlier times than by lawn grass. The rhizomes of plants more often penetrated through softer or thinner membranes.

When examined in more detail, however, the order of time to penetration does not necessarily agree with the order of the thickness of membranes. For instance, a PVC sheet-applied membrane 0.5 mm in thickness was punctured by bamboo grass earlier than the same membrane 0.2 mm in thickness, and an EPDM sheet-applied membrane 1.5 mm in thickness was punctured but the same membrane 1.0 mm in thickness was not punctured. Detailed observation by dismantling the specimens after a year revealed that, in specimens with non-punctured membranes, rhizomes were bent at the membrane surfaces and grew along the membranes thereafter. Whether rhizomes penetrate the membranes or bend at the membrane surfaces appears to depend on the relative strengths of rhizomes and membranes. These vary due to the fact that the penetrating forces vary form one rhizome to another in actual plants. Generally speaking, however, soft membranes tended to be punctured more than hard membranes.

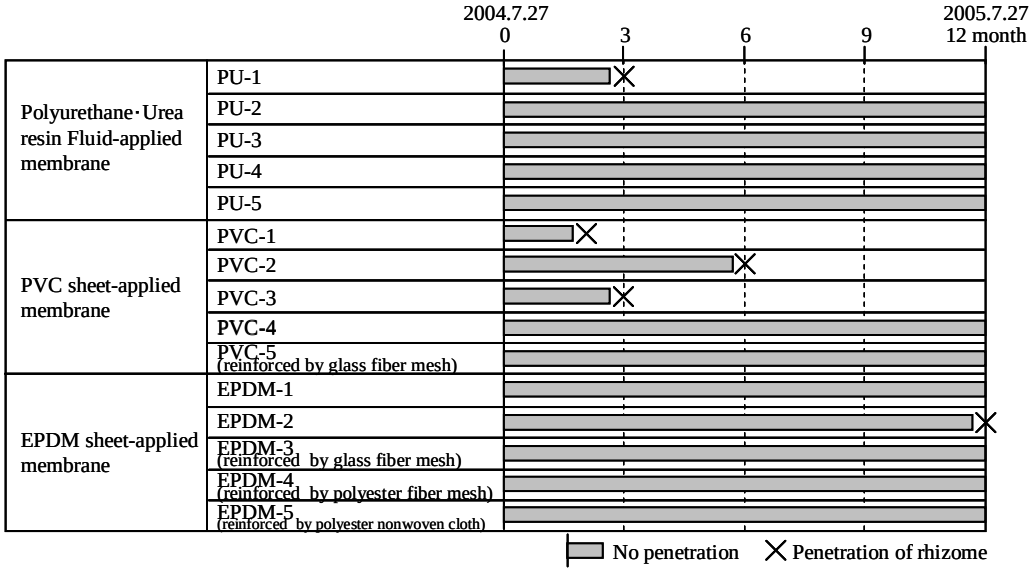

Figure.9 Results of resistance test to root/rhizome penetration(Bamboo grass).

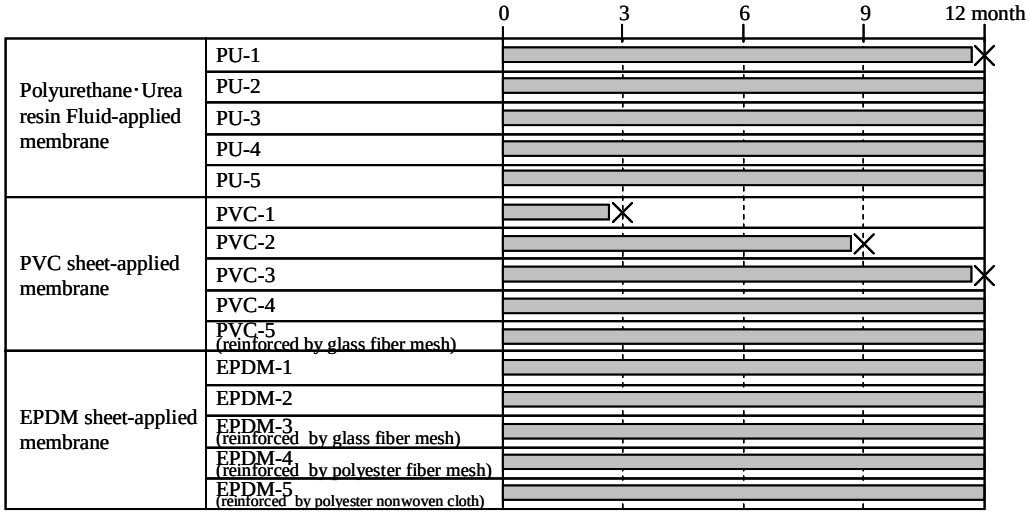

Figure.10 Results of resistance test to root/rhizome penetration(Lawn grass).

5 DISCUSSION

Various physical values in the penetration tests of waterproofing membranes using simulated needles were compared with root resistance test results by using actual plants. The load-stroke curves up to 50 N were organized in the four values such as the maximum load, load at 1.0 mm of needle stroke, maximum needle stroke at penetration, and deformation energy to penetration (i.e., area under the load-stroke curve to penetration) as shown in Figure 11. The results of membranes punctured by actual plants are shown in black in the figure.

5.1 Relationship between Maximum Load and Root Resistance Test Results

When the needle tip diameter was 0.1 mm, five membranes with a maximum load of 4.9 N or less were penetrated by testing using actual plants. However, four membranes with a maximum load lower than this remained intact. When the needle tip diameter was 0.3 mm and 0.5 mm, membranes with a maximum load of 7.2 N and 14.3 N, respectively, were penetrated. Membranes with maximum loads lower than these were all penetrated excepting two types in both cases. These maximum penetrating

loads of simulated needles 0.3 mm and 0.5 mm in diameter can therefore be utilized as an index of root resistance evaluation.

5.2 Relationship between Load at 1 mm of Needle Stroke and Root Resistance Test Results

With a needle tip diameter of 0.1, 0.3, and 0.5 mm, membranes with a load at 1 mm of needle stroke of 2.1, 2.7, and 2.9 N or less, respectively, were penetrated by rhizomes in testing using actual plants, excepting only one type of the EPDM sheet-applied un-reinforced membrane. The load at 1 mm of needle stroke appears to strongly correlate with the root resistance and also be usable as a measure of root resistance evaluation for waterproofing membranes.

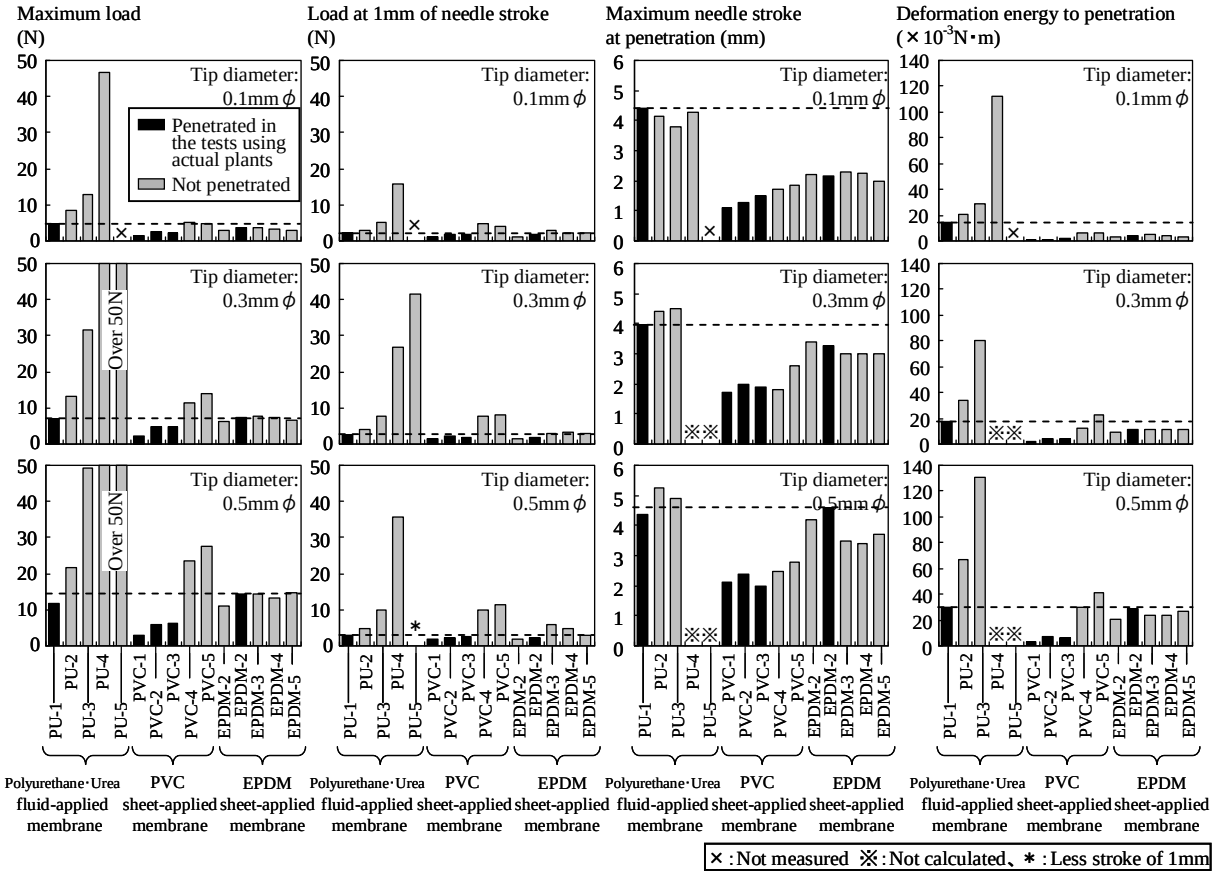

Figure 11. Various physical values obtained from needle penetration test and 1year result of root enetration test for bamboo grass.

5.3 Relationship between Needle Stroke at Penetration and Root Resistance Test Results

It is difficult to draw a line by a specific value of the needle stroke at penetration, and no correlation with the test results is observed.

5.4 Relationship between Deformation Energy to Penetration and Root Resistance Test Results

Membranes with a deformation energy to penetration of 14×10^{-3} N·m, 18×10^{-3} N·m, and 30×10^{-3} N·m were penetrated by rhizomes when the needle tip diameter was 0.1, 0.3, and 0.5 mm, respectively. However, 6, 5, and 4 membranes with a deformation energy to penetration lower than these remained intact with the needle tip diameter of 0.1, 0.3, and 0.5 mm, respectively. This parameter is therefore not likely to be usable as an index of root resistance evaluation.

Judging from all these results, the load at 1 mm of needle stroke and the maximum load may be used as rough indices of root resistance evaluation. Simulated needles with a tip diameter of 0.3 and 0.5 mm are particularly correlated with the root resistance test results. Nevertheless, it is also necessary to consider the effect of factors other than mechanical breakage in regard to penetration of the tips of root systems, such as chemical effects of acid secreted from root systems. Therefore, it is desirable to use this test method for the purpose of screening for root resistance evaluation.

6 CONCLUSIONS

The conclusions of this study are as follows:

(1) A simple test method for root resistance evaluation was proposed using needles simulating the rhizome tips of bamboo grass and lawn grass.
(2) The load required to penetrate various waterproofing membranes were measured by this test method to elucidate their load-stroke relationships.
(3) Root resistance tests were conducted using actual bamboo grass and lawn grass. Rhizomes penetrated thin or soft membranes.
(4) The results of penetration tests using simulated needles and root resistance tests using actual plants were compared. The maximum load and load at 1 mm stroke with needle tip diameters of 0.3 and 0.5 mm were found usable as simple indices of root resistance evaluation for waterproofing membranes, such as for screening of these materials.

Condensation Problems in Cool Roofs

Christian Bludau [1]
Daniel Zirkelbach [2]
Hartwig M. Künzel [3]

T 22

ABSTRACT

In some regions of the United States so called cool roofs have become mandatory in order to save cooling energy in summer and it is expected that these roofs will also become more widespread in other parts of the world. A cool roof uses a bright surface to reflect incident solar radiation which significantly lowers the day-time surface temperature compared to conventional roofs with bituminous felt. However, since most energy savings measures involve some sort of moisture related issue, the question is whether the widespread application of these roofs may lead to durability problems. There are already rumors that the so-called self-drying roofs that do not have a vapor barrier might face moisture accumulation when equipped with a reflective surface, because the solar vapor drive helping to dry out the roofs during summer time is diminished.

In order to clarify this important durability issue experimentally verified hygrothermal simulations have been carried out on light-weight flat roofs with and without reflective surface layer. Because the long-wave radiation to the sky is an important factor for the night-time roof temperature and thus also for the risk of interstitial condensation, the sky radiation has been measured as part of the meteorological data collection at the field test site in Holzkirchen. Together with continuous surface temperature recordings of different roofs these meteorological data have been used to validate the new radiation exchange model of a hygrothermal simulation tool. Afterwards a typical light-weight cool roof has been selected and its moisture behavior simulated under different outdoor conditions. The results show that severe moisture accumulation will only occur in colder regions of Europe and North-America. However, among these regions there are also some where cool roofs could be beneficial for cooling energy savings.

1 INTRODUCTION

In order to build energy efficient buildings nowadays it is very important to optimize the building envelope. The roof provides a large part of the envelope so it is obvious to try saving energy at this area. There are already some approaches and solutions to save energy by building a so called 'cool roof'. A cool roof uses a bright surface to reflect incident solar radiation which significantly lowers the day-time surface temperature compared to conventional roofs with bituminous felt. Cool roofs bring along the risk of moisture accumulation in colder regions of Europe and North America due to the reduced surface temperature during the day. Furthermore the long wave radiation can lead to overcooling of the surface beneath the ambient temperature. Such low temperatures during the night can cause the temperature to drop beneath the dew point followed by condensation of moisture in the construction. New simulation models are able to consider this effect.

2 FUNDAMENTALS

2.1 Cool Roofs

The temperature occurring on a roof depends on several factors. When the solar radiation hits the roof's surface, a part is reflected, another is absorbed. A part of the received energy is emitted back to the sky as infrared radiation. Another part of the heat is exchanged with the environment by convection. The remaining heat flows through the roof and interacts with the room. This heat flow depends on the temperature gradient between the roof surface and the interior temperature, the thermal conductivity and the thickness of the construction materials (e.g. insulation) of the roof. Unlike conventional roofs, cool roofs keep a moderate temperature even during hot summer days by having a higher solar reflectance and higher thermal emittance than conventional roofs. Many publications, especially from the United States, talk about cooling energy savings of up to 25%.

2.2 Self Drying Roofs

Self-drying roofs are designed to eliminate accumulation of moisture in the construction. The occurring moisture can dry out to the interior of the building (downward drying). The construction is usually sealed to the outside by a roofing membrane acting as water and vapor barrier. In the interior the construction consists of an insulation core made from materials which do not rapidly degrade mechanically in the presence of moisture. To the inside no vapor retarder is used to guaranty the possibility to dry out. The interior finish can be formed for example by a gypsum board in habitations or profiled sheeting in industrial buildings. A widespread research about self-drying roofs was performed by Dejarlais [Desjarlais *et al.* 1995 and 1998].

3 CALCULATIONS

3.1 Climatic Data

For the studies performed at the Fraunhofer Institute for Building Physics in Holzkirchen measured climatic data are used. The climate at Holzkirchen is representative for a critical climate situation in Germany. At the institute's weather station many kinds of metrological data are collected. To carry out these investigations the following data have a significant influence. The surface temperature on black and white surfaces (measured since 1998), the global, diffuse and west radiation (measured since 1987) and the atmospheric counter radiation (measured since 2002). A further experimental setup was built up in 2007, to research the influence of the night time long wave radiation in detail.

3.2 Hygrothermic Simulations

A validated method for simultaneous calculation of heat and moisture transport in building components WUFI® [Künzel 1994] was used for the simulations in this paper. As boundary conditions the climatic reference data (hourly values) from the investigated location was used. This file contains hourly values for temperature, humidity, rain, wind, solar-, atmospheric radiation etc.. For the interior climate the specifications from EN 15026 [2007] for 'normal moisture load' was used. The interior conditions are shown exemplary for Holzkirchen in Fig. 1. In this standard the indoor conditions are derived from the outdoor climate. Depending on the outdoor air temperature the indoor conditions vary between 20 and 25°C, respectively 30 and 60% RH. The material properties needed to perform the calculations are taken from the WUFI material database.

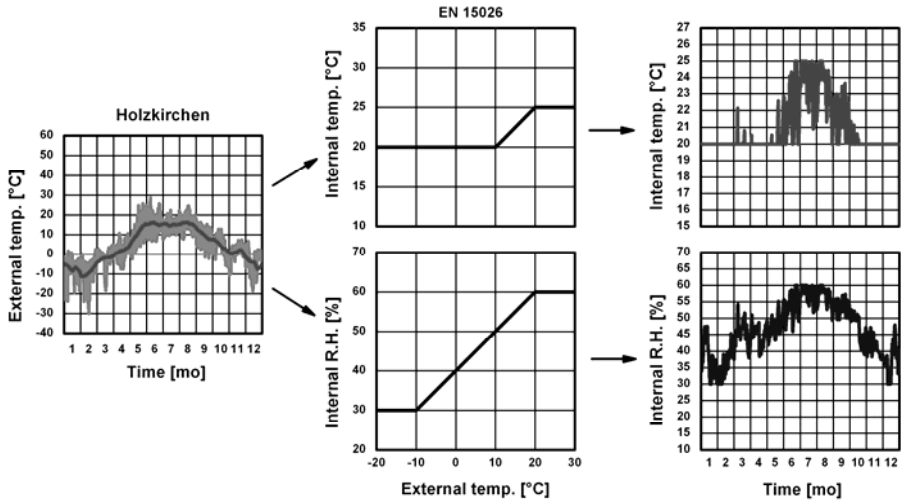

Figure 1. Example of the used interior conditions for the calculation in Holzkirchen derived from the outdoor temperature according to EN 15026 [2007].

3.3 Comparision of Measurement and Calculation Using An Explicit Long-Wave Radiation Model

For validating of an explicit long-wave radiation model in WUFI® [Kehrer and Schmidt 2006] many calculations where performed. This model considers an explicit exchange of the long wave radiation while in earlier applications the radiation effects were only lumped together with the convective heat transfer coefficient. In this section only one example is shown comparing measurement with calculation. In this case a flat roof is considered, built up with mineral wool insulation and sealed with an elastomeric bitumen roofing sheet covered with dark red colored mineral granules.

In Fig. 2 the measured surface temperature of the flat roof is displayed in blue. The red line is the temperature calculated by WUFI® using the measured ambient air temperature (green graph) as boundary conditions and the radiation values collected by the weather station. The surface temperature values are in a range of -10°C to 50°C while the air temperature only show values between -3°C and 20°C. Surface temperatures below ambient air temperature are due to long-wave radiation to the clear sky at night. The calculation shows a good accordance to the measured values; the lower temperatures during night time as well as the higher temperatures during day are captured. The days between the second and fifth November during which the calculation shows a much higher temperature than the measurement, the roof was covered with snow. The model does currently not take into account the effect of snow.

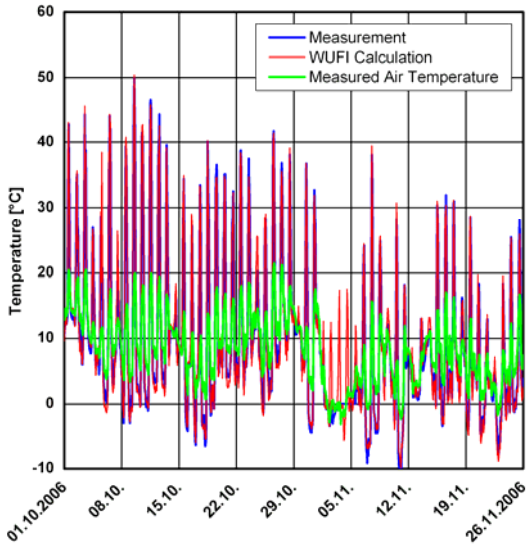

Figure 2. Comparision between measuremnet and calculation.

3.4 Self-Drying Flat Roofs in North America

The considered self-drying roof is built up as shown in Fig. 3. To the outside it is sealed by a roofing membrane, to the inside the construction is completed with profiled sheeting. The interior is filled with foam insulation (Polyisocyanurate).

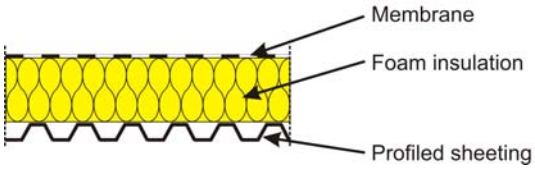

Figure 3. Composition of the self-drying roof.

The simulations were carried out for different locations in North America to find out, if there is a problem using a reflective layer on a self-drying roof. Phoenix (Arizona) was selected as warm location, Chicago (Illinois) as temperate location and Anchorage (Alaska) as cold location. The following parameters were used for the calculation: Vapor permeability of the profiled sheeting was set to s_d=3.3m (1US perm – equivalent diffusion resistance considering perforations and joints) according to Desjarlais [1995] and for the roofing membrane to s_d=1000m. The short-wave absorption factor for a white surface is 0.2 and for a black surface is 0.88. For the long-wave emission ε=0.9 is used. The calculation starts at the first of October and is continued for five years to see if a moisture accumulation will occur. The simulations results are compared by examining the total water content in the construction. If a water content of more than 0.5kg/m^2 occurs there is a risk of water dripping out of the construction. Furthermore the annual average of the moisture content should not increase over time.

The temperatures at the examined locations are shown in Fig. 4. The curves displayed in gray are hourly values of the temperature; the black curve is the floating monthly average. Comparing the average curves, in Phoenix the temperature ranges between 10 and 35°C with minimum temperatures of 0°C and maximum values of about 45°C. In Chicago the average temperature fluctuates between -9 and 23°C with minimum values of about -22°C and maximum values of about 34°C. The average temperature in Anchorage lies between -12 and 15°C with minimum values of -29°C and maximum values of 24°C.

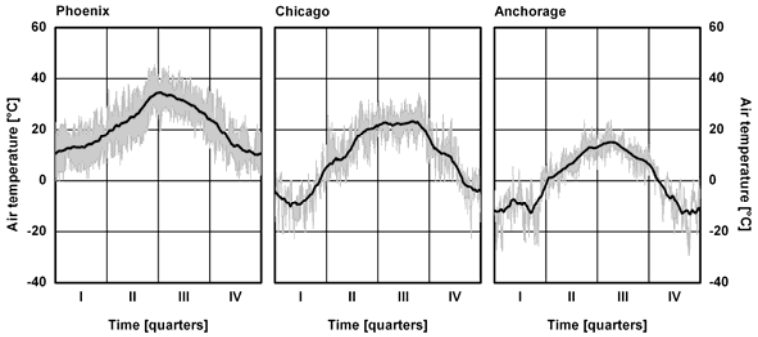

Figure 4. Air temperature in Phoenix, Chicago and Anchorage. The gray line are hourly values, the black line shows the floating monthly average.

The temporal variations of the total moisture content in the construction are displayed in Fig. 5. For the warm location Phoenix the total water content reaches up to 0.05 kg/m^2 in case of the white surface. The roof with the black surface stays dry almost all year. Concerning the roof in Chicago, a difference between the black and the white surface is recognizable. The bright roof reaches a total water content of about 0.3 kg/m^2, the dark roof about 0.1 kg/m^2. At the cold location Anchorage the roof with the dark surface shows maximum total water content of 0.35 kg/m^2 while the roof with the white surface is not able to dry out during the summer time. An accumulation of water over the years is clearly visible.

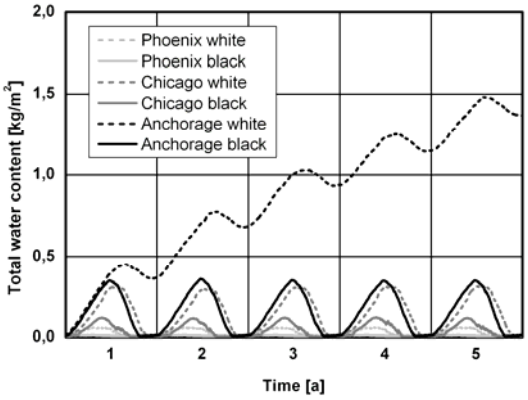

Figure 5. Total water content flat roof at different locations with white and black surface.

The self-drying roof works in most locations independent of the applied surface color under the conditions that the only source of moisture is vapor diffusion from the interior. Only in locations with low average temperatures moisture accumulation due to a bright surface color cannot be ruled out.

3.5 Bright and Dark Flat Roof in Holzkirchen

For the following comparison of the influence of the different surface colors on the moisture behavior a flat roof which is typical for European constructions is considered.

The composition is shown in Fig. 6. The roof is constructed with mineral insulation between wooden rafters, sheeted by an OSB panel and is sealed with an elastomeric bitumen roofing sheet. This roofing sheet is calculated with a radiation reflecting white surface (absorption factor 0.2) and a typical used black surface (absorption factor 0.88). The long-wave emission factor ε=0.9. To the inside the construction is closed using a vapor retarder (s_d=2m) and a gypsum board. In this example the insulation layer has a thickness of 200mm.

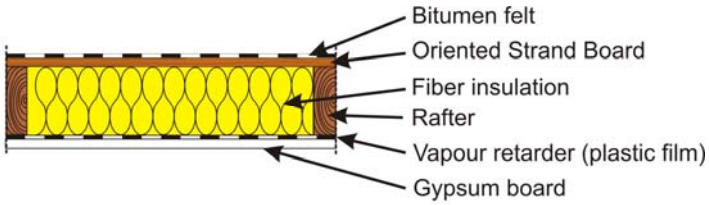

Figure 6. Composition of the flat roof.

For the calculations the Holzkirchen climate data are used. For the interior conditions 'normal occupacy' is assumed according to EN 15026 [2007] (see also paragraph 3.2). The calculation starts at the first of October and is performed for five years to see if a moisture accumulation will occur.

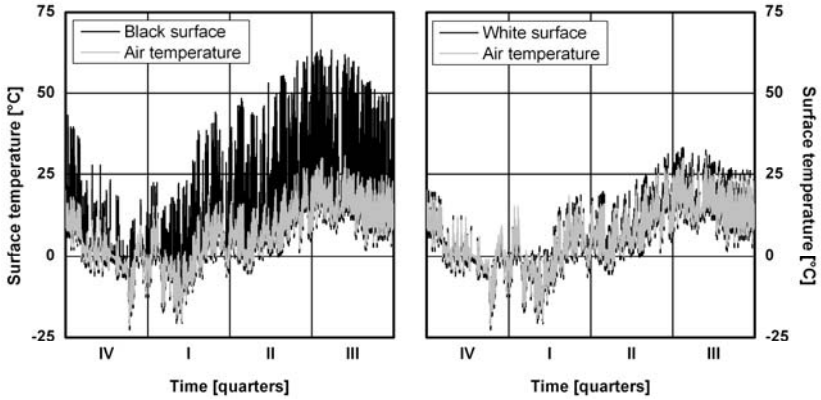

Figure 7. Comparision of black and white roof surface temperature and air temperature in Holzkirchen.

The calculated surface temperatures are shown in Fig. 7. On the black surface maximum temperatures of about 60°C develop. The fluctuation of the white roof temperature is similar to that of the ambient air temperature, with maximum values of about 30°C. On both roofs there is some overcooling below the outdoor temperature.

The cold time during night and winter is the crucial factor for vapor diffusion into the roof. If there is no sufficient drying during daytime or summer moisture accumulation can occur.

Fig. 8 shows the development of moisture in the OSB layer beneath the roofing membrane. Using a bright roof membrane the construction cannot dry out due to the reduced temperatures during the day. During night time moisture is permeating into the construction and leads to an increasing accumulation of water in the OSB layer. The moisture penetrating during winter cannot dry out during the summer time due to the reduced solar heat gain.

After five years a water content higher than 26M.-% will occur and it is still increasing. The moisture content in the wood over 20M.-% is considered to be critical because it may lead to degradation of the material. The roof with the dark sheeting shows a much better behaviour, the moisture content of the OSB layer varies between 11 and 16M.-%.

These calculations show the problems of using bright, energy saving roof sheeting in areas with cold winters. Before using such bright membranes for this kind of construction the moisture behaviour should be checked by hygrothermal simulations using the regional climate conditions.

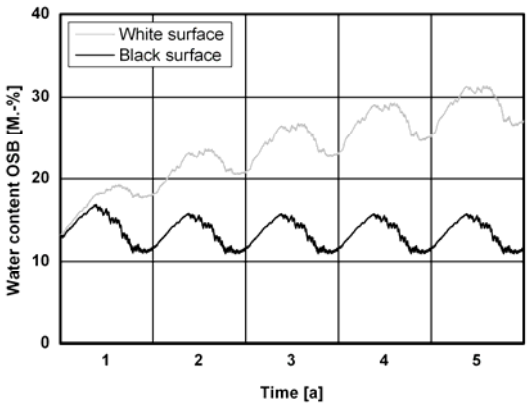

Figure 8. Comparision of the development of moisture in the OSB layer under a black and white roof sheeting in Holzkirchen.

3.6 Bright and Dark Flat Roof at North American Locations

The same construction shown in chapter 3.5 was investigated using North American climate conditions. As locations Phoenix, Chicago and Anchorage are selected again (annual temperature variations see Fig. 4). The calculations were performed for white surfaces and only if the moisture content in the OSB layer exceeded the limit of 20M.-% the simulations were repeated for black surfaces.

Figure 8 shows the water content developing in the OSB layer depending on the surface color. The white surface in Phoenix shows moisture contents between 11 and 16M.-%. In this warm region the flat roof works with every surface color.

The flat roof in Chicago reaches values between 17 and 23M.-% in the OSB sheet. For this reason the roof with the black surface is simulated as well. The black surface in Chicago leads to a water content of 10 to 15M.-%. In Chicago such a construction should be built up with a dark surface to avoid damage by accumulating moisture.

In Anchorage the white roof shows a fast increase of the average moisture content in the OSB layer signifying that such a roof will fail. If a black roofing membrane is used the moisture in the OSB layer ranges between 14 and 20M.-% which is just below the critical limit. A brighter color can not be recommended for this location.

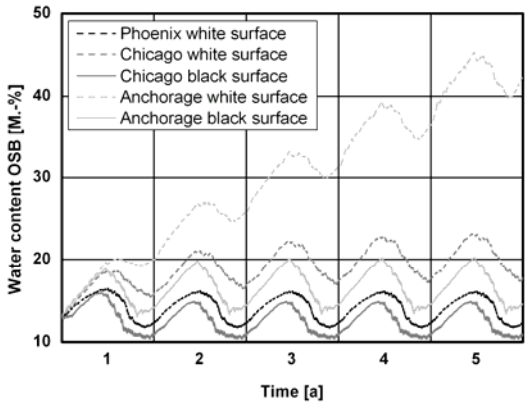

Figure 9. Comparision of the development of moisture in the OSB layer roof sheeting in North America.

3 CONCLUSIONS

Self drying roofs with foam insulation can be applied with all kind of surface colors in most parts of Northern America. Only in regions with very cold ambient temperatures there is a risk of moisture accumulation especially in case of using a bright surface. Bright roof sheeting is saving cooling energy during hot summer days. Using this sheeting at temperate climatic locations an accumulation of moisture can occur in constructions where a vapor retarder is applied at the interior side.

If a cool roof is designed for a temperate or cold climate its moisture behavior should be analyzed by hygrothermal simulations in order to avoid critical water content in the construction. If necessary a darker color of the roof surface should be considered.

Design of Mineral Fibre Durability Test Based on Hygrothermal Loads in Flat Roofs.

Daniel Zirkelbach [1]

Christian Bludau [3]

T 22

ABSTRACT

The durability of mineral fiber insulations depends to a large extent on coinciding temperature und humidity conditions within these materials. Existing test procedures use combinations of rather extreme temperature and humidity conditions above 60 or 70 °C and 95 to 100 % RH. However, these test conditions lead to a significant reduction of the mechanical strength of glass fiber insulation materials which cannot be observed in real life. Subject of this work is to evaluate these loads in light-weight flat roofs with mineral fiber insulation and dark roofing membranes. Therefore a test roof was built up at the field test site of the Fraunhofer IBP in Holzkirchen (alpine region of Germany, 680 m a.s.l.). The solar radiation and the night sky radiation at this altitude lead to rather extreme temperature conditions in the test roof. In order to achieve the most unfavorable humidity conditions within the insulation two liters of water per m² were inserted to the roof before closing the construction. The measured conditions in the roof serve also to validate hygrothermal simulation results which allow in a second step to “transfer” the test roof to other locations in northern and southern Europe. Thus, the most extreme temperature and moisture conditions likely to occur in the glass fiber insulation layer of light-weight flat roofs can be determined. A material test procedure for durability assessments should accelerate the normal degradation process but not make fail a solution which performs well in reality. Therefore, new test conditions are proposed which are closer to the conditions occurring in real life while still allowing the normal aging process to be accelerated. The result will be a more realistic decrease of the material strength compared to the present procedures.

1 INTRODUCTION

To assess the durability of mineral fibre insulation there are currently several different laboratory tests available, e.g. Nordtest, DUR2 (prEN 14509), Florida test. All these tests have in common that the hygrothermal conditions are rather extreme which often cause durability problems for glass fibre insulation products. While it makes sense to perform tests which allow an acceleration of the natural degradation process, it is also important to ensure that tests do not make products fail that perform well in reality. Therefore the hygrothermal conditions prevailing during these tests should not exceed the temperature and humidity conditions in real life by far. An acceleration of product aging can still be achieved by prolonging the duration of peak loads derived from field tests.

The aim of this study is therefore to determine test conditions that allow an acceleration of the natural aging process without damaging the insulation product in a way that will never occur in reality. The testing conditions have to be backed up by results from field tests and validated hygrothermal simulations to develop the basis for new test methods with more realistic temperature and humidity conditions.

2 INVESTIGATIONS

2.1 Field Test

Subject of this study are the measured and simulated hygrothermal conditions in an insulated flat roof with the following composition from inside to outside:

- Load bearing wooden sheathing
- Vapour barrier (aluminium foil, s_d > 1500 m)
- Insulation layer: 90 mm respectively 175 mm glass fibre boards
- Impermeable roofing membrane (elastomer bitumen)

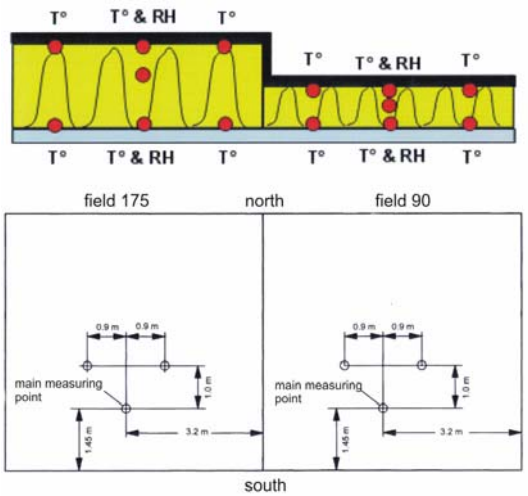

Figure 1. Sensor positions in the test roof (side and top view). The data recorded at the centre positions are used for validating the hygrothermal simulations.

A schematic drawing of the flat roof construction with the measurement positions is displayed in Fig. 1. The placement of the sensors at the positions where peak loads are expected has been selected according to preliminary calculations. The temperature measurements are performed by using PT100 temperature sensors. The relative humidity is determined by capacitive sensors. Prior to the installation, all sensors are calibrated in the laboratory. The roof was set up at the field test site of the Fraunhofer Institute for Building Physics (IBP) in Holzkirchen (South Germany) in August 2006.

In order to get an extreme scenario with a high initial moisture content about 2 kg/m² of water are added to the glass fibre insulation. It is expected that this moisture will be trapped in the construction between the vapour barrier and the vapour-tight roofing membrane. With the temperature variations during changing seasons or during a night and day cycle the moisture is expected to migrate between bottom and top of the insulation.

2.1 Hygrothermal Simulations

The hygrothermal simulations are performed by applying WUFI® [Künzel 1995], which allows the transient calculation of the coupled heat and moisture transport in building components under real climate conditions. The model was developed at the Fraunhofer Institute for Building Physics and has been experimentally validated by comparison with numerous field tests. For the mineral wool a moisture retention curve based on the paper by Peuhkuri *et al.* [2005] and adapted to fit the measured results was used. The other material parameters are taken from the WUFI® database. As outdoor conditions the measured climate from August 2006 to January 2007 in Holzkirchen including solar radiation and long wave sky radiation from the atmosphere is used. As indoor climate serve the recorded temperature and humidity conditions in the attic space beneath the flat roof. The time period for which experimental and calculation results are compared lasts from August 2006 to January 2007.

If a good agreement between measurement and calculation in Holzkirchen can be achieved, the investigation may be broadened by repeating the simulations with climate conditions at other locations. The selected locations are Copenhagen in Denmark representing a Northern European climate and Naples in Southern Italy representing the warm regions of Europe. The meteorological data sets for Copenhagen and Naples are taken from the ASHRAE [2001] climate data which were compiled for building energy calculations. While the climate of Copenhagen appears to be mild compared to Holzkirchen, Naples shows higher air temperatures but not much difference in peak radiation. The indoor climate is assumed to be the same at all locations. According to the WTA-Guideline 6-2 [2004] sinusoidal curves between 20 °C / 40% RH in winter and 22 °C / 60 % RH in summer represent the indoor conditions in residential buildings with normal moisture load. However, since the roof is water and vapour tight the humidity conditions are rather irrelevant.

3 RESULTS

3.1 Field Test

The field test described above is still ongoing - for the current paper a time period of six months from August 2006 to January 2007 is analyzed. The temperatures during the winter 2006 / 07 were quite moderate with only little snow. There were only a few days with temperatures below -5 °C while in a normal cold winter the temperatures can drop to -20 °C at times. The measured temperature and relative humidity within the construction are shown and discussed in comparison with the calculated results in the Figs 3 to 5. In the result diagrams the three sensor positions located at the centre of the roof sections are labelled from outside to inside with “exterior”, “middle” and “interior”.

3.2 Comparision of Calculation and Experiment

Figure 2 shows the measured (blue curve, sensor beneath the roofing membrane) and calculated (red curve) surface temperature of the roof with 90 mm insulation layer. The agreement between the two curves is very good - only sometimes the peak values show a small difference of two or three degree Celsius. The comparison with the outdoor air temperature (black curve) shows the strong influence of solar radiation (energy source during day-time) and sky radiation (energy sink during night-time) which is accurately captured by the new model for radiation and surface heat exchange in WUFI® version 4.1.

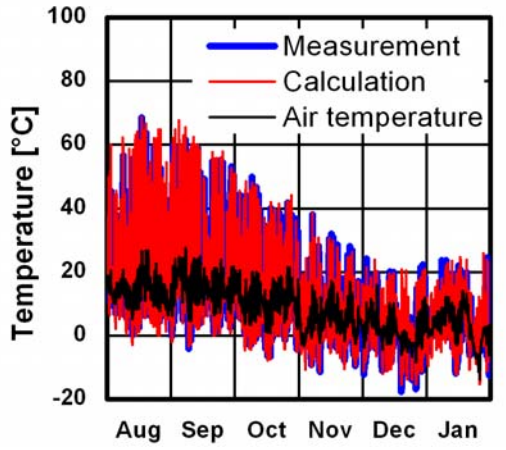

Figure 2. Comparison of measured and calculated exterior surface temperature variations of the roof with 90 mm insulation and the outdoor air temperature at Holzkirchen.

Figure 3 shows the relative humidity at the three positions within the insulation layer. The overall agreement between measured and calculated curves is quite acceptable. At the exterior position of the insulation the calculated and the measured curves coincide rather well. This is important, since the most extreme temperature and humidity conditions in the insulation layer are observed at the exterior sensor. In summer the RH at this position varies between 20 % at noon (when the sun shines and heats up the exterior surface) and 100 % during night. With lower temperatures and shorter days in autumn and winter the RH at noon increases and remains from midmonth of November permanently at 100 %. At the middle and the interior positions of the insulation layer the mean progression of the curves is very similar, but the spread of the measured values is slightly larger to both directions compared to the calculation. This difference may be due to a remaining uncertainty concerning the material properties (sorption isotherm, vapour diffusion resistance) of the glass fibre boards or the assumption of the initial water content in the roof.

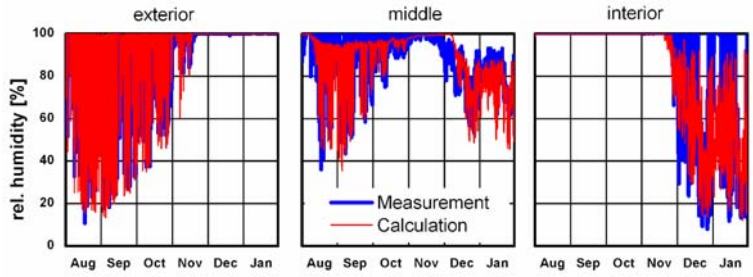

Figure 3. Comparison of measured and calculated relative humidity variations at the three sensor position in the roof with 90 mm insulation under the indoor and outdoor climate conditions recorded during the test in Holzkirchen.

A more detailed plot of the hygrothermal conditions for two single weeks in summer and winter (Fig. 4) at the exterior sensor position confirms the generally good agreement between simulation and experiment. The deviation in surface temperature on Dec. 20 is due to a thin snow cover of the roofing membrane which is disregarded in the simulation. An important observation concerning the durability assessment of the glass fibre insulation is the opposed variation of temperature and RH beneath the surface of the roofing membrane in Fig. 4. Every time, the temperature rises the relative humidity measured res. calculated for the same position drops in an inverse manner. That means high temperature and high RH never coincide at this point.

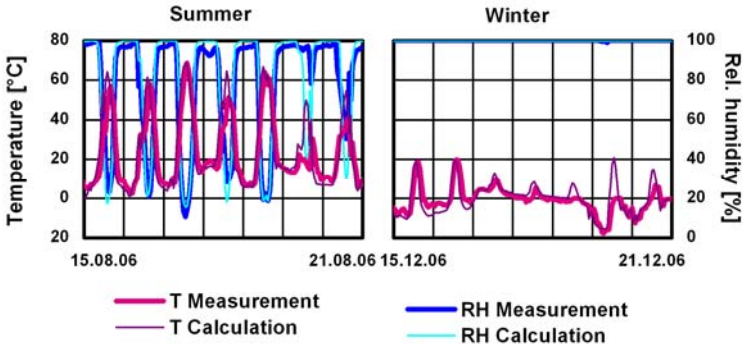

Figure 4. Comparison of measured and calculated temperature and humidity variations at the exterior sensor position in the roof with 90 mm insulation for two selected weeks in August and December.

The results of the roof with 175 mm insulation layer show less severe hygrothermal conditions with similar good agreement between measurement and calculation. Therefore these results are not plotted and discussed in this paper.

3.3 Evaluation of Peak Conditions

Laboratory test have shown that the coincidence of high temperature and high humidity has a significant degradation effect on glass fibre insulation. Under dry conditions, a high temperature doesn't do any harm and a high relative humidity is not a great problem as long as the temperature remains low. Therefore, the measured and calculated hygrothermal conditions in the roof are displayed in a special graph where temperature and humidity are plotted against each other for time intervals of one hour. Such a graph is shown in Fig. 5 for the three sensor positions in the roof with 90 mm thick insulation. The highest temperatures with more than 60 °C (maximum 70 °C) occur at the exterior position beneath the roofing membrane. However, the coinciding RH values remain very low, between 10 % and 30 %. The maximum RH of 100 % is frequently reached at all sensor positions. While the coinciding temperatures stay around 20 °C at the bottom of the roof (interior position) they can reach a maximum of nearly 40 °C in the middle and upper parts of the roof. The limit curve that will not be exceeded at any position in the insulation layer of the investigated roof can be drawn as a straight green line from 40 °C / 100 % RH to 80 °C / 0 % RH.

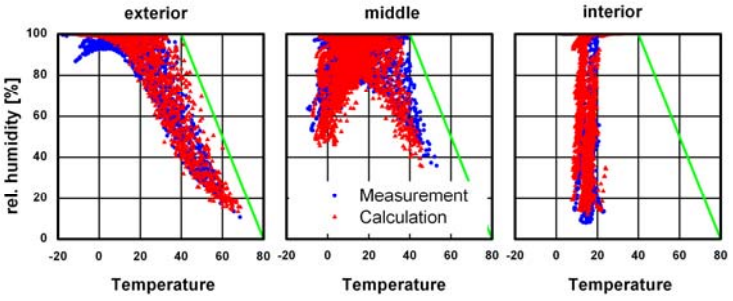

Figure 5. Coinciding temperature and humidity conditions on an hourly basis measured and calculated at three sensor positions in the roof with 90 mm insulation. The green line represents the limiting curve for the hygrothermal conditions determined for the climate conditions in Holzkirchen.

The selected locations for the further hygrothermal simulations are Copenhagen and Naples. The plot of the calculated hourly RH plotted over temperature at Copenhagen is displayed in Fig.6. The results are very similar to the data of the flat roof in Holzkirchen (Fig. 5). However, the Copenhagen results for the exterior position come a bit closer to the limit curve (green line) and go even slightly over the limit a couple of times.

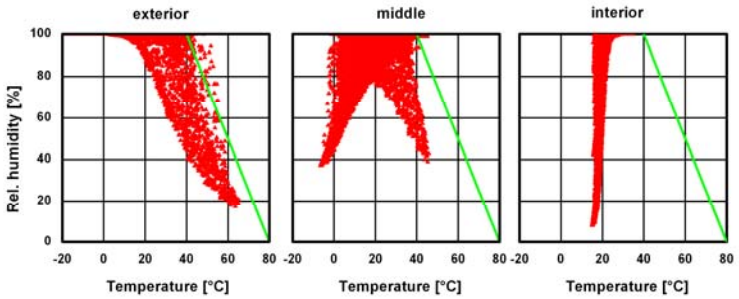

Figure 6. Coinciding temperature and humidity conditions on an hourly basis calculated at three monitor positions within the roof with 90 mm insulation located in Copenhagen. The green line represents the limiting curve defined in Fig. 5.

In order to obtain more detailed information the coincident temperatures and relative humidities are classified in steps of 10 % RH starting with 50 % and steps of 10 K between -10 and +80 °C to analyse the different peak levels. The accumulated results are listed in Table 1. About 7700 hours a year a RH between 90 % and 100 % prevails, more than 3200 hours thereof at a temperature range between 0 and 10 °C and 1600 between -10 and 0 °C. In the higher temperature ranges the hours where RH exceeds 90 % become increasingly scarce. At Copenhagen the temperature within the construction never exceeds 70 °C. A temperature above 40 °C and a coincident relative humidity of above 80 % occurs during about 90 hours a year - this represents only 1.0 % of the service life of a roof.

Table 1. Hourly classification of the simultaneous RH and temperature at the exterior position of the flat roof with 90 mm of glass fibre insulation for Copenhagen.

Temperature °C	*Relative Humidity* [%]					
	0 - 50	50 - 60	60 - 70	70 - 80	80 - 90	90 - 100
< -10						189
-10 - 0						1634
0 - 10						3262
10 - 20					1	1618
20 - 30			8	47	86	640
30 - 40	16	48	86	61	74	305
40 - 50	143	67	52	52	35	49
50 - 60	197	14	7	6	3	2
60 - 70	56					
70 - 80						
>80						

The same hygrothermal analysis is repeated with the climate data for Naples. The relative humidity over temperature plot is displayed in Fig. 7. Compared to Copenhagen the values show a similar distribution - only the maximum temperature level in summer is 15 K higher but with a lower humidity of just about 10 % RH.

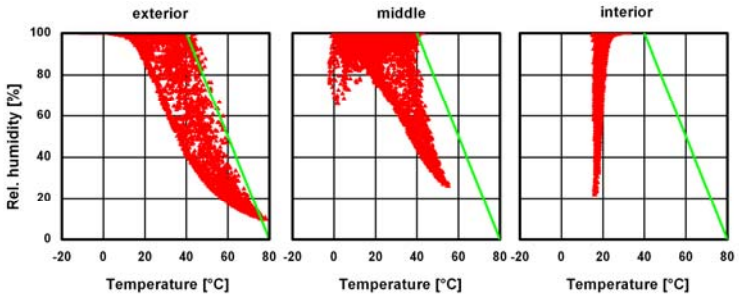

Figure 7. Coinciding temperature and humidity conditions on an hourly basis calculated at three monitor positions within the roof with 90 mm insulation located in Naples. The green line represents the limiting curve defined in Fig. 5.

The hourly classification of temperature and humidity in Table 2 shows with about 6600 fewer hours between 90 and 100 % RH than the locations further north. Due to the higher surface temperature in summer the RH decreases faster during day. Most frequent in Naples are with about 2700 hours conditions from 90 to 100 % RH combined with a temperature between 10 and 20 °C followed by 2200 hours with the same RH at temperatures between 0 and 10 °C. Values above 80 % RH and 40 °C occur during less than 100 hours - so apart from the higher temperatures of 80 °C the number of hours in a higher range of RH and temperature differs hardly from the situation in Copenhagen.

Table 2. Hourly classification of the simultaneous RH and temperature at the exterior position of the flat roof with 90 mm of glass fibre insulation for Naples.

Temperature °C	*Relative Humidity* [%]					
	0 - 50	50 - 60	60 - 70	70 - 80	80 - 90	90 - 100
< -10						11
-10 - 0						599
0 - 10						2177
10 - 20					26	2659
20 - 30			37	56	166	778
30 - 40	41	108	53	67	110	348
40 - 50	240	80	83	41	49	48
50 - 60	384	26	10	4		
60 - 70	409					
70 - 80	148					
>80						

4 CONCLUSION

The measured conditions in the flat roof in Holzkirchen as well as the simulation results for locations in northern and southern Europe show, that a RH above 95 % in combination with a temperature of more then 60 °C will never occur in a vapour permeable insulation material like mineral fibre - even if there is a high initial water content in the roof of about 2 kg/m². The simultaneous occurrence of humidity conditions above 80 % RH and maximum temperatures between 40 and 50 °C at the most critical position within the insulation layer of a flat roof (beneath the roofing membrane) does generally not exceed 100 hours a year under European climate conditions. It should be noted that these conditions do not prevail continuously for several subsequent hours and they do not affect the entire insulation layer. They represent only short peaks that happen under particular weather situations at the most exposed part of the insulation layer, the zone directly below the roofing membrane. Other parts of the glass fibre boards experience less severe conditions.

It is therefore proposed to define new durability test conditions based on the study presented here. Both the experimental results and the simulations have shown that coinciding peaks of temperature und relative humidity ranging from 40 °C to maximum 50 °C res. from 80 % to 100 % (average 90 % RH) add up to less than 100 hours per year. Consequently, there is good reason to set the durability test conditions to 50 °C and 90 % RH. However, the question concerning the duration of such test remains. Field tests periodically checking the durability of mineral fibre insulation in external wall insulation systems have shown that the greatest loss in pull-off strength happens in the first few month of service life. After that period the mechanical properties remain stable [Zirkelbach *et al.* 2005]. Continuous exposure of mineral wool to constant test conditions in the laboratory may show a slightly different picture (e.g. [Franke & Deckelmann 1999]), but they do not reflect the permanently altering hygrothermal conditions in the real world. The field tests indicate that there are periods (probably those with dominantly dry conditions) where the insulation material seem to recover its strength. This cannot happen during prolonged laboratory tests with constant peak conditions lasting 1000 hours or more. Thus, a test period in excess of the summed-up intervals of peak conditions occurring during a year in a real flat roof do not make much sense. It is therefore proposed to limit the test period to one week which is still on the safe side compared to the 100 hours of peak conditions actually occurring.

For this conclusion, the long-term performance of glass fibre boards in flat roof constructions is assumed to be comparable to that of mineral fibre boards in external thermal insulation composite systems (ETICS), where the temporal development of the pull-off strength has been determined by field tests. In order to confirm this assumption field tests monitoring the compressive strength of glass fibre insulation in flat roofs should be carried out in future.

A Model for Determining Accelerated Ageing Cycles in Durability Research: A Case Study on Continuous Roofing

Maurizio Nicolella [1]
Alba De Pascale [2]

T 22

ABSTRACT

This paper introduces research about a model for determining the experimental ageing cycle in laboratory tests for evaluating durability. The model has been implemented with computer software that uses an algorithm in which the input is comprised of a series of climatic data that was obtained from various national climatic database sources. The model was implemented specifically for evaluating a continuous roofing sub-system, as part of a broader Italian national research project, related to the durability of building components. The Italian national research project has one that encompassed a network of research organisations from the Universities of Brescia, Catania, Milan, Naples, Palermo and Turin. Research on the durability of continuous roofing has typically been based on a comparison between the results from artificial ageing tests (conducted in a laboratory) with those obtained from natural weathering tests on the same sample. The approach taken in this research project was to attempt to simulate - in the laboratory - the environmental actions that roofing sub-systems are typically exposed to, in relation to the various climatic conditions in which they are expected to perform. The computer output derived from an application of the model provides for the duration of laboratory ageing sub cycles - each one representing, and essentially reproducing a climatic season - with respect to temperature, humidity, sunlight radiation, and rainfall to which the sample is subjected. In this way a "virtual year" is obtained comprising four climatic seasons, each having different values for temperature, humidity, sunlight radiation and rainfall. The values to consider in laboratory tests are those, for the region and the time of year, which represent the season in question. The necessary values for implementing the model proposed are fixed and given in the research for three particular contexts (Milan, Naples and Palermo). Actually, a method to compose the cycles test in any climatic context for various kinds of experimentation in laboratory about the simulation of environmental effects on each part of building has been already implemented.

1 INTRODUCTION

This paper introduces the first part of a study project (part of a national research on the durability of building components) that was conducted and coordinated by Prof. M. Nicolella,. The Naples part of this research concerned the behaviour of roofing subsystems in specific climatic contexts, estimated by comparing laboratory ageing tests with natural weathering tests on similar samples of roof systems. To obtain successful and suitable laboratory tests, and, therefore, a more reliable re-scaling of data, the research group has defined some specific ageing cycles that simulate the appropriate environmental test conditions. Building from that model, the research group has generalized a system defining the method to determine the ageing cycles to apply in the laboratory for the simulation of every specific environmental context. In this paper, we intend to introduce this model and, in so doing, provide a general method to determine the accelerated ageing cycles in durability research. This effort comes from the lack of standardized approaches in defining accelerated ageing tests.

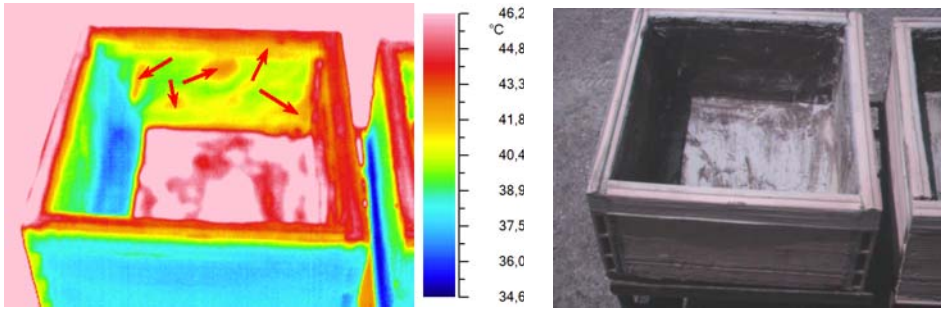

Figure 1. Infrared videothermography inspection on a sample of one of the roofing systems analyzed.

2 IMPORTANCE OF THE STANDARDIZATION OF ACCELERATED AGEING TEST METHODS

Durability standards for building materials and components provide different approaches for estimating service life, but, nevertheless, only generic procedures are given. A general approach is also adopted when determining the service life of components in comparison to results from laboratory ageing with natural weathering tests. For example, the ASTM E 632-82 - "*Standard Practice for Developing Accelerated Test to Aid Prediction of the Service Life of Building Components and Materials*" –one of the most important references on the matter - does not provide a detailed description of the way in which accelerated, or in-service performance testing, should be carried out.

The accelerated ageing tests advocated in this standard have been carried out by imposing higher than normal stress levels on components in order to increase the rate of degradation such that the component will fail within a relatively short period of time in relation to its expected service life. The performance and failure-time data derived from these tests have been analyzed by fitting a degradation model to the data to estimate the relationship between performance, time to failure (age), and stress level.

Although the theoretical procedure introduced in the standard ASTM is very clear, some important and typical shortcomings about the use of accelerated tests to estimate the service life, include:

- Difficulty simulating the degradation mechanisms of the various materials and their interaction;
- Difficulty reproducing the stochastic nature of the degradation factors affecting the building components;
- Difficulty correlating accelerated laboratory test results with the actual in-service results;
- Difficulty defining suitable accelerated ageing tests to reproduce the effects of specific environmental conditions.

Generally, in National and International standards dealing with ageing test methods, as is the case with this ASTM standard, only a limited series of criteria for determining the environmental conditioning cycle is provided. This, in turn, leaves a certain degree of attitude for defining experimental ageing conditions in the laboratory.

On the contrary, we believe, that the obligation to proceed to a re-scaling should influence the conditioning cycle, which must necessarily be differentiated according to the diverse contexts in which the re-scaling occurs. Otherwise, only comparative tests and studies would be possible, through which we could only determine analogous patterns of behaviour between the different ways in which the same element is used. In other words, we do not believe to be reliable a re-scaling performed in significantly different climatic contexts, where a sample is subject to the same artificial action.

On this basis, an attempt was made to design an ageing conditioning cycle which provides an accelerated reproduction of what really occurs to different extents, and in different environmental conditions, to which components may be subjected to over their service life.

3 COMPOSITION OF THE AGEING CYCLE FOR A SPECIFIC TEST CONDITION

The starting point in an attempt to standardize a procedure for the definition of accelerated ageing tests on building components was the need to outline a correct cycle within the national study on roofing sub-systems. We tried to simulate a specific context in the laboratory,, the typical environmental conditions of the city of Naples, and later, we tried to extend and generalize the results by designing a cycle which provides an accelerated reproduction of what occurs in different environmental contexts. This model uses an algorithm in which the input data comprises a series of climatic data which can be obtained from various sources (principally, air force). The output provides the duration of the sub cycles (each one of which represents, and reproduces a climatic season) with the temperatures, humidity, sunlight radiation, and rainfall to which the sample has been subjected. In this way, we obtain a kind of “virtual year”, comprising the four seasons in succession, with different values for temperature, humidity, sunlight radiation, and rainfall, with the values inserted for the region and time of year that represents the season in question (as shown in Table 1 below):

Table 1.

Sub cycle	*Action*	*Value inserted*
Freezing	Temperature Humidity Sunlight radiation Rainfall	Absolute minimum Mean - -
Hot / Dry	Temperature Humidity Sunlight radiation Rainfall	Highest among means Mean Xenon lamp lights -
Hot / Humid	Temperature Humidity Sunlight radiation Rainfall	Absolute maximum 95% Xenon lamp lights -
Rainy	Temperature Humidity Sunlight radiation Rainfall	Lowest among means Mean - Splash or puddling

Climatic data was collected in advance from various official sources, covering a period no longer than the last 5 years, on account of the extreme variability in recent times. The values necessary for implementing the proposed model together with related definitions are given in Table 2 below:

Table 2.

Action	*Value inserted*	*Definition*
Rainfall	Number of rainy days in one year	Value obtained from mean annual value
	Intensity of rainfall	Value obtained from mean annual value
Temperature	Absolute minimum	Value obtained from mean absolute minimum value
	Mean minimum	Value obtained from mean monthly value, calculated as daily mean minimum value, taking lowest value into account
	Absolute maximum	Value obtained from mean absolute maximum value
	Mean maximum	Value obtained from monthly mean value, calculated as daily mean maximum value, taking highest value into account
Humidity	Relative humidity	Value obtained from monthly mean for work for each year
Sunlight radiation	Number of sunny days in one year	Value obtained from annual mean value
	Sunlight radiation hourly trend	Value obtained from annual mean values

It is interesting to note that across the different climate zones in Italy there is little difference between the absolute values for many of the environmental actions.

Two examples suffice to illustrate this point:

- Where absolute maximum temperature is concerned, there is no significant difference between Milan and Palermo. What distinguishes the two contexts is the *number* of days per year in which they reach high temperatures;
- The intensity of rainfall recorded in Naples in the last five years exceeds, to a considerable extent, that of Milan in some winter months.

It so happens that for contexts and climates which differ significantly, the seasonal sub cycles determined have (for example) similar temperatures. It is the length of the segment, or the combined effect of the other environmental actions, which characterizes each context.

The final output generated by special simulation software providing the values for Naples are shown in Table 3 below:

Table 3.

Sub cycle Naples	*Dur.*	*Temp.*	*Hum.*	*Sun rad.*	*Rainfall*
Freezing	6 hrs	4 C°	70%	No	No
Hot / Dry	9 hrs	25 C°	60%	Yes	No
Hot / Humid	9 hrs	40 C°	95%	Yes	No
Rainy	6 hrs	10 C°	75%	No	Yes

The values in the Table are provided in Figure 2 below.

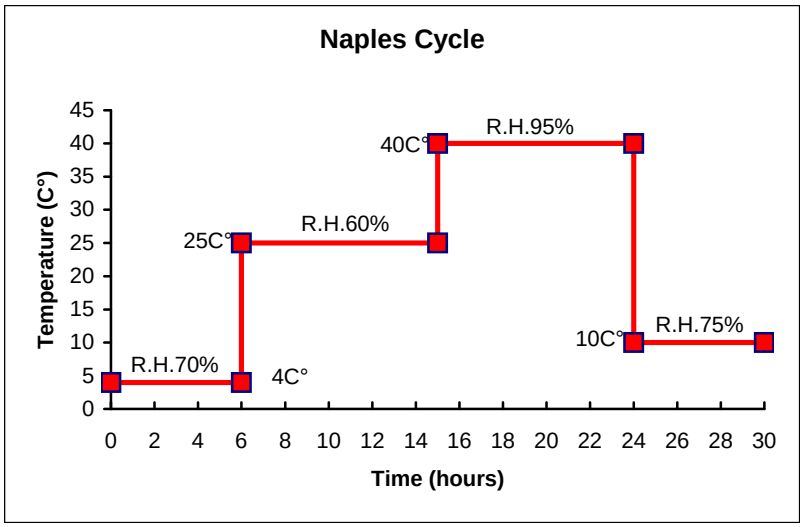

Figure 2. Proposed accelerated ageing conditioning cycle for ageing components in Naples.

4 COMPOSITION OF AGEING CYCLE FOR ANY CLIMATIC CONTEXT

By adopting the criteria previously described, one can develop – as was done for Naples – a simulated cycle for any environment. A schematization has been provided with the options to be exercised by the operator with regard, not only to specifically climatic data (temperature and humidity) but, also, the lamp activation mode in the two heat segments, and, above all, the duration of the various segments in which the sub cycles are contained. Therefore, the process should first be conducted for the individual sub cycles, and then, used as a direct indicator for the selection of climatic data and durations by the user wishing to compile and customize the cycle for the local climatic context. Note that the length of the segments is not only established in relation to climatic data in terms of temperature and humidity, but is also evaluated, as mentioned above, in terms of the longevity of the season in relation to the annual climate. For example, maximum temperatures recorded in the hottest months in Milan are as much as those in Palermo, regardless of the fact that these two locations belong to climatically diverse contexts. What is important is the duration of elevated temperatures, indeed, and the effect on the climatic trend for the entire year. Such periods of oppressive heat in which temperature peaks occur, can vary significantly from location to location. To assist in the schematization of this process, the Italian National Zoning Plan (Italian directive 412/93) has been used, based on the number of degree-days* recorded for the different districts. This directive provides information on the delineation of Italy into 6 subdivisions**. For the present purposes, given the similarities of performance between pairs of subdivisions, they were examined two by two; hence the observed subdivisions include zones A and B, C and D, and E and F , for. By crossing the climatic data (absolute or mean values) with the impact percentage of the reference climatic season for the trend of the climatic year (here illustrated by zones A to F, as determined by the legislation), we will be able to correctly estimate the duration for which the season in question must be schematized in the reference sub cycle.

* The "degree-days" of a designated district are the sum, for all the days in a conventional annual warm period, with the daily positive differences between ambient temperature, conventionally set at 20 degrees centigrade, and the daily mean outdoor temperature; the unit of measurement used is the degree-day (DD).

** The Italian territory is divided into six climate zones according to their degree-days, regardless of their geographic location:

Zone A: districts with degree-days less than 600; Zone B: districts with degree-days between 600 and 900; Zone C: districts with degree-days between 900 and 1,400; Zone D: districts with degree-days between 1,400 and 2,100; Zone E: districts with degree-days between 2,100 and 3,000; Zone F: districts with degree-days greater than 3.000.

In light of the above considerations, the following schematizations are proposed:

Sub cycle A – FREEZE: Definition of climate conditions		
Parameter	*Instruction*	*Value*
Temperature	Enter absolute zone minimum value recorded in period of year represented by season in question	X C°
Humidity	Enter zone mean value for season in question	Y %
Sunlight radiation	Keep lamp switched off from now on	---
Rain	Switch off water	---
Climate zone	Establish zone	Zones A/B/C/D/E/F

Sub cycle A – FREEZE: Definition of length of segments	
Climate zone	*Value*
Zones A/B	4 hrs
Zones C/D	6 hrs
Zones E/F	9 hrs

Sub cycle B – HOT / DRY: Definition of climate conditions		
Parameter	*Instruction*	*Value*
Temperature	Enter the absolute zone mean maximum value recorded in the period of the year represented by the season in question	25 C°
Humidity	Enter the zone mean value for the season in question	Y %
Sunlight radiation	Light lamp for zones A/B/C	Maximum value
Rain	Switch off water	---
Climate zone	Establish zone	Zones A/B/C/D/E/F

Sub cycle B – HOT / DRY: Definition of length of segments	
Climate zone	*Value*
Zones A/B/C	9 hrs
Zone D	6 hrs
Zones E/F	4 hrs

Sub cycle C – HOT / HUMID: Definition of climate conditions		
Parameter	*Instruction*	*Value*
Temperature	Enter the absolute zone maximum value recorded in the period of the year represented by the season in question	X C°
Humidity	Enter a fixed value	95 %
Sunlight radiation	Keep lamp switched on always	Maximum value
Rain	Switch off water	---
Climate zone	Establish zone	Zones A/B/C/D/E/F

Sub cycle C – HOT / HUMID: Definition of length of segments	
Climate zone	*Value*
Zones A/B/C	9 hrs
Zone D	6 hrs
Zones E/F	4 hrs

Sub cycle D - RAIN: Definition of climate conditions		
Parameter	*Instruction*	*Value*

Temperature	Enter the mean zone minimum value recorded in the period of the year represented by the season in question	X C°
Humidity	Enter the zone mean value for the season in question	Y %
Sunlight radiation	Keep lamp switched off from now on	---
Rain	Water	30 mm of water
Climate zone	Establish zone	Zones A/B/C/D/E/F

Sub cycle D - RAIN: Definition of length of segments	
Rainfall band	*Value*
Band 1: less than 50 days/year	4 hrs
Band 2: 50 – 90 days/year	6 hrs
Band 3: over 90 days/year	9 hrs

From these results, we have also developed specific software to automatically compose the seasonal sub-cycles using the criteria introduced above. An image of this software is provided in Figure 3.

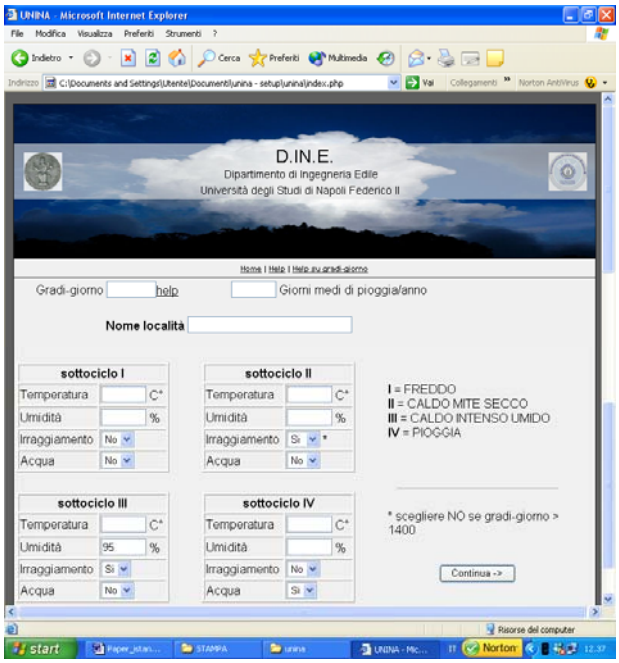

Figure 3. A screen from the software for the automatic composition of accelerated ageing sub-cycles in any climatic context.

Durability of Clay Roofing Tiles under Salt Mist Atmosphere

T 22

ABSTRACT

Clay tiles are largely used in traditional construction in Portugal. In coastal zones some cases of accelerated decay have been affecting the roofing tiles durability, apparently due to the exposition to a salt mist atmosphere. To evaluate the performance of the clay roofing tiles subjected to a sea environment, an experimental study is being carried out based on artificial accelerated weathering tests. The study includes the roofing tiles characterization, the development of accelerated weathering tests, the evaluation of the weathering effect through observation and physical and chemical tests and also the comparison with roofing tiles that suffered natural weathering in coastal zones of Portugal. The study aims at reproducing the pathology mechanisms observed in real conditions, and identifying the parameters - of both composition and manufacture - having a higher contribution to the decay of roofing tiles to provide industry with relevant data to improve the manufacturing process.

This paper presents tests performed on several kinds of tiles and the results obtained regarding soluble salt effects in the specimens' microstructure. Mercury Intrusion Porosimetry (MIP) was used to assess differences in the porous structure. Soluble salt content profiles after weathering were also performed, aiming to determine the depth of salt crystallization.

Accelerated weathering tests can cause different levels of alteration and degradation to ceramic roofing tiles. Hydrophobic tiles may resist longer to salty mist but they can suffer high damage if there is some penetration of salty solution. Tiles present rather diverse porosimetric structures. The concentration of salt crystallization on the outer layers may induce the destruction of thin superficial layers.

1 INTRODUCTION

The crystallization of soluble salts is considered one of the main causes for the degradation of porous construction materials [Rodrigues J. D. and Gonçalves T. D. 2006]. To simulate, in the laboratory, the weathering defects due to salty mist, specimens from different types of tiles have been subjected, in a climatic chamber, to artificially accelerated weathering test sets of 10, 20 and 30 cycles of wetting with a salty mist and subsequent drying. The effects of weathering cycles were studied through visual assessment, weight variations and water absorption tests performed before and after weathering. The changes in microstructure were assessed through determination, before and after weathering, of the pore size distribution by Mercury Intrusion Porosimetry (MIP). After weathering, soluble salt content profiles were performed, to determine the depth of salt crystallization.

2 MATERIALS AND METHODS

2.1 Test Specimens

5 specimens from each tile were prepared through transversal cuts. In these tests the specimens cut from the mid transversal area of the roofing tiles were preferentially used, having the width of the tile and circa 9 cm length (Fig. 1). The cut faces of the specimens were sealed with epoxy resin. Roofing tiles from two manufacturers (F1 and F2) were used:

F1 NH - manufacturer 1, model 1, non-hydrophobic red tiles
F1 B - manufacturer 1, model 1, non-hydrophobic white tiles
F1 H - manufacturer 1, model 1, hydrophobic red tiles
F2 NH - manufacturer 2, model 1, non-hydrophobic red tiles
F2 B - manufacturer 2, model 1, non-hydrophobic white tiles
F2 H - manufacturer 2, model 1, hydrophobic red tiles
F2 T2 NH - manufacturer 2, model 2, non-hydrophobic red tiles
F2 T3 NH - manufacturer 2, model 3, non-hydrophobic red tiles

2.2 Artificial Accelerated Weathering Tests

Tests were designed based on the European Norm EN 14147:2003 and adapted to what was thought to be realistic conditions for this product [Cruz et al, 2007]. These tests were carried out in a climatic chamber where the specimens are subjected to sets of cycles of wetting under salt mist atmosphere and subsequent drying, the temperature in the chamber maintained at 35ºC. Salt mist is produced by spraying a salt solution into the chamber with a concentration of 110g of sodium chloride per litre of de-ionised water. The results of two preliminary tests with cycles of 48 h (10 h of salt fog + 38 h of drying) and 24 h (8 h + 16 h) allowed the selection of the 24 h cycles for the final tests. For each type of tiles, one or two specimens were subjected to 10 cycles, another one or two to 20 cycles and three or four to 30 cycles.

Figure 1. Specimens before and during tests.

2.3 Characterization Tests

Before the cycles, the specimens were dried at a temperature of 60ºC to constant mass, as a basis for the weight variations tests. They were also subjected to a water immersion test based on Annex B of EN 539-2:2006, which measures the specimen's weight increase after 48 h of water immersion. For some types of tiles, 'new condition' specimens taken from the same tile as those used for weathering tests, where subjected to Mercury Intrusion Porosimetry (MIP) tests, based on ASTM D 4404 [ASTM 2004], to determine their microstructure.

After weathering and desalinization, specimens of all but one type were subjected to water immersion under vacuum, for characterization purposes. This test, based on EN 1936:1999, measures the weight increase after 72 h of immersion (24 h under vacuum followed by 24 h under water + vacuum and more 24 h under water at atmospheric pressure). Finally, the specimens are weighed twice: once submerged, and after being wiped. This test permits the determination of apparent density, open porosity, and water absorption under vacuum.

2.4 Weathering Effect Evaluation Tests

During the weathering tests, the specimens were visually inspected. After desalinization, they were submitted to water absorption, and samples of some specimens were subjected to Mercury Intrusion Porosimetry. These tests were carried out for comparison of results and evaluation of their sensitivity to the degradation suffered by the specimens. To determine the depth of salt crystallization, salt content profiles were obtained on weathered and non-desalinised samples of two different kinds of specimens, using the hygroscopic moisture content (HMC) method [Gonçalves T. D. and Rodrigues J. D. 2006]. After being submitted to 30 cycles of salt mist wet/drying, one specimen of F2T3NH and another of F2B4 were dry cut and, in this way, two C1 samples were obtained (Fig. 2). In each of the C1 samples 5 layers were marked and from them 5 samples were obtained using sandpaper (from the upper face to the under face: C1 A, C1 B, C1 C, C1 D and C1 E), control samples with sodium chloride by itself and with new tile powder were also used (Fig.3). All the samples were dried at 60ºC and then inserted in a climatic chamber at 20ºC 85%HR, their weights were measured to constant mass and HMC values were calculated.

Figure 3. Grounded layers and control samples.

3 RESULTS

3.1 Visual Assessment, Weight Variations and Water Absorption

Visual inspection results (Table 1) demonstrate different types and levels of degradation caused on the specimens by the weathering tests.

Table 1. Alteration and degradation forms with some examples.

Specimens	*Degradation*	*Examples*
F1 NH	Pitting Granular disaggregation	
F1 B	Pitting Granular disaggregation Peeling	
F1 H	None Bowing Plaques	 
F2 NH	Pitting Granular disaggregation	
F2 B	Pitting Granular disaggregation Peeling	
F2 H	None	---
F2 T2 NH and F2 T3 NH	Pitting Granular disaggregation Peeling	 
Hydrophobic specimens didn't show immediate defects but some of them suffered huge degradation following the access of the salty solution to the material under the protected surface. Hydrophobic tiles from manufacturer 2 seem to be more resistant to weathering than those from manufacturer 1. Non-hydrophobic tiles, both red and white, showed low to medium degradation levels characterized mainly by pitting, some disaggregation and peeling, with a slightly higher level in the white ones.

In general, weight determinations before and after weathering didn't show significant differences, thus they do not quantify the visual degradation at the present level. However, for white tiles of both manufacturers and some hydrophobic red tiles of manufacturer 1, where degradation is higher, weight loss is more significant.

The results of water absorption under vacuum obtained (Table 2) show that the white tiles present higher porosity and higher water absorption than the red tiles, for both manufacturers. Concerning the red tiles, the water absorption and porosity are higher for those from manufacturer 1. The lowest values concern the hydrophobic tiles from F2 and the model T3 also from F2. There is a significant increase of water absorption after weathering (Table 3) in the hydrophobic red tiles of manufacturer 1 (F1H). For the other specimens, so far the water absorption does not quantify the visual degradation.

Table 2. Water immersion under vacuum test results (characterization tests).

Manufacturers 1 and 2				*Manufacturer 2*

3.2 Mercury Intrusion Porosimetry

The pore size distributions obtained (Fig. 4) show some differences among the various tiles: the red non-hydrophobic model 1 tiles of both manufacturers F1 and F2 have the largest pores within a very thin range of values (around 0,2-0,5 μm); the white tiles from manufacturer F1 show a large range of pore dimensions, including the finest pores around 0,05-0,09 μm and some larger pores of the range 0,2-0,4 μm; the non-hydrophobic tiles of the model T2 from manufacturer F2 have finer pores than the other non-hydrophobic red tiles (mainly in the range 0,1-0,3 μm).

The curves also show that the deterioration didn't provoke significant changes on the pores dimensions. Possibly, the type of degradation obtained is still rather superficial and only longer tests will produce the rupture of pores due to salt crystallisation.

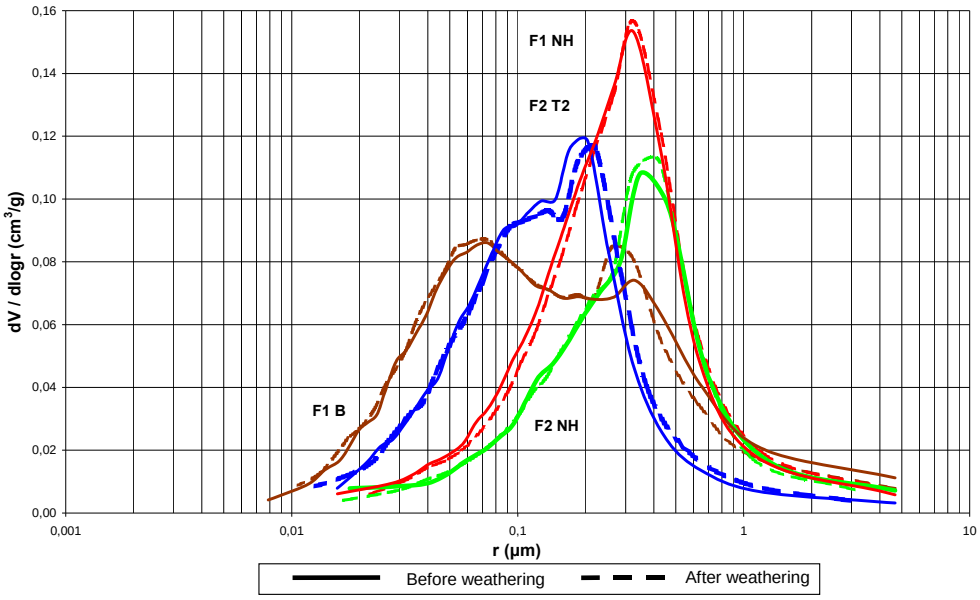

Figure 4. Pore size distribution.

3.3 Salt Content Profiles

Figure 5 shows the Hygroscopic Moisture Content over time of the five grounded layers (Fig. 3) of each of two C1 samples (Fig. 2) obtained from weathered non-desalinised specimens F2T3NH7C and F2B4C.

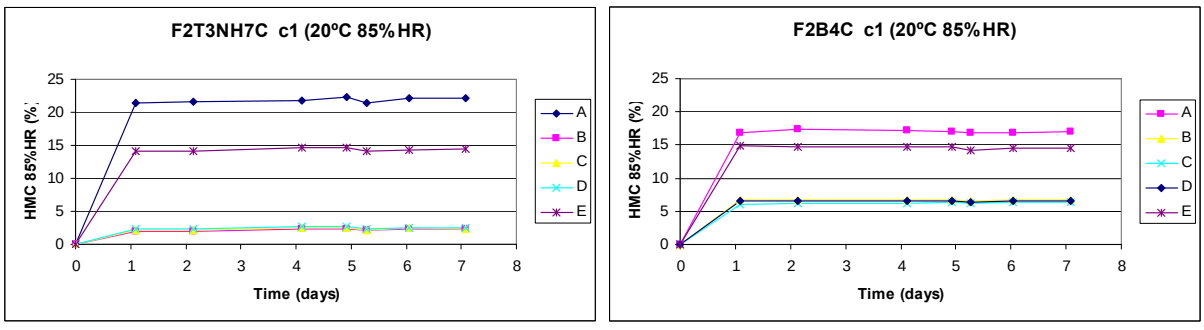

Figure 5. HMC graphics of grounded layers A, B, C, D and E.

Figure 6 shows the same HMC over time of the grounded layers, but now together with the HMC of sodium chloride control samples (Fig. 3). The last chart shows the HMC over time of control samples with powder from new tiles (Fig. 3).

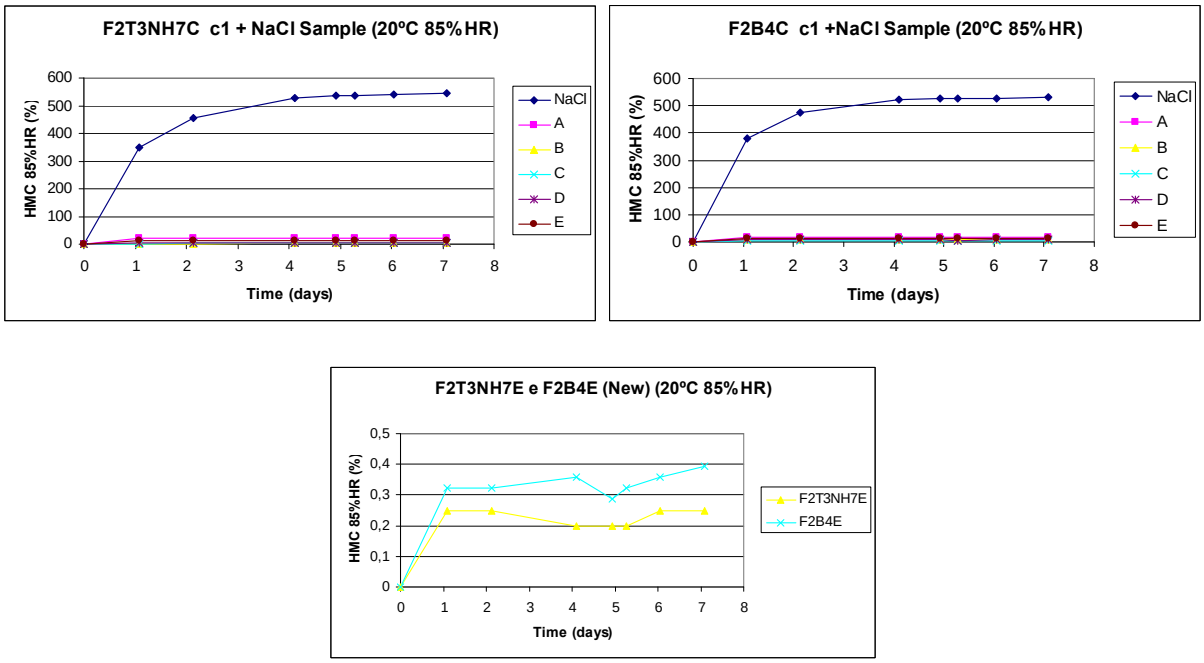

Figure 6. HMC graphics of grounded layers and of control samples.

From HMC values on day 7 the NaCl content of each layer was obtained (Table 3). In both types of samples, NaCl content is much higher in the outer layers. In the inner layers of the white sample the content of NaCl is higher than in the inner layers of the model 3 red tiles.

Table 3. NaCl contents

Layers	NaCl content (%)	
	F2T3NH	F2B
C1 A	4.0	3.1
C1 B	0.4	1.2
C1 C	0.4	1.1
C1 D	0.4	1.1
C1 E	2.6	2.7

4 DISCUSSION OF RESULTS

Visual inspection results demonstrate different types and levels of degradation caused by the weathering tests on the specimens. Hydrophobic specimens don't show immediate defects but they can suffer huge degradation if the solution can pass through the protected surface. Hydrophobic tiles from manufacturer 2 seem to be more resistant to weathering than those from manufacturer 1. Non-hydrophobic tiles, both red and white, show low to medium degradation levels, with a slightly increased level in the white ones. Characterization tests demonstrate different physical characteristics of the various types of tiles. Naturally, hydrophobic tiles show much lower water absorption than non-hydrophobic tiles, especially in manufacturer 2 tiles. This difference is less evident in vacuum conditions. For both absorption conditions, non-hydrophobic tiles from manufacturer 1 have higher absorption than model 1 tiles from manufacturer 2, whose model T2 is nevertheless the most

absorbent. White tiles show slightly higher water absorption and higher porosity than non-hydrophobic model 1 red tiles. These characteristics can explain the difference also detected in visual degradation. In general, weight variations and water absorption tests do not quantify the visual degradation at the present level. The MIP results show some differences in the porous structure of the four models tested. Tiles F1 B and F2 T2 present larger ranges of pore sizes and they are also those where higher degradation was observed. The finest and more homogeneous range of pores is of non-hydrophobic model 1 red tiles from both manufacturers, which showed intermediate levels of degradation. The salt content profiles demonstrate higher concentration of sodium chloride in the outer layers, in the upper and lower faces, especially in the case of the red tile tested. These crystals may be harmless if they are upon the surface but they may also provoke peeling if they concentrate under a very thin layer of material, which can be easily detached. The concentration in outer layers may thus indicate a potential for quick deterioration.

5 CONCLUSION

Cycles of wetting with a salty mist and subsequent drying can be used to cause different levels of artificial weathering alteration and degradation to ceramic roofing tiles. Hydrophobic tiles may resist longer to salty mist but they can suffer high damage if there is some penetration of salty solution. White tiles showed higher levels of degradation than the non-hydrophobic red ones. The tiles present rather diverse porous structures, which could be the cause of different behaviour under the testing cycles. The white and the non-hydrophobic model T2 red tiles, which show higher degradation, have larger ranges of pore sizes. The concentration of salt crystallization on the outer layers may induce the destruction of thin superficial layers.

To simulate real adverse conditions it is necessary to get higher degradation levels. The intention is to pursue the study and achieve these results by increasing the number of cycles or changing some of the parameters of the weathering tests.

ACKNOWLEDGMENTS

The authors thank the manufacturers of the roofing tiles and CTCV (Centro Tecnológico da Cerâmica e do Vidro) for the specimens and information delivered and acknowledge the collaboration of the Materials Department of LNEC and its personnel, where the tests have been done.

Designing Replacement Roof Systems to Achieve Long Term Service Life: A Sustainable Solution

Thomas W. Hutchinson [1]

T 22

ABSTRACT

As an architect who has chosen to specialize in roof system design I have come to realize that roof system design is a skill set unto itself and equal in importance with structural, mechanical, plumbing and electrical design. Replacement roofing and the unknown conditions dealt the designer require knowledgeable and skilled designers. This paper will endeavor to review the process by which roof system designers should approach replacement roofs in order to achieve sustainable low slope roof systems with service lives in excess of 30 years and how the replacement roof system design should take into consideration all the building elements that impinge upon the roof.

KEYWORDS

Replacement roofing, Long Term Service Life. Sustainability, Thermal performance, 30 year roof systems

[1] Hutchinson Design Group, Ltd., Principal, Barrington, Illinois 60010, USA, Phone 1-847-756-4450, Fax 1-847-756-4451, hutch@hutchinsondesigngroup.com

1 INTRODUCTION

Every roof system ultimately reaches a stage where serviceability cannot be maintained by repairs; an investment in a new roofing system is necessary to preserve the usefulness of the building. Sixty percent (60%) of all roofing work in the United States of America is roofing replacement. Of the sixty percent (60%), two thirds (2/3) is considered recovery and one-third (1/3) involves the complete tear-off of the existing roofing system down to the existing roof deck. A large inventory of aging buildings in the United States assures a continued growth of reroofing opportunities*.

Roofing replacement, defined as removal of the existing roof systems and the installation of a new roof system, allows for the opportunity to improve upon the existing roof system, bringing it into line with current codes and standards, while also providing an opportunity to design a new sustainable, robust roof system increasing thermal efficiency thus enhancing the buildings energy conservation, reducing the buildings carbon foot print and striving to achieve long term service life (defined as having a service life of at least 30 years)**, the essence of sustainable construction.

The difficulties facing today's architects and roof consultants are almost overwhelming. Roofing replacement design is exceedingly more difficult, time consuming, and complex than new roofing system design. Today's multiple varieties of roof systems and components, code requirements and the interjection of 'cool roofing' concepts that are typically not very well thought out, require that the architect/roof consultant or roofing contractor have a full knowledge and understanding of the existing building structure and reroofing options. The investigation and analysis of existing building components, selection of the appropriate solution, and acumen to properly detail a project requires a great deal of knowledge and experience that few possess. Therein lays a major concern contributing to poor roofing replacement design. All too often the designer possesses one, or possibly two, rarely all three qualities required to succeed. While many architects may be knowledgeable about building components, they are lacking in knowledge about appropriate roof design, let alone roofing replacement design. They are a product of our educational system, which places roofing design at the lowest of priorities. Contractors often lack empirical knowledge of building systems, and roof consultants often lie somewhere in the middle.

Further complicating the roofing replacement design is the need to maintain the building's use during the reroofing construction. Ultimately, reroofing is an exercise in roof analysis, the subtle balancing of advantages and liabilities requiring knowledgeable and clean judgment in weighing design factors***.The roof system designer must not only possess a great deal of knowledge and empirical experience, but he must also possess an enthusiasm for his work, as the challenge before him is formidable, a challenge that can only be satisfied by the complete dedication of a competent designer.

The options in roofing replacement are great as there are numerous differing types of low slope and steep slope roof systems, each with differing requirements. In order for a roofing replacement system design to be successful, two conditions must exist: An excellent working relationship between architect/roof consultant, owner and contractor must be established, and work must be predicated on a set of construction documents that reflect a roof system design consideration of all building components. It further requires the education of building owners. Owners seldom comprehend the technical complexities and substantial risks entailed in roofing replacement. The owner almost always concludes that if the building leaks it is because of a faulty roof system. Not only may this not be a faulty assumption, but may lead to the errant spending of money, which will not correct a supposed problem. It is also inherent on the roof system designer to inform the owner about the cost involved in correcting original design errors.

** Roofing Canada, "Keys to Sustainable Roofing", Spring/Summer 2007, pg. 16-30.
*** Roof Design, "A conservative approach to reroofing." Sept/Oct 1985, pg. 24.35, 51.

In order to accurately determine the condition of the existing roof system, an accurate investigation and analysis of the existing roof system, building components that impinge upon the roof and the activities both within the building and atop the roof system is required. Inappropriate selection of corrective action will lead to less than desirable results. The installation of a new roofing system without giving consideration to the results of the investigational analysis, code review and the owner's goals may lead to a new roofing system selection that does not provide a long term, sustainable design solution.

2 INVESTIGATION / ANALYSIS

Prior to giving consideration to the selection of a roofing system, a complete and thorough investigation and analysis of all existing building components impinging upon the roof system must be undertaken. Failure to do so may not only result in the failure of the new roof system, but also reflect a complete misunderstanding of the roofing replacement design process, as well as be a disservice to the client. Neglecting to respond to the investigation and analysis of existing building components may not only result in the repeat of previous errors such as continued ponding of water, but may also assist in the deterioration of the existing building components; a condition which will compound existing problems.

Roofing replacement design needs to take into account the "whole picture". A successful solution will address all concerns. The smallest of details must be examined. Most roof leaks are caused by inappropriate attention to the design and detailing of building components that impinge upon the roof. All too often, building owners conclude a building leak is the result of a faulty roof system, but unfortunately, this is not always true. Most leaks are a result of faulty building components, faulty roof system component installation, or faulty building interfaces.

2.1 Investigation

Prior to the design of a new roofing system, a complete investigation of the existing roof system as well as related building components which impinge upon the existing roofing system must be undertaken. The intent is to understand the existing conditions and the causes of concern. Designers must know the existing conditions and problems before they can propose a solution for them. The existing roof system must be examined. The current causation of problems and condition of the existing roof should be determined by analysis, observation, and possibly testing, including moisture surveys and destructive analysis such as 'test cuts'. This analysis will provide the designer with a set of parameters on which to design the new roof system. Results of test cuts performed on the existing roof system will provide data on the existing roof systems to be removed as well their thickness.

A thorough investigation should endeavor to review: 1) Historical records, including a leak history of the existing roof system; 2) existing "as-built" drawings; and 3) any warranties that may exist on the roof system, and through discussions with the owner, determine the existing building use, its occupancy and future plans. The existing roof system should be observed, noting concerns such as the areas and depth of ponding water, wind damage and evidence of repeated foot traffic. It is very important that drainage deficiencies are noted, as they are a major contributor to roof problems.

The existing roof perimeter, as well as the exact location of existing roof drains, penetrations, HVAC curbs, penthouses, chimneys, and all building components impinging upon the roof should be observed, their condition investigated and their exact location noted. The exact location of these components is imperative, especially as they affect the design of a tapered insulation system.

All details of the existing conditions should be sketched. A complete photo record of the entire roof system, its building components and all conditions that may require detailing should be taken and labeled accordingly. This photographic record will prove invaluable in aiding the designer in the

design and detailing of the new roof system. Test cuts should be performed to determine not only the material components of the existing roof system, but also the depth of the roof system; information which is required when designing tapered insulation systems and their results on roof edge design considerations. The existing roof system should also be tested for asbestos containing materials (ACM).

The condition of building components such as the following; should be observed, photographed, sketched, and their existing condition fully evaluated:

a) Roof drains: Their size, location, and condition.
b) Parapets and adjacent masonry walls: Examine the masonry and mortar for deterioration, structural cracks; is tuckpointing and sealing required, are the coping stones and joints in need of restoration, do weep holes and through wall flashing exist, if so, what are their locations in relation to the existing roof system and base flashings?
c) Previous roof patching: Quality of patch, check roof deck condition below.
d) Gutters: What is their general condition? Are they rusted? Is repainting required? Are they properly sized? Are they well supported? Are expansion joints properly located? Are the gutter downspouts properly sized? Are downspouts missing? Do they properly displace the water at grade?
e) Roof deck: Age must be considered for the potential mechanical fastener attachments. Are there any visible areas of deterioration? Were there any "soft" areas experienced during the walk through?
f) HVAC equipment, curbs, associated piping, and the existing condition of these penetrations as they penetrate the roof system. Are there multiple pipes penetrating through a single pitch pan? Is the unit itself leaking? Are weep holes plugged? Are there penetrations from the unit through the top of the curb cap that may be taking on water?
g) Expansion joints: Are the cover joints watertight? Are the expansion joints properly located? Is the height proper?
h) Penthouse walls, base flashings considerations: Metal siding on penthouses is often notoriously low to the roof membrane. Identification of the siding support system is required as the new roof system may rise higher than the bottom of the siding.
i) Cooling towers: How are they supported? Does any associated piping penetrate the roof membrane? Is the piping grouped together?
j) Drain pipes: Is the roof drain/downspout connection watertight?
k) Abandoned curbs, pipes, etc. that may be removed should be noted. These items should be reviewed with the owner's maintenance personnel who may be of great assistance in identifying roof top penetrations that could be removed.
l) Structure: It must be analyzed. Is it a viable structural system to carry any additional weight that you may be adding? Columns and beams should be checked for structural integrity as well as the roof deck. Are there any new adjacent tall buildings which may have changed the design and roof load considerations involving snow loads? Are there any new tall additions that would also change the loading factor?
m) What is the current access, not only to the existing roof system via scuttles or ladders to the high roofs, but also to the site for construction equipment ?
n) Location of any IT cabling, tower conduit and refrigerant piping that currently transverses the roof.
o) Current roof top maintenance traffic patterns.
p) Interior Conditions: Evaluate and determine the interior occupancy, climate conditions and space use, and whether they have contributed to the existing roofs deterioration or will affect the performance of the new roof system.

The roof designer, while investigating, analyzing and documenting the existing roof system, must ask himself/herself questions such as the following:

a) Are there sufficient roof drains to adequately and quickly remove water from the roof? Can additional drains be installed and/or the existing moved to facilitate efficient tapered insulation layouts.
b) Are existing HVAC units currently in working order? Does the owner wish to upgrade existing units or incorporate additional units? Can any abandoned units and their curbs be removed.
c) Are there masonry parapets or walls that require restoration or maintenance that can be performed prior to the installation of the new roof system?
d) Are there any roof penetrations that are not currently in use and may be removed?
e) Are skylights currently cracked, requiring replacement and/or removal? Are additional required?
f) What are the conditions of the existing roof drain-downspout connections? Are the roof drain bowls secured to the roof deck?
g) What kind of access is available for the construction equipment such as dumpsters and cranes?
h) On adjacent masonry walls, are weep holes and through wall flashing present? Is their location above the existing roof system? What is the distance to the existing roof drains and will the incorporation of tapered insulation rise above the through wall flashing?
i) Has the base flashing and/or counterflashing covered existing through wall flashing and weep holes?
j) Are there TV antennas, IT equipment of antennas or weather stations that need to be removed and reinstalled? How will they be anchored, and will they penetrate through the roof? How will this be detailed?
k) Are there gas pipes, electrical conduit or other types of piping transversing the roof, and can they be relocated along a parapet, wall or below the roof deck?
l) Are parapet coping stones loose? Do they require restoration, replacement or installation of a throughwall flashing below? Should they be removed or abandoned and covered with sheet metal? What are the joint conditions, do they need to be restored?
m) Are the parapet walls structurally sound? Will they require rebuilding, tuckpointing and sealing, or should they be covered with metal siding?
n) Are there any masonry components, such as interior parapet walls that can be removed?
o) What is the integrity of the large masonry chimneys? Do they require tuckpointing and sealing, rebuilding, new chimney caps? Can their heights be reduced as a result of new boiler systems? Have they been abandoned?
p) What type of access is there to the roof from the interior? Is it through a roof scuttle? Is a new scuttle required? A new ladder? Are exterior ladders required to high roof areas?
q) What type of roof traffic is anticipated on the new roof system? How often? Foot or mechanical traffic? Where?
r) Are air intakes located such that fumes from the new roof system installation could enter the building's air circulation systems?
s) What is the intended use of the roof system beyond that of water repelling? Will it be required to perform as a working surface?
t) What is the height of the specific roof areas and what is the climate and type of geographical location the building in? Urban? Rural?
u) What types of wind can be expected?
v) What is the existing height of all roof curbs? How much will they be required to be raised to accommodate the new roof surface height?
w) What type of effluents from below will come in contact with the new roofing system? From adjacent or neighboring buildings? From planes?
x) Grouped piping penetrating the roof through pitch pans: What will be involved in separating them?
y) Are new expansion joint covers required? Can roof penetrating expansion joints be eliminated and designed into the roof substrate below the roof membrane?
z) How would increased roof top energy efficiency affect the interior HVAC air balancing?

aa) How will roof top construction disturb interior finishes and worker production?

bb) How are the roof areas laid out? Will any specific roof areas require special consideration or roofing replacement priority over other areas, e.g., high roofs over low roofs?

2.2 Analysis

With the results of the field investigation and assessment, an analysis of the existing building conditions can be undertaken, roof cover type selected and the scope of work determined. This decision, as well as all others, must be based on sound engineering principles so that enhanced and/or long term roof system service life can be attained. A sustainable roof system cannot be achieved if decisions are made that 'short circuit' the optimization of the roofs service life and the attainment of the long term performance.

Tear-off and removal of the existing roof system down to the existing roof deck, prior to the installation of a new roof system allows for the inspection of, and if required, replacement of deteriorated roof deck. Unknown conditions that may affect obtaining long term service life are often eliminated in total or at least observed corrected when the old roofing is removed. It also allows for the clean installation of thermal insulation, especially tapered insulation, thus enhancing drainage and thermal performance (energy conservation and a reduction of carbon footprint).

Once the analysis phase has been completed and a scope of work delineated, a budgetary construction estimate can be arrived at and reviewed with the building owners for approval. Following approval of this budget, the roof replacement design process may begin.

3 DESIGN

Items that must be given design consideration, researched and answered include:

a) Potential roofing systems.
b) The appropriate insulation, type and method of attachment must be investigated. What are the owner's energy efficiency requirements?
c) Calculation of the dew point and the decision whether to use a vapor retarder.
d) The fifth façade: The roof is part of the building envelope, and as such should be considered the fifth façade after the walls. The interface of the wall and roof systems needs to be understood and considered. Is there an air barrier in the wall construction that the new roof air or vapor barrier should be incorporated into? Planning for potential façade replacement and the implementation of a wall air barrier may also be prudent.
e) Future maintenance concerns: All roofs require maintenance, whether they are new or existing. In designing a roof replacement an opportunity exists for minimizing the required maintenance. That means the installation of maintenance-free components such as prefinished sheet metal.
f) Give consideration in designing the new roof system to easily provide for future recover or partial removal and replacement.
g) Plan for future reroofing with conditions such as copings, gravel stops, and counter flashings that can be screw fastened and facilitate future removal and reinstallation.
h) Appropriateness of materials.
i) Availability of materials. Are the materials available during the time of the year when the reroofing will be undertaken?
j) The roof system design should have a respect for and reflect the intent of the existing building design.
k) What is the availability of local knowledgeable installers? When working on a project in southern Japan, it was found that although SPM installers existed in Japan, they were almost exclusively located in the north. Qualified installers of metal roof systems existed in southern Japan, and lead to the design of a structural standing seam roof system, which was installed with excellent workmanship.

l) Are there experienced roofing contractors who are able to correctly install the selected roof system?
m) What is the existing building's expansion and contraction requirement across the roof? Are expansion joints required? Can they be eliminated?
n) Plumbing: Do the existing roof drain locations facilitate the layout of new tapered insulation? If not, you may wish to relocate some drains. Will the new roofing system require the installation of new roof drains and downspouts? Can the current drainage systems handle the anticipated water volume? Do existing roof drain conditions require the replacement of existing with new? The renovation of existing? The abandonment of existing? Consideration should also be given to the type of appurtances required by the drains, including sump pans, extension rings, and under deck clamps. Plumbing concerns also involve the raising of existing vent stacks.
o) Drainage: On steep slope roofing, gutters and downspouts should be sized for the appropriate design parameters. The dispersement of the water at grade should be given consideration as to the effect on the surrounding area during the various seasons. Do not install downspouts to sidewalks or driveway locations in areas in which the winter seasons will cause icing. The appropriate method of downspout support should be determined, as well as appropriate downspout materials to protect against anticipated vandalism.
p) With the multitude of insulations on the market today, the roofing designer must be cognizant of the differing types and the densities that are available. Chlorofluorocarbon (CFC) free insulation should be used? Consideration at this time should be given to the use of utilizing tapered insulation in order to remove water from the roof as expeditiously as possible. Rapid removal of roof top water is paramount to a successful long term roof system design. How do HVAC roof curbs, masonry walls, and roof edge considerations impinge upon this tapered insulation, especially at valleys? Consideration should also be given to the required R-value. Double layers of insulation with offset joints to create thermal breaks from the roof deck to the roof cover is mandatory for optimizing energy performance, and in many climates for preventing the formation of condensation below the roof cover.
q) Asbestos removal should also be reviewed. In the United States, regulations exist that govern the removal of asbestos containing materials, including those imbedded in asphalt as well as pipe installation around drains and asbestos siding. Penalties for ignoring the appropriate removal and disposal of asbestos containing materials can be severe. Personal opinions must be set aside in adherence to the law.
r) Many older buildings have beautiful, albeit deteriorating masonry and lime stone detailing that impinge upon the roof and will require restoration and waterproofing at the time of roof replacement. This is work that should be performed prior to the installation of any new roofing system; so that foot traffic is minimized and chemicals utilized by various trades do not come in contact with the new roofing system.
s) Building height, geographic location, climate and wind considerations and requirements should be considered.
t) The aesthetic appearance of the roof system should be given consideration, especially in steep slope roofing work and when observable from building areas above.
u) Consideration should be given to sheet metal materials for uses and detail appropriateness. Remember the long term performance goal and maintenance free aspect; under no circumstances utilize galvanized metal.
v) Recognize that unknown conditions will exist, and in your specifications, incorporate unit prices for materials in which potentially unknown conditions or replacement of existing building components will be necessary. Such items include roof deck, HVAC curbs, roof drains, wood blocking, skylights, and labor.
w) Evaluate the existing roof edge construction as it pertains to the installation of the new roof edge wood blocking to increased thermal (tapered) insulation systems and in regards to wind uplift considerations. Raising the roof edge is often required to accommodate the increased thermal insulation installed.
x) Whenever raising a roof edge, it is imperative that the new roof edge wood blocking be adequately secured to the existing building and structure. If the existing wood blocking or

perimeter conditions are not adequately fastened, they themselves should be fastened. Detailing such as requiring scarfed joints will reduce the deformation of roof edge sheet metal due to the warping of treated lumber.

y) Are there any building components, abandoned or otherwise not required that could be removed from the roof?

z) How will the removal of the existing roof system affect structural components with camber; for example, with the weight removed camber will manifest itself and may cause interior damage such as cracked plaster and/or masonry unit light lens displacement.

aa) Will heavy equipment, utilized during roofing replacement construction work vibrate the deck and cause damage or disruption of the work place?

bb) Will the building's security system or fire alarm be disturbed?

cc) Will the use of ballast or reflective membrane be beneficial over the life of the roof?

dd) If a garden roof is a consideration, structural integrity, soaked weight, growing medium depth and type of plantings need to be considered.

Review and consideration of the "Tenants of Sustainable Low Slope Roofing" arrived at by the CIB/RILEM Joint Committee on Roofing Issues should be undertaken.

Once the appropriate decisions to the above referenced design considerations are made, the architect or roof consultant may proceed to the design of the new roofing replacement system. Beginning with the preliminary design and roof plan, the designer should lay out the new roof system and insulation systems. It should be noted here that if a roof system did not incorporate a sloped structure, under no circumstances should a flat roof be incorporated into the design. If the roof deck is not structurally sloped then tapered insulation should be incorporated into the new roof system design. This may require the intensive design and detailing of roof edge conditions, especially of existing gravel stop conditions. Following the completion of a preliminary plan, all building components must be given consideration and thought for detailing.

Once this overall roof plan layout has been conceived, thought given to other building components and reviewed, the designer now enters the most critical phase of the roof replacement design; that is producing a final set of construction documents taking into account all of the information gathered. Attempts to perform roof replacement without quality contract documents (and quality is the key word), often result in roof systems with premature failure. The goal of the construction documents is to clearly communicate to the roofing contractor your design intent. In association with bringing the roof plan up through final stages in the construction document phase, roof details such as roof edges, are to be sketched simultaneously. Following completion of the roof plan, roof edge details are finalized. All details should be drawn to the largest scale possible so as to indicate as much detail as possible. Each detail should be thoroughly noted so as to leave no question as to what is required. These are the details that specifically relate to the building components. Following the completion of general details, attention should be given to specific details; the details that will make or break your roofing replacement system design.

They should include: 1) Elevation drawings of terminations such as when a roof edge terminates into a masonry wall; 2) counter flashing; 3) intersection of gravel stops, copings and masonry as they abut adjacent structures; 4) end wall gutter details; 5) built-in gutter details; 6) ridge vents; 7) tie-in details between two differing roof systems, etc. The general thought in this phase of detailing is to do whatever is necessary to properly communicate to the roofing contractor as to what is required. Sometimes this may require three or four isometrics in a series that build on each other as they progress to indicate exactly how the concern is to be handled. The details should indicate existing components to be removed, existing components to remain, as well as indicating new roof systems and their attachment.

Following a final review of the construction drawings, the specifications should be prepared specifically for the project in question. These specifications should include technical sections on all building components involved in the new roofing replacement system construction, i.e., new roof drains, wood blocking, masonry and limestone restoration, as well as components of the building system that may be damaged during construction or will require repair such as existing grass and landscaping areas, and bituminous and concrete paving.

4 BIDDING

Following a review of the contract documents and specifications, and the coordination of same, the project is ready for bidding. In order to arrive at a set of construction documents for bidding purposes, the architect/roof consultant designer has gone through a painstaking and comprehensive investigation of not only existing building components, but of roof system options, materials, causes and effects, as well as having been involved in a multitude of decisions, and an evaluation of value between costs and results. This author firmly believes that the architect/roof consultant must continue to be involved during the bidding process, to be available to answer questions, issue addenda, hold pre-bid conferences, inform the roofing contractors of the specific requirements of the project, and to answer all questions concerning the project design.

5 CONSTRUCTION PHASE

Once bids have been received, references should be contacted, verified and confirmed prior to making a recommendation to the building owner. Preconstruction meetings must be held; verification of submittals, as well as continued observation of the installation of same must be upheld. Site visits allow for the verification of compliance with the contract documents, allow for the answering of questions as well as to review unknown conditions and to advise the roofing contractor on how to proceed. Continued communication between the roof system designer and the contractor during all phases of construction is invaluable to the success of the roofing replacement system and the achievement of a sustainable long term roof systems.

6 CONCLUSION

The successful completion of a roofing replacement system design with a goal of sustainability and long term service life is not easy. It involves a tremendous amount of work by the roof system designer; involving investigation, analysis, design, decision making, continued communication and problem solving, and the observation of the construction. A well thought out systematic procedure will lead to successes. Owners will be happy with results, the built environment enhanced and the roofing replacement designer will obtain the self satisfaction of knowing that they have been involved in one of the most important comprehensive construction processes that a building owner can undertake.

The Specification and Selection of CE Marked Reinforced Bitumen Membranes for Low Sloped Roofs to Ensure Their Durability in the UK

Gerry Saunders [1]

T 22

ABSTRACT

In order to ensure the specifier can select the right quality of reinforced bitumen membrane for a given roof type a new British Standard , BS8747, has been developed. This paper presents the development process and the methodology used to establish BS8747. It shows how the key parts of BS8747 lead to the successful specification and selection of reinforced bitumen membranes so that a durable roof is achieved.

Bitumen membranes have been used in the United Kingdom for waterproofing low sloped roofs for many years. They have been covered by a British Standard (BS747) where the membrane is identified by the materials it contains. The standard can be called a recipe standard which had 5 separate types of base reinforcement. The best membrane type in terms of performance and durability is type 5 which uses a polyester based carrier. If a high performance membrane is required the specifier could easily require those to BS747:type 5 to be used.

Recently a new European standard (EN13707) has been produced by CEN TC254 which refers to flexible sheets for roof waterproofing. This presents data according to a number of test methods which have been based upon the regulatory requirements of the various member states. It is a requirement that EN13707 refers to all products that are legally placed on the market. This means the CE mark covers low quality as well as high quality products. The product information given with CE marking is in the form of results from a series of tests. This means that an in-depth knowlede of material properties would be needed to assess quality and durability.

Bitumen, Membranes, Durability

[1] Building Research Establishment, Watford, WD25 9XX United Kingdom , Phone +44 1923 664382, Fax +44 1923 664991, saundersg@bre.co.uk. Chairman CEN TC254 Flexible sheets for waterproofing.

1 THE HISTORICAL USE OF BS747

BS 747:2000 – Reinforced bitumen sheets for roofing - Specification [British Standards Institution] was first published in 1937. Other editions have been published in 1952, 1961, 1968, 1970, 1977, 1994 and the last in 2000. The products that have been covered by this standard have been traditionally known as 'bitumen felt' but to better reflect the latest European standards they are now referred to as ' reinforced bitumen sheets for roofing'.

The various types of materials covered by this standard have a matted fibre base which is coated with bitumen. There are a number of types which have been identified according the material used for the base. These are shown in table 1 together with their reference within the standard.

Table 1. The types of pre-formed base materials covered by BS747.

Types of pre-formed base roofing sheets	*Type 1 Fibre base*	*Type 2 Asbestos base*	*Type 3 Glass fibre base*	*Type 5 Polyester base*
Fine mineral surfaced sheet, e.g. fine sand, talcum etc.	-	-	3B	5B and 5U
Granule surfaced sheet, e.g. slate, granite or ceramic	-	-	3E	5E
Reinforced sheet	1F	-	-	-
Venting base layer	-	-	3G	-

There are marked differences in the performance and durability of the various materials. Those of type 1 with a base of organic fibres, often referred to as 'ragfelt', performed so poorly in the application of waterproofing for flat roofs that they were removed from BS747 in the 1994 amendment. The only reference for type 1 products (type 1F) is for use as underlays for the use beneath slates or tiles in pitched roof construction.

Type 2 products were manufactured using an asbestos base but these were formally withdrawn probably in the 1977 version.

Type 3 products are manufactured using a glass fibre base are for general use in what are now considered to be relatively low performance situations. The building may be temporary or the substrate maybe be stable so the membrane is at low risk of failure due to building movements. The life of this type of membrane, usually comprising at least two layers is generally accepted as being about 10 years.

The type 3G is specifically manufactured to provide a venting base layer. This was developed to lay over new concrete decks and avoids blisters due to entrapped moisture during construction. More recently it has been used as a first layer over certain types of insulation board.

Type 4 is a specialist product for a specific application beneath mastic asphaltic and is not included in table 1 and are not considered further here.

Type 5 products are made from polyester. The base is provided in a variety of weights (mass per unit area) and has been manufactured by one of two methods. The lighter and medium weight sheets are non-woven materials while the heaviest can be needle punched. The combination of a light weight underlay (125 g/m^2) and a heavyweight capsheet (350 g/m^2) has been responsible for a service life of at least 30 years.

The last version of BS747 developed in 2000 also recognised that different weights of membranes based on polyester were in use so the additional types were added. These included the refined types 5B/180, 5B/250 and 5B/350. Type 5E with a mineral surface were also denoted in this way.

In the manufacturing process the base material maybe impregnated first with straight run bitumen and then coated with oxidised bitumen. BS747 does not cover products developed more recently that use polymer modified bitumen. Reinforced bitumen membranes manufactured using polymer–modified bitumen have generally been covered by third party certification.

2 THE INTRODUCTION OF EN13707:2006 – BITUMEN SHEETS FOR ROOF WATERPROOFING [CEN]

The reason for the development of a series of Europen Norms (ENs) was the agreement of the Construction Products Directive in 1989 between the member states of the European Union (EU). The intention was to establish free trading of construction products throughout the EU. After an initial period of development the European Committee for Standardization Technical Committee 254 (CEN TC254) was established to produce test methods and product standards for a particular group of products callled 'flexible sheets for waterproofing'.

The requirements for product standards was established by the requirements in member states based on their (building) regulations. These requirements were collated by the Standing Committee for Construction and issued as a mandate. This mandate was sent to CEN or European Office for Technical Approval (EOTA) who responded with a reply which contained relevant product standards and test methods.

Within the structure of CEN TC254 bitumen sheets for roof waterproofing were dealt with by Sub-committee 1 (SC1) and the same for plastics and rubbers in SC2. It was recognised that there would be some common test methods and separate working groups (WGs) were established by CEN TC254 to produce test methods.

EN13707 is the product standard developed by CEN TC254/SC1 for bitumen sheets for roof waterproofing. It refers to a series of test methods and contains information which leads a manufacturer to be able to CE mark a product. The CE mark on a product or a label, can contain information based on results of test methods. This information may only refer to a few tests results (such as external fire performance) necessary for satisfying the regulation of any member state where the product may be sold. A wider range of information about the product can be found on the manufacturers data sheet including tensile properties, tear resistance and shear and peel of joints.

The value assigned for a particular material property may not give the same value as stated by a manufacturer. This is because EN13707 requires information to be stated as a manufacturers declared value or a manufacturers limiting value and there are rules which relate to both of these.

EN13707 contains reference to product characteristics for which a series of test methods have been developed. They are for initial characterisation of the product or for factory production control. The characteristics as listed in Table 2.

Table 2. Product characterisitcs in EN13707.

Initial type tests	*Tests for Factory Production Control*
Watertightness	Visible defects
External Fire performance	Length & width
Reaction to fire	Straightness
Watertightness after stretching at low temperature	Mass per unit area and thickness
Joint strength (peel and shear resistance)	Tensile properties
Water vapour properties	Resistance to tearing (nail shank)
Resistance to impact	Dimensional stability
Resistance to static loading	Flexibility at low temperature
Resistance to root penetration	Flow resistance at elevated temperature
Form stability under cyclic temperature change	Adhesion of granules
Artificial ageing behaviour	

3 THE DEVELOPMENT OF BS8747:2007 [BRITISH STANDARD INSTITUTION]

BS8747:2007 was developed by a British Standards Institution (BSI) committee reference B 546/1. The committee has been Chaired by the author of this paper for over 10 years.

The initial decisions made were firstly to refer to bituminous products as ‘reinforced bitumen membranes’ (RBMs). Previously the word ‘felt’ had been used and tended to convey a meaning of poor performance and failure. Secondly, it was found to be possible to retain the numbers ‘747’ in the new British Standard thereby ensuring a continuance with the industry in the use of these numbers in reference to bituminous products.

The task faced by the committee was to determine how to link the old standard BS747 and the new European standard EN13707 so that the end user and would be able to select and specify bituminous products based on performance and durability.

The committee identified a need to concentrate on a number of items of work;

- To identify the product characteristics from the list in EN13707 which could best be used to determine a change in levels of performance and durability
- To match the chosen product characteristics with the end use conditions ensuring compliance with existing Codes of Practice
- To produce a simple coding system which would allow specifiers to select bituminous products according to performance
- To compile a list of test results for the product characteristics for a range of the most widely used reinforced bitumen membranes.

All of these were needed to develop the final document so two working groups were established, a users group and a manufacturers group.

The committee were mindful that a system had been developed in France called the 'FIT' system (Chaize 1991). This was based on fatigue, impact and temperature. Impact and temperature are referred to in the product characteristics in EN13707 i.e. resistance to impact and flexibility at low temperature.

A problem that was recognised was that as far as end users were concerned they only needed 3 levels of performance – low, medium and high. This was also strongly linked to short, medium and long term requirements for service life (and hence durability). On the other hand the typical manufacturer has about 40 different bituminous products and wants to sell all of them. A standard with just 3 levels of performance would not be acceptable to the industry.

This can be considered against the old standard which had effectively 3 levels of performance through type1, 3 and 5 products. However, this only referred to products manufactured using oxidised bitumen. BS8747 needed to encompass those manufactured with polymer-modified bitumen also.

3.1 The Coding System Developed

A classification for RBMs for roofing was developed. The system is based on two parameters, tensile strength and indentation and is used to define the following:

a) the performance achieved by any particular membrane
b) the performance required by any particular roof construction.

The characteristics chosen from EN 13707 were tensile strength (S) and resistance to puncture or indentation (P). Hence the SP classification. Each letter is assigned a numerical suffix that increases with performance level. The lowest perfoming membrane is hence S1P1. A total of 5 levels were chosen so the highest performing is S5P5.

The tensile strength is determined according to EN12311-1:2000 [CEN]. The S class is determined by a number levels e.g. 150 to 350 N/50mm for S1 and 350 to 450 N/50mm for S2. The values stated are minimum values as quoted by the manufacturer and are required in both the longitudinal and transverse direction. The class for the P parameter is determined from 2 sub-classes based on the resistance to impact (EN 12691:2006 [CEN]) for Dx and resistance to static loading (EN12730:2001[CEN]) for Lx. Table 3 below shows how these are combined to determine the P class.

Table 3. Combinations of D subclass and L subclass to give P class.

Subclass D	*Subclass L*	*Combination*	*P class*
D1	L1	D1L1	P1
D2	L2	D2L2	P2
D2	L3	D2L3	P3
D2	L4	D2L4	P4
D3	L4	D3L4	P5

The values from the impact test are a drop height e.g. up to 700mm for subclass D1. The values for static loading are expressed as a load e.g. 5 kg for subclass L1.

3.2 How to Use The Snpn Classification System.

Two approaches have been taken in BS8747 to use the SnPn system.

The French FIT system was used as a basis to deveop a table which gave membrane classification by performance requirement. A small part of the performance table is shown in Table 4 as an example.

Table 4. A small part of the performance table.

Substrate below the membrane	*Slope/Falls*	*Roof use and type of protection*	
		No access apart from maintenance	
		Self-protected	*Ballast (coarse gravel)*
Concrete	1 to 5	S3P2	S2P3
	>5	S3P2	-
Plywood, OSB or timber boarding	1 to 5	S3P2	S2P3
	>5	S3P2	S2P3

In the performance approach the specifier is free to modify the performance if other factors are involved. An example may be to increase the puncture resistance (Pn +1) if a softer substrate is used i.e. thermal insulation.

A flow chart was also developed which gave a system selection for warm deck roofs and for inverted roofs. Table 5 is based on a small section of the flow chart.

Table 5. System selector for a typical warm deck roof.

Step 1	Choose a deck/substrate Preparation	Close boarded timber Correct any uneven planks and punch in nail heads
Step 2	Select a vapour control layer	RH low: nailed RBM to minimum of S2P2 with sealed laps RH medium: nailed RBM as above, and fully bond a second S2P2 layer RH high: nailed RBM S2P2 and fully bond a metal-cored second layer
Step 3	Select thermal insulation After bonding/fixing insulation boards, for pour and roll or torch-on systems the following preparations are needed before the application of the first working layer	e.g Polyurethane (PUR) Apply a type 3G layer (specialised product originally developed in BS747 for use over wet concrete. Experience has shown blisters can develop when membranes are fully bonded to PUR boards)
Step 4	Select working waterproofing layer	First working layer: could be S2P2 but specifier is free to choose Final Layer: depends on application (see performance table) typical choice could be S3P2

3.3 Other Information in BS8747

Before considering the specification of the RBM waterproofing layer it has been assumed that the roof has been designed by a competent person and that the roof design has been considered for wind loading, condensation risk, designed for drainage and complies with the UK building regulations. For consideration as an RBM in BS 8747 the RBM must pass the following tests in EN13707:

- watertightness , for all applications
- root resistance for green or garden roofs.

BS 8747 also considers other product information and gives a typical range of values for tensile strength, elongation, nail shank tearing, static load resistance, impact resistance, flexibility at low temperature, flow resistance at elevated temperature, durability, external fire performance and reaction to fire.

Information is also given as to what performance level would be acceptable. For example a minimum value for nail shank tearing of greater than 175 N would be acceptable in all instances. Durability is

assessed by exposure to heat aging in an oven for 12 weeks (EN1296 [CEN]) and then assessing flexibility at low temperature. The UK expectation is that no change will take place for durable products. Such is the performance of polymer-modified polyester reinforced bitumen membranes that a service life in excess of 50 years is anticipated.

3.4 Worked Examples

The BSI committee did realise that the new approach taken to help the specification and selection of RBMs might, in the first instance, not be readily understood so a series of worked examples have been given in an annex. The worked examples chosen are:

- Single-storey rural school classroom
- Three-storey block of flats/offices
- Swimming pool
- Hospital refurbishment
- Garage block(domestic).

All of the worked examples follow the same format and blank forms are included for copying to aid the development of a specification.. The reasons for the choices made in the worked examples are given in each case.

4 CLOSING COMMENTS

The BSI committee reaslised the need to develop guidance for the specification and selection of reinforced bitumen membranes. This has in part been due to the active UK participation in the relevant meetings of CEN TC254 in developing EN13707. It has been the case that British Standards tend to lag behind the current practices of the day and only incorporate these practices into a Standard as they become the accepted and successful method of construction. In this context BS8747 is ground breaking in that it leads the industry into the use of EN13707 products rather than waiting to see what the industry would do. It would be difficult to produce effective specifications without the guidance in BS8747. The rag based felts were withdrawn from the old BS747 sometime ago because of their poor perfromance in construction methods incorporating thermal insulation on flat roofs. Such products will be legally marketed within Europe with a CE mark. It is therefore essential that a system is developed so that the lower performing products are used only in those applications for which they are suited. The use of low perfoming products could result in unexpected costs due to early replacement. It is anticipated that the use of BS 8747 will avoid such expense and result in the correct selelction and specification of reinforced bitumen membranes.

ABSTRACT

The wind resistance of mechanically anchored waterproofing systems depends on the reliability of the fasteners. For designing safer mechanically anchored various waterproofing membrane systems, it is necessary to make clear the behaviour of them under strong wind. In this study, the wind tunnel test with various mechanically anchored waterproofing membranes was carried out to gain an understanding of the behaviour of waterproofing membranes and its relation to wind parameters against high wind speed. Two types full-scale size waterproofing membranes were exposed to high wind speed in wind tunnel. They are polymer-modified asphalt roofing sheet layered and poly-vinyl-chloride (PVC). The size of test specimen is 2.4-m wide by 5.5-m length and 0.5-m height without parapet. The space of fasteners used for the mechanically attached membrane was 600-mm. Wind tunnel test was carried out in condition of uniform flow and wind speed from 18m/s to 35m/s. The behaviour of membrane to high wind speed was observed, and the strain of waterproofing membrane and the axial force occurring at a fastener was measured. Both membranes were lifted up by negative pressure of wind and tensile force induced in a fastener. Each modulus in waterproofing membrane is different, and modulus in same type is different depending on the direction. The billowing condition of waterproofing membranes depended on their modulus and the strain was greater at the bias direction of fastener. The modulus of waterproofing membrane exerted an influence upon the frequency and fluttering patterns. It is necessary to consider the mechanical property of waterproofing membranes when the waterproofing membrane system was designed against high wind speed.

1 INTRODUCTION

Typhoons 18 and 22 caused great damages to waterproofing membranes in Japan in autumn, 2004. In particular, as for the mechanically anchored waterproofing system for which waterproofing membrane are fixed only by fasteners on a ground, it was found that some of such membranes could not endure strong winds. In recent years, use of this method increases rapidly mainly on repair works since it is hard to be influenced by grounds however immaturity of such system was exposed in the technical aspects by occurrence of these damages. In particular, it seems the cause of such damages is the point that wind-resistant designs of the waterproofing membranes were performed with static wind loads as references and behaviours of a mechanically anchored waterproofing membrane system under strong winds were not clarified for the said designs. A number of studies on wind resistance of waterproofing membranes have been conducted by tests with simple and easy suction box systems. However, behaviours under a windy condition have not been actually reproduced. Winds, as an external force, were clarified by wind tunnel tests Baskaran & Savage [2003] conducted however behaviours of an entire waterproofing system have not been clarified yet.

The authors have undertaken a study on behaviours of mechanically anchored waterproofing membrane systems in a wind tunnel to grasp such behaviours. There are various types of waterproofing membranes and it is assumed that their dynamic behaviours are greatly affected by mechanical properties of waterproofing materials. From the above viewpoint, for this study, the authors selected waterproofing materials with different mechanical properties and discussed differences on behaviours of waterproofing membranes under a strong wind by wind tunnel tests of a mechanically anchored waterproofing membrane system using the materials.

2 WIND TUNNEL TESTS BY ACTUAL-SIZED SPECIMENS

2.1 Type of Waterproofing Membrane and Basic Physical Property

The authors selected two types of waterproofing membranes with different mechanical properties as specimens for the study, an asphalt waterproofing membrane in which two polymer-modified asphalt roofing sheets (reinforced type) are layered (denoted as "layered asphalt membrane") and a poly-vinyl-chloride (PVC) membrane (general composite type) as roofing sheets of synthetic polymer. Test pieces of 200 mm in length and 50 mm in width were cut off from the same materials as those used for the tests (three pieces from each of lengthwise, crosswise and diagonal 45 degrees directions). Woodcuts of 50 mm square was affixed to both ends of a specimen to prevent fractures of chucks during a tensile test and an effective test piece length was 100 mm. These test pieces were strained at 100 mm/min in a temperature condition of 20 degrees Celsius, and tensile strengths and extension rates were measured. Fig. 1 shows results obtained from the tests. Waterproofing sheet layers or reinforcing materials were inserted to the specimens. And so tensile strengths of the

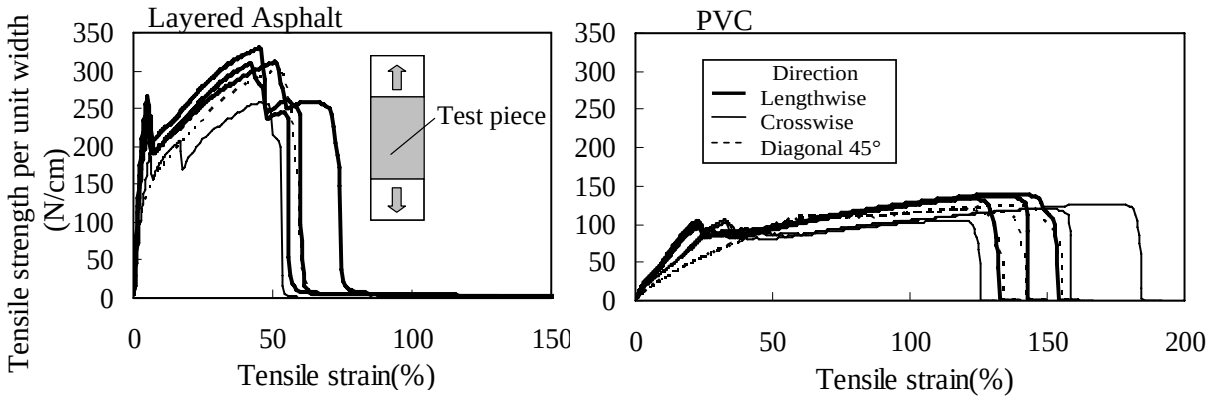

Fig.1 Results of tensile test concerning waterproofing membranes.

membranes were not uniform. The results were presented in "tensile strength per unit width". In the process of their behaviours, a reinforcing material breaks at first, then a waterproofing material strains and finally reaches a fracture. However, in the test piece cut off in a diagonal 45 degrees direction, remarkable tensile peaks were not found at an initial stage of straining.
According to Ichikawa *et al.*[2005], mechanical properties with an expansion lower than 1% in an initial region of a tensile test engage with a waterproofing membrane's behaviours under a strong wind. 1% modulus (tensile strength at 1% deformation) was higher in a layered asphalt membrane for all directions and the lower 1% moduluses were obtained from a PVC sheet respectively.

2.2 Measurement Item and Measurement Condition

2.2.1 Wind Tunnel and Specimen
Specimens without parapets of 2.4m in width, 5.5m in length and 0.5m in height shown in Fig. 2. They were set in a circuit boundary layer wind tunnel with a section area of 2.3m in height and 2.4m in width. According to Bienkiewicz & Sun [1997], various wind tunnel tests were carried out by their great efforts. Using models of roof pavers made of plexiglass and graphic tape as spacers were excellent. However, their objects are solid and thick. It is impossible to reduce the waterproofing membrane to be thin, transformable and not uniform. Though problem in the effect of the scale had been understood, to make clear the behavior of mechanically anchored waterproofing membrane against strong wind, it was necessary that the specimen used real material was exposed high wind speed of a wind tunnel. The tests were conducted under a condition without obstructions on the windward. A blockage rate of this wind tunnel test was 21.7%(= aspect area of specimen/wind tunnel cross section * 100). An ALC panel with a thickness of 100mm was used as a bed for membranes. The membranes were fixed in the bed with M12 bolts and nuts in 0.6m intervals(0.5m intervals for the upwind edge) through a circular metal plate of 75mm in diameter and 1.7mm in thickness.

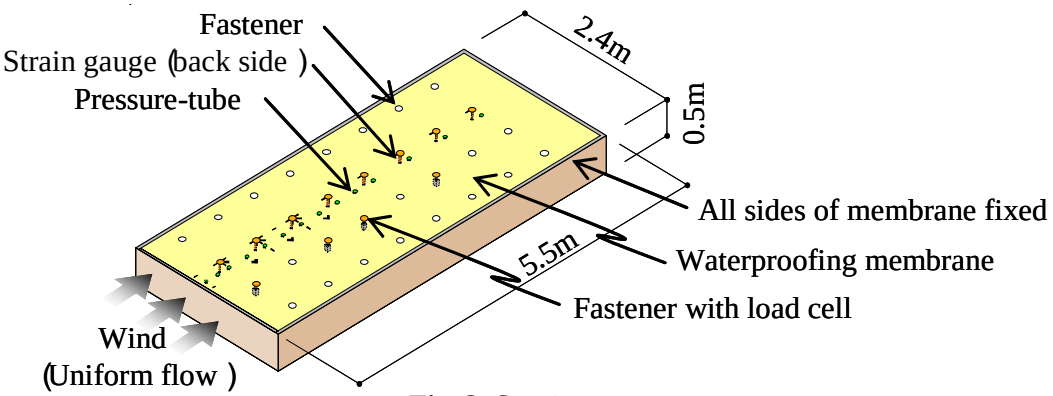

Fig. 2. Specimen.

2.2.2 Measurement Method
Figure 3 shows the measurement method. 14 wind pressure measuring taps were placed in the wind direction in a straight line. For wind pressures act on waterproofing membranes, pressures on the external and underneath (a gap between the membrane and the bed) of a membrane were led to a pressure anemometers from vinyl tube installed on the waterproof membrane with the aluminum pipe and differential pressure of external and internal on sheet were measured. The scale was put on the window of the wind tunnel, and the top of the swelling of the membrane was measured. Wind speed in the wind tunnel were measured in a pitot static tube installed at the position of 0.9m above the specimen's center. Deformations of membranes were measured by strain gauges (strain limit: 5%) attached on the membranes' back side. The temperature in the wind tunnel was around 15 degrees Celsius. Axial forces of the fastener fixing the membranes were measured by load cells (rated capacity: ±9.8kN, non-linearity : within 5%) set in the vicinity of the center, which was not affected by the wall effect. 8192 values were obtained from a tubing compensation for the data measured at 200Hz for 60 seconds in each measuring point.

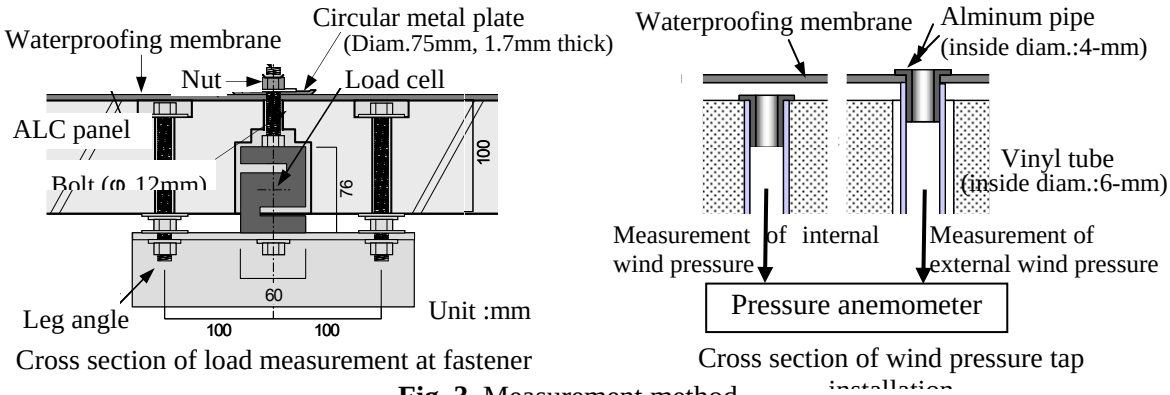

Fig. 3. Measurement method.

3 TEST RESULTS AND DISCUSSIONS

3.1 Observation Results of Waterproofing Membranes' Behaviours Caused by Wind

Figure 4 shows blister shapes in a fastener line of the specimen's center part at a wind speed of around 30m/s, for which the shapes are five times strained in the height direction as in the length direction.

Waterproofing membranes are sucked up by a wind and their shape become a swollen shape however the swells are divided since the membranes are fixed in the bed at certain intervals. Swellings on a PVC membrane were identified visually from wind speeds of around 10m/s and those on a layered asphalt membrane were identified visually from a wind speed of around 20m/s.

The wind speed at which a waterproofing membrane begin to swell is related to its mass. Large swellings are seen in the windward on each membrane. Swellings are higher in the PVC, followed by the asphalt and the membranes tend to be easy to swell as modulus is lowered. Fluttering motions were quick in the windward direction and slow in the leeward direction for all the membranes.

3.2 Wind Pressures Acting on Waterproofing Membranes

Distributions of wind forces coefficient acting on each waterproofing membrane are shown with a plane surface without waterproofing membranes in Fig. 5. One of the relation between the and the wind speed simulated beforehand shown in the right of Fig.5. A layered asphalt membrane has small swells and its wind pressure distribution is similar to the plane surface. On the other hand, for a PVC membrane, negative pressures, which are larger than those on the plane surface, are generated at the windward end and they decrease drastically on the leeward since their shapes change irregularly by behaviours of the waterproofing membranes.

The difference of wind force coefficient is thought to be an influence by the swelling of the membrane. A layered asphalt membrane has small swells and its wind pressure distribution is similar to the plane surface. On the other hand, for a PVC membrane, negative pressures, which are larger than those on the plane surface, are generated at the windward end and they decrease drastically on the leeward since their shapes change irregularly by behaviours of the waterproofing membranes.

The difference of wind force coefficient is thought to be an influence by the swelling of the waterproofing membrane.

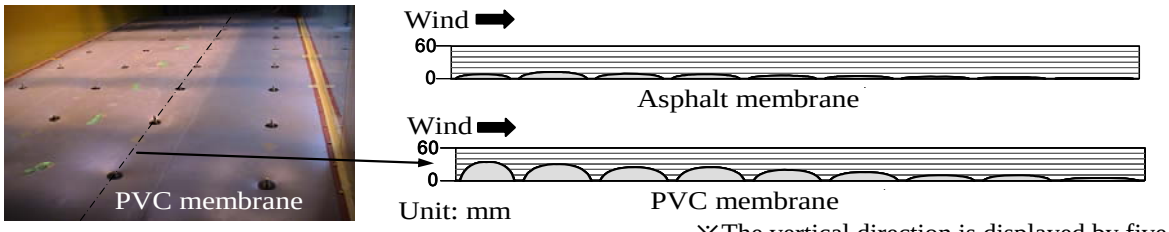

Fig.4. Swelling of waterproofing membrane by wind (wind speed: 30m/s).

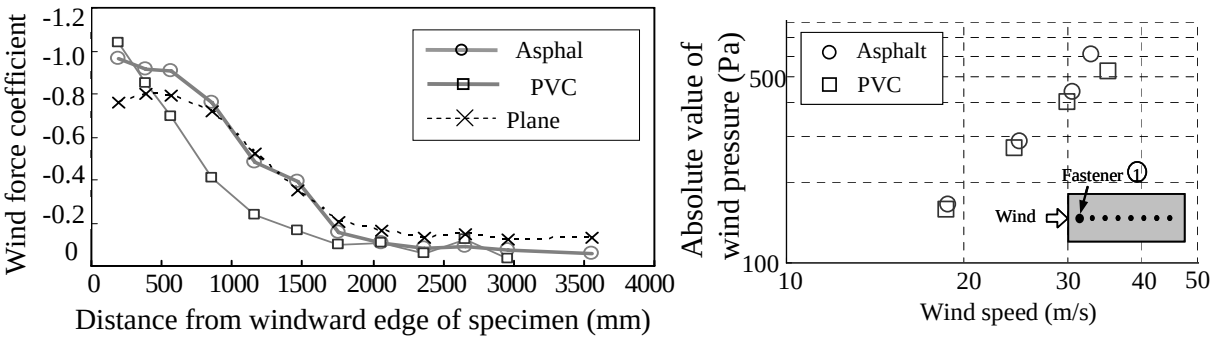

Fig.5. Distributions of wind force coefficient on each waterproofing membrane

3.3 Deformations and Behaviours of Waterproofing Membranes

Figure 6 shows strain changes of layered asphalt and a PVC membrane in one second in the upwind direction at the wind speed of 33m/s.

Tensile strains of the membranes are large on the windward, and small on the leeward same as the average wind pressure distributions.

This is similar to swells on membranes visually observed. Frequencies of the waterproofing membranes' fluttering motions were 10-16Hz on the windward and around 10Hz on the leeward therefore the cycle of fluttering motions on the leeward are longer than those on the windward. Moreover, a layered asphalt membrane with high modulus billows small and slowly, and a PVC membrane with low modulus do quickly and greatly.

Strains, variations and frequencies of the waterproofing membranes are influenced by mechanical properties of themselves.

Figure 7 shows tensile strain and tensile force of the membranes in one second in each direction from the fastener. For waterproofing membranes studied this time, strains around the fasteners were large. The average maximum strain for the PVC membrane was 0.27% and that for the layered asphalt membrane was 0.12% at the wind speed of 33m/s. Each maximum strain was measured at the first point on the windward or the second point on the leeward approximately 1m away from the windward, at which negative pressures are large, and in crossward direction or diagonal 45 degrees direction, in which moduluses are low.

The maximum momentary strain for the PVC membrane was 0.39%.

The tensile strain of the PVC membrane with lower modulus is larger, and the membrane in the directions in which modulus is lower deform easily as shown in the left of Fig. 7. However, the tensile force of the asphalt membrane with higher modulus is larger as shown in the right of Fig. 7.

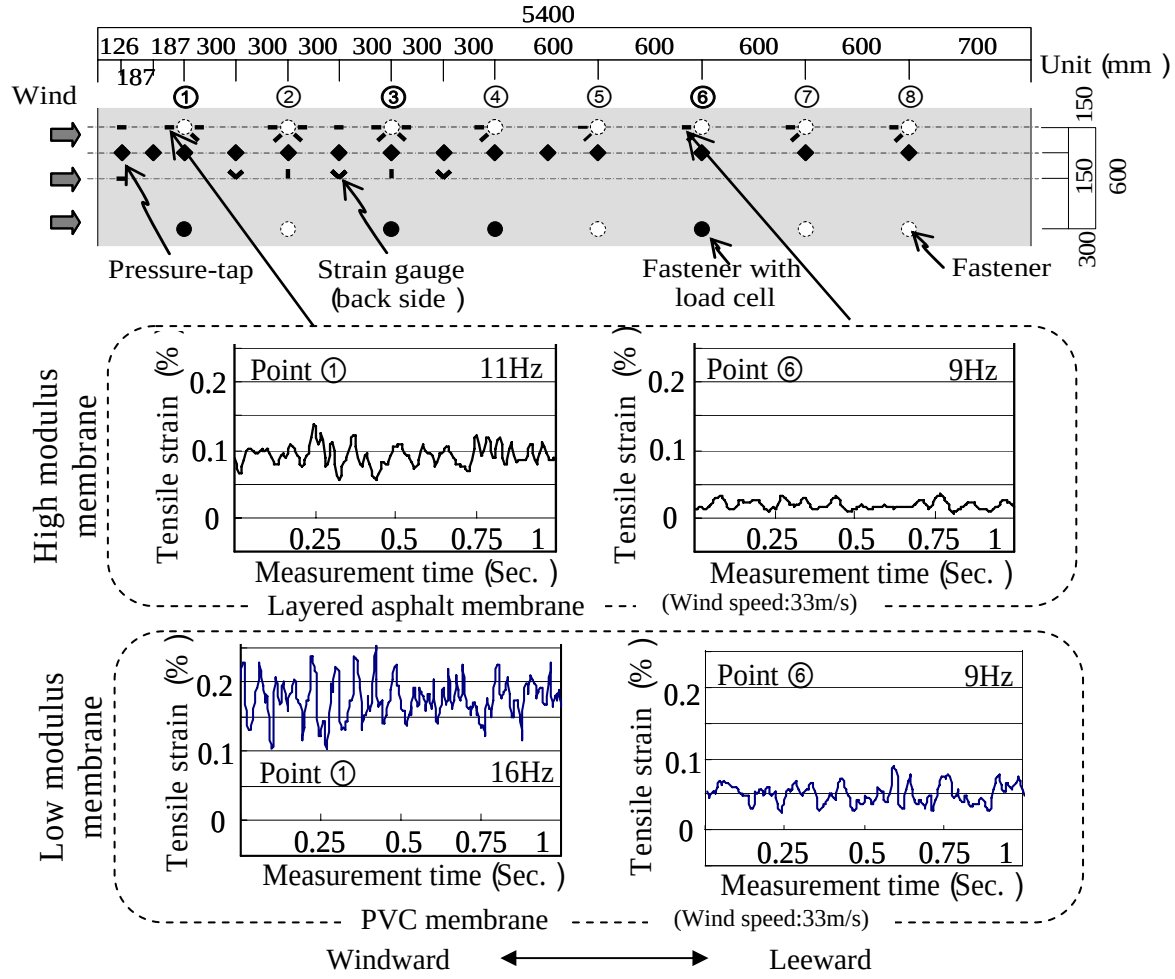

Fig.6. Tensile strain of membranes in one second on the windward direction of each position.

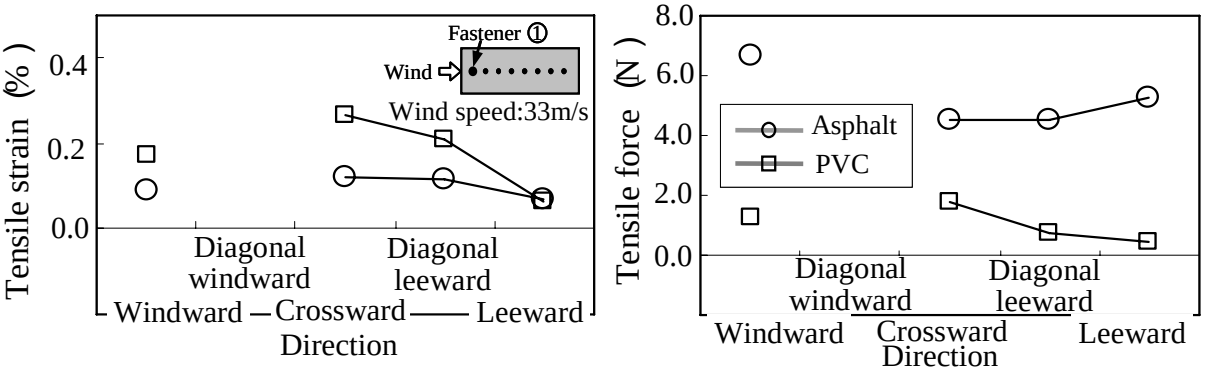

Fig.7. Tensile strain and tensile force of the membranes in each direction from the fasteners.

3.4 Relations of Wind Load and Waterproofing Membrane Tensile Forces

Figure 8 shows wind effect on mechanically anchored waterproofing membrane system. A typical mechanically anchored waterproofing membrane swells by the suction of the wind on them, as shown in the left of Fig. 8. Thus, tensile forces are generated in the waterproofing membrane as well as tensile and shear loads induced in the fasteners. The tensile force of the membrane balances wind force with perpendicular element. Therefore, the total of the perpendicular element force caused by the tensile force of the membrane on the edge of a fixing plate becomes equal to wind load on membranes that one fastener bears as shown in the right of Fig. 8. The axial force is generated in the fastener resisting the force pulling out fastener. Similarly, it is thought that the difference of the horizontal

component of the tension on the membrane around a fixed plate generates the shearing force in the fastener.

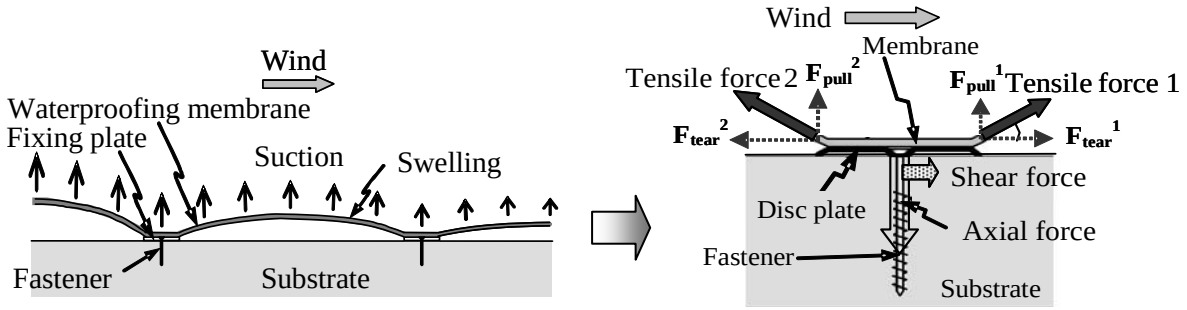

Fig.8. Wind effect on mechanically anchored waterproofing membrane system.

Figure 9 shows relations between tensile forces of the membranes and wind loads acting on them. The area of wind loads acting on membranes that the first fastener on the windward bears is 0.33m^2. In the case of the same wind speeds, larger tensile forces are generated in almost horizontally on a layered asphalt membrane with high moduluses than them in a upward direction on PVC membrane with low moduluses.

As previously mentioned, this means the tensile forces of the membranes balance wind force with their perpendicular element. Furthermore, in a same waterproofing membrane, a tensile force turns up as a wind load increases.

This is because the membrane expands by the wind load as shown at the right of Fig. 9. Therefore, the tensile force of membranes does not double even if the wind loads doubles. This tendency is strong because asphalt with high moduluses is horizontally near as shown in Fig. 9. On the other hand, the tensile force of PVC membrane with low moduluses does not change so much.

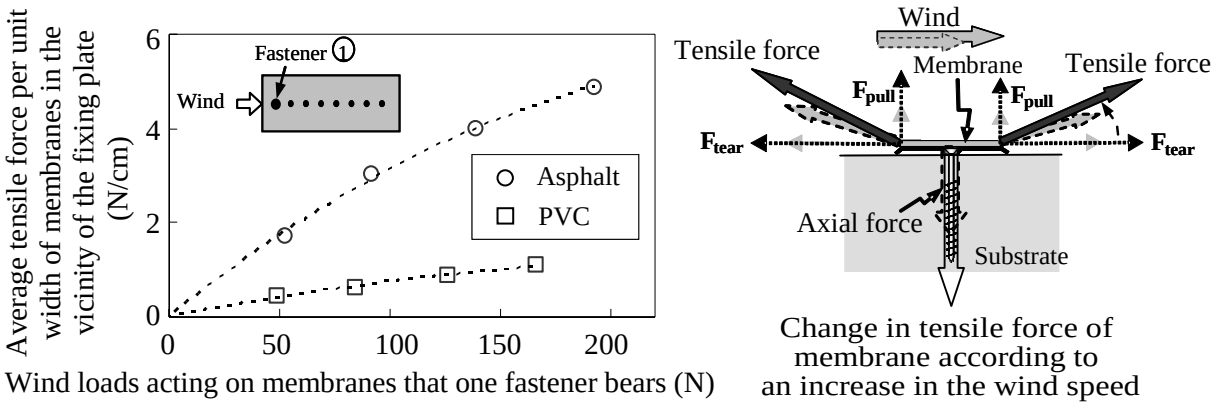

Fig.9. Relations between tensile forces of the membranes and wind loads acting on membranes.

3.5 Relations between Wind Speeds and Fastener Axial Forces

Relations between wind speeds and fastener axial forces in each membrane are shown in Fig. 10.

It has the fastener axial force and the wind speed in a linear relation. An axial force at a wind speed of around 30m/s (wind force = 551Pa) was an almost constant value of around 130N in a PVC and layered asphalt membrane, considering the mass of the membrane. Therefore, the mechanism that each membrane transmits the wind force to the fastener was confirmed.

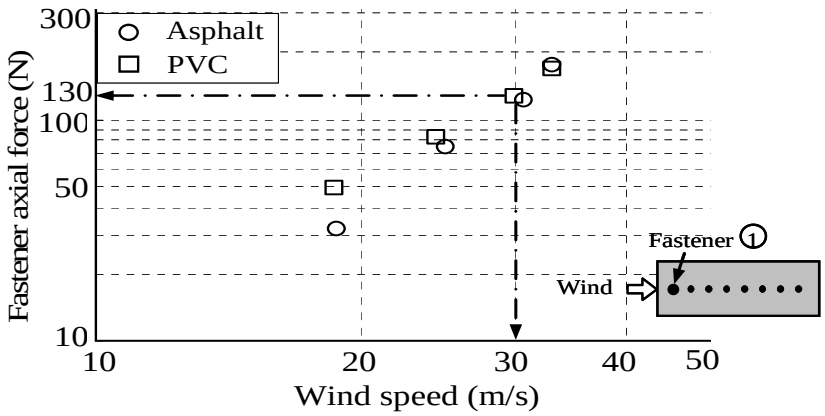

Fig.10. Fastener axial force and wind speed.

4 CONCLUSIONS

For two types of waterproofing membranes with various mechanical properties, behaviours of them in strong wind were studied by wind tunnel tests. Results are summarized as follows.

(1) A height of a waterproofing membrane's swell is related to a modulus of a waterproofing material and a waterproofing membrane with low modulus is easy to swell. In addition, a waterproofing membrane does not swell uniformly since it strains in a direction where a modulus is low.
(2) Behaviours of a waterproofing membrane are quickly in a windward and slowly in a leeward. Behaviours are different in each waterproofing material. A layered asphalt membranes with high modulus billows small and slowly and a PVC membrane with low modulus do quickly and greatly.
(3) A waterproofing membrane strains greatly around of a fastener and tensile forces are generated accompanied with such a motion. In the same wind speed, larger tensile forces are generated in a waterproofing membrane with high modulus around a fastener, and tensile forces of a waterproofing membrane with low modulus are small.

Wind tunnel tests of a mechanically anchored waterproofing membrane system were performed by waterproofing materials with various mechanical properties. From the tests, we have clarified some qualitative properties of strains of waterproofing membranes with various waterproofing materials and those of forces generated in a fastener. The study will be continued so as to propose safer wind-resistant designs for mechanically anchored waterproofing membrane systems.

Service Life (Model) for Bituminous Roofing

Erik Brandt [1]
Tommy Bunch-Nielsen [2]

T 22

ABSTRACT

Leaking low-sloped roofs, i.e., roofs with roofing felt or roofing membranes, have been responsible for extensive major damage to buildings all over the world. The causes have been several, e.g., bad materials – or rather materials and materials combination used in a way they were not suited for - bad design with difficult details hard to make at a building site and bad workmanship. In Denmark the problems have been dealt with in different ways including requirements for minimum slope, for the substrate and for the roofing felt/membrane. To avoid problems a model for service life prediction of low-sloped roofs was developed some years ago. The model was based on experience. The paper explains the background for the model and discusses how the model fits also with later gained experience. In addition, the paper describes an investigation on service life of SBS modified bituminous roofing carried out in cooperation between the Danish Bituminous Roofing Manufacturers, The Danish Roofing Advisory Board and the Danish Building Research Institute. The findings confirm the predictions of the model as regards SBS modified roofing felt.

1 INTRODUCTION

Leaking low-sloped roofs, i.e., roofs with roofing felt or roofing membranes, have been responsible for extensive major damage not only to the roof covering itself, but also to the underlying parts including underlay, trusses and occasionally to furniture and fixtures In Denmark the causes for the problems have been several.

Earlier the use of horizontal roofs was quite common, as it gave an architectural impression which was popular at the time and besides alterations or expansion of the buildings was relatively simple. However the horizontal roofs led usually to ponding of water followed by destruction of the roofing felt/membrane due to formation of ice and prolonged exposure to humidity. Also the materials used earlier were less durable than materials used today, e.g., the glass fibre reinforcement in earlier generations of roofing felt led to brittle products and for PVC-roof membranes big problems were caused by shrinkage due to evaporation of plasticisers. Finally problems occurred due to the use of materials or combinations of materials used in a way they were not suited for, bad design with difficult details hard to make at a building site and bad workmanship.

In Denmark the problems have been dealt with in different ways. The horizontal roofs were abandoned when requirements for minimum slope were introduced in the building codes in 1981. New generations of materials have come to the market e.g., new reinforcement and plastic modified bitumen for the roofing felt and more suited plasticisers for PVC membranes. Also the underlay for the roofing is of importance for the service life of the entire constructions and here requirements have been set by the involved key partners, e.g., Danish Roofing Advisory Board.

2 SERVICE LIFE MODEL FOR ROOFS

It is not possible to state a precise service life for roofing materials because it is dependent on a number of different factors. Some years ago a model for service life prediction of low-sloped roofs was developed based on experience taking into account the factors considered most important for the deterioration of roof membranes in the past [Bunch-Nielsen, T., 1997]. The factors in the model are:

- The type of roof membrane (p - product)
- The number of plies (n)
- The slope of the roof (s)
- The substrate (u – underlay)
- The fastening to the substrate (f)
- The design, especially the details (d – design)
- The traffic on the roof (t – traffic)
- The maintenance (m)

Based on the factors the service life can be expressed as:

$$L = T \bullet p \bullet n \bullet s \bullet u \bullet f \bullet d \bullet t \bullet m$$

T is the anticipated service life for a reference roofing material. The remaining factors all have values between 0 and 1, i.e., T is the maximum service life on condition that all other factors are at their maximum.

2.1 Roof Membrane – The Product

In Denmark an important property for a roofing membrane is its ability to function in a cold climate with many freeze-thaw cycles. From assessments, we find that this is, on the average, best achieved with a SBS-modified bitumen. Consequently a roofing felt made from SBS-modified bitumen and reinforced with polyester carrier - which is the most commonly used roof membrane in Denmark – is

used as the reference in the model and the service life for a roof of this type is estimated to be 50 years, i.e., the factor T in the formula is 50 years. For other types of roof coverings a reduction factor is used according to the following:

Roof covering	SBS-modified bitumen	APP-modified bitumen	Oxidized bitumen	PVC reinforced	EPDM
Factor p	1.0	0.7-0.9	0.8	0.8	1.0

2.2 Number of Plies

The number of plies in a roof covering has bearing on the service life. In Denmark roof coverings are traditionally made with 2 plies (earlier in built-up roofs even more plies were used). The factors used are the following:

Number of plies	2	1
Factor n	1.0	0.8

2.3 Slope of The Roof

The slope of the roof is of importance for the time of wetness and for the risk of water ponds. Ponds on the roof may lead to a risk of a build-up of ice which can remove the protective granules or even tear the roofing material apart due to temperature movements under freeze-thaw cycles. The influence of the slope is expressed according to the following:

Slope	≥ 1:5	≥ 1:20	≥ 1:40	< 1:40
Factor s	1.0	0.9	0.8	0.6

2.4 The substrate – Roof Underlay

In Denmark a number of different substrates have been used and quite a few have been abandoned due to problems, e.g., lack of dimensional stability under in use conditions. Nowadays are used products with a record of satisfying performance under in use conditions, mainly boards such as plywood, oriented strand board (OSB), and insulation materials. In case "soft" insulation materials (compressive strength less than 40 kN/m²) are used it is necessary to apply a hard load distributing layer on top of the insulation. In addition, it is normal to renovate old roofs with roofing felt by applying a new layer on top of the old. The influence from the substrate is expressed as the following:

Substrate/underlay	"Soft" insulation	"Hard" insulation	Boards, Plywood, OSB	Old roofing On hard substrate	Other substrates without documentation
Factor u	0.7-0.9	0.9-1.0	1.0	1.0	0.6- 0.4

2.5 The Fastening to The Substrate

Fastening of a roof membrane to the substrate can be achieved in different ways. Traditionally roofing felt is bonded or torched to the substrate, but mechanical fastening has been the dominant method for the last 15 years. Membrane securement might also be achieved by ballasting the membrane. The influence from the fastening is expressed as the following:

Fastening	Bonded or welded roofing felt	Mechanically fastened 2 ply roofing felt	Mechanically fastened 1 ply roofing felt	Membrane fastened with ballast	Mechanically fastened synthetic membrane
Factor f	1.0	1.0	0.9	0.9	0.8

2.6 The Project – Design of Details

The design has a major influence on the service life and especially the design of the details. It is important to include here a requirement that the details shall be buildable, i.e., it shall be possible to construct the details on a building site. The risk for failures increases with the number of details on a roof and consequently the factors mentioned below should be reduced, e.g., by a factor 0.8 for roofs with many details. The factors used are the following:

Details	Details in accordance with TOR[1] directions	Details not in accordance with TOR
Factor d	1.0	0.8

[1)] TOR is the Danish Roofing Roofing Advisory Board

2.7 Traffic on the Roof

The roofing material and the details can been damaged due to compression of the underlay from traffic on the roof. The influence of the traffic is expressed according to the following.

Traffic	Pedestrian traffic for maintenance of roof only	Pedestrian traffic for maintenance of mechanical installations, rooflights etc.	
		Hard substrate e.g., plywood	Soft substrate e.g., mineral wool
Factor t	1.0	0.8	0.6

2.8 Maintenance

The roof membrane itself is not anticipated to require maintenance, but details, e.g., flashings and joints and the drainage system need maintenance as part of preventive maintenance. The influence of the maintenance is expressed according to the following:

Maintenance	Maintenance according to TOR requirements	Maintenance not in accordance with TOR req.	No maintenance
Factor s	1.0	0.8	0.6 – 0.4

Because the assessments naturally are performed with a considerable uncertainty, the service life should only be given as the closest 5 year interval found as result of the calculation, e.g., 25-30 years.

3 SURVEY OF ROOFS WITH ROOFING FELT

To verify some of the assumptions in the service life model, 12 roofs have been surveyed. The roofs were all with bituminous roofing produced by Danish manufacturers. The inspected roofs are taken from a database of more than 15000 roofs under a warranty system for roofs in Denmark.

The warranty system was established in 1989 and was in full service in 1991 with approximately 1 x 10^9 m^2 of roofs added each year. The warranty period is 10 years and in that period less 0.5 percent of the roofs experience problems.

Please note that service life and warranty period are two different things and the expected (and experienced) service life time is fortunately much longer than the 10 year warranty period.

UV- radiation and heat from the sun is normally considered to be the main mechanism regarding ageing of bituminous roofing. To protect the surface of the membrane against UV-radiation it is normally protected by slate granules. It is of utmost importance that the uppermost protective layer is not damaged e.g., during the laying of the roof, from ice build-up or during maintenance in the service life of the roof.

The survey included a visual inspection of the roofing felt as such, the condition of the details and a subjective assessment on the remaining service life of the roof covering.

Besides specimens of the membrane were taken out form the surveyed roofs and the membranes were tested on the labs of the producers to detect any changes in properties during the use.

3.1 Visual Inspection of Roofs

The surveys were done according to an inspection list made for the purpose. The list included relevant information about the building owner, geographical position, etc. The technical evaluation was assessed as shown in the following example:

Roof covering:	2 ply SBS-modified bitumen Slope about 30°
When applied:	1991
Description:	The roof is made as a saddle roof with felting on angle fillets. The roof is build together with a lower low-sloped roof. This roof is assessed separately.

Visual inspection:

Overall impression:	Some deformations in the substrate (roof elements) are clearly visible. The roof covering itself looks acceptable.
Granule covering:	Generally good. ”Surface cracks” on the west side of the building
Tightness of welding seams:	Ok
Fastening:	Ok
Cracks in the roofing felt:	Starting to appear on angle fillets
Blisters:	None
Folds in the covering:	None
Cracks at flashings etc.:	None
Damage around roof lights:	No rooflights
Algae etc.:	Some algae on north facing surfaces of angle fillets
Valleys:	No valleys
Drain:	The roof is drained over the edge of the roof
Further remarks:	None

Estimated remaining service life based on the visual inspection: at least 15 Years

Using the service life model for this roof gives the following result:
L = 50 • 1 • 1 • 1 • 1 • 1 • 0.9 • 1 • 1 = 45 years.

Similar, the other roofs give in average results corresponding to the subjective assessment of the roof.

3.2 Laboratory Analysis on Test Samples

Laboratory tests on samples taken from the inspected roofs were performed by the 2 Danish producers in their own laboratories. The properties tested were those considered most crucial for a long service life. The roof membrane must remain watertight, weather-resistant and be able to resist influence from the underlying substrate.

All roofs are exposed to high temperatures in summer time and it is for that reason important that the bitumen is high quality and not sensitive to heat ageing. Temperatures of 70 to 80 ^{o}C can easily be reached on a hot summer day even in Scandinavia.

Table 1. Relevant properties for bituminous roofing.

Softening point/flow resistance	The flashings must be fastened so that they remain intact.
Cold bending:	The membrane must remain flexible in cold weather to resist traffic on the roof and the protective bitumen must not crack
Adhesion of the protective layer:	The membranes granule coating must remain intact to protect the bitumen from UV-radiation.
Tensile strength and elongation:	The membrane must remain flexible and be able to resist small movements in the substrate.
Shear and peel strength of joint:	The shear and peel strength of the joint must remain high to render the membrane watertight.

It is not possible to test the shear and peel strength of the joint on samples taken out from the roof as all roofs inspected are 2 layer systems. The results of the laboratory investigations were:

4 DISCUSSION AND CONCLUSION

Based on the findings from the visual inspections it is believed that well performing membrane roofs can be achieved provided that the above mentioned factors are taken into account when designing and executing the roof, i.e.:

- to obtain a good roof a high class roof covering is necessary,
- two plies will generally provide better protection than one layer,
- a roof with a well defined slope will eliminate/reduce the risk of ponding and decrease the time of wetness and the risk of ice building,
- the construction including the underlying substrate shall be stable enough to avoid deflections that may damage the roof covering,
- the roof shall be designed taking into account not only the constructions but also the installations and any complications that may arise due to the severe exposure to water and high relative humidity,
- the structure that supports the roof shall be stable enough to avoid deflections that may damage the watertight layer and the surface covering,
- the fastening shall secure the roof covering and must not cause unintended, increased load on the membrane itself,
- all details shall be well described/illustrated, easy to construct at the building site and preferably with a good use record (or tested for watertightness),
- pedestrian traffic should be avoided as far as possible or measures should be taken to protect the membrane from direct contact,
- the roof shall be maintained regularly--preferably on the basis of regular inspections and especially regarding details etc.

Undoubtedly the factors mentioned are crucial for the service life . The findings from the visual inspections and the laboratory tests seems to confirm that the service life model - at least for bituminous roof membranes - gives a good estimate of the service life.

It should be emphazised that the model is rough and with considerably uncertainties as some of the factors are based on individual evaluation.

The experience from the few problems in the warranty shows that it is often the details of the roof that fail – which is in accordance with the findings in the survey.

Therefore the service life time model should emphazise the use of correct details in the roof design more in order to secure against water infiltration etc. It is proposed that the model is improved by using a more detailed factor for design as shown below.

Details	No critical details[1)]	≤2 critical details per 100 m² roof	≤10 critical details per 100 m² roof	≤20 critical details per 100 m² roof	>20details per 100 m² roof
Factor d	1.0	0.8	0.6	0.4	0.3

[1)] Critical details are details not in accordance with the design rules as stated in the Danish design guide for roofs or wrongly executed details, e.g., too close together to ensure watertightness. An example of a critical detail is a flashing with a height lower than the minimum height 150 mm as stated in the Danish design guide. In the table 1 m flashing is considered equivalent to 1 penetration.

Figure 1. Example on two roofs with different slope but same roofing felt. Both were assessed during the survey.

Figure 2. Example of a dead low-sloped roof with ponding water. Ponding water leads to a risk of reduced service life due to increased exposure of the roof membrane to moisture and freeze-thaw cycles.

Figure 3. Example on different penetrating details normally seen on a roof.

Figure 4. Superficial "cracking" in the bitumen on steep surfaces leads to reduced protection by the granules.

Figure 5. Example of ponding water in a valley. In this case the water remained in the valley almost permanently and, as a consequence, the protective granules were gone.

Flexible Polyolefin Roofing Membranes: 15 Years Of Field Experience

Hans-Rudolf Beer [1]
Anthony Mayr [2]

T 22

ABSTRACT

Flexible polyolefin (FPO/TPO) roofing membranes were introduced in 1991 and have since gained wide acceptance in the European as well as in North American market place. The first TPO test roofs were installed in 1988. Hence in 2008 there are data available looking back on twenty years of field experience. At the occasion of 15 years of experience with installed TPO roofs a European TPO manufacturer has undertaken a field study on the long term behaviour of such products.

The paper presents the results of the constant monitoring of 42 installed roofs aged up to 15 years old. These data are compared with two specific sampling and testing projects carried out on six roofs by a third party testing institute after 10 and 15 years of field exposure, respectively.

Mechanically-attached and gravel-ballasted roofs have been considered. On site roof inspections showed all investigated roofs in good and fully functional conditions. Samples were taken for subsequent laboratory testing. All sample cutting spots could be securely patched by overwelding with new membrane pieces. Laboratory testing included properties such as tensile strength and elongation at break, low temperature flexibility, peel and shear strengths of the welded seams, accompanied by surface examinations using optical and electronic microscopy. No or marginal deterioration of the material properties were found.

The conclusions are that the investigated types of flexible polyolefin roofing membranes will fulfil their waterproofing and protection function for at least several decades.

1 INTRODUCTION

Durability of building materials is – besides aesthetics – the most often discussed topic among building owners and architects. Upon introducing new materials, the subject of service life is of crucial importance. Lacking track records, the extrapolation of accelerated ageing tests data is the only means for meaningful predications on the durability of the new products.

Flexible polyolefins for roof waterproofing have been introduced to the market in 1991. Since then they have gained wide acceptance in the European as well as in the North American market place [Baxter, 1998; Beer, 1995; Beer, 1997; de Palo, 1995, Foley]. The common designation for flexible polyolefins is FPO in Europe, whereas they are named TPO (for thermoplastic polyolefins) in North America. Taking into account the trial phase prior to market introduction more than 15 years of field experience in roofing applications have now been gained with these materials.

When TPO roofing membranes were first introduced in Europe for flat roofs the service life of the product was predicted at several decades. This prediction was supported by manufacturer experience, testing programmes, and a series of field tests which had begun in 1989. Definitive statements on the durability of roofing membranes are only possible on the basis of long-term field investigations. Several such studies on the durability of the first TPO membranes have been conducted.

The most comprehensive study was carried out by Rieche and Wehrle [1999] on behalf of the membrane manufacturer at the occasion of ten years of field experience. The results were presented to the waterproofing community by Beer and Keiser [10]. The overall assessment of these studies was very positive regarding the durability of the manufacturer's TPO roofing membrane.

The fact that the observed deterioration of the material properties was only marginal, supports the previous assumption of a service of several decades.

Having reached 15 years of field experience with TPO membranes the study carried out after 10 years has been repeated. The results of this 15 year update are presented in this paper.

2 METHODOLOGY

The investigation described here is based on a field study of roofing membranes on 42 roofs covered with TPO membranes with fibre glass mat reinforcement (G type) or combined reinforcement of fibre glass mat and polyester scrim (S type). On behalf of the manufacturer the German Institute for Building Protection, Building Materials and Construction Physics [11] examined and evaluated four roofs of various age, taking into consideration the overall evaluation roofs monitored by the manufacturer. Thus a total of 162 samples (Fig. 1) of TPO roofing membranes with ages up to 15 years were collected and examined.

The roof assessment and testing of samples of the four roofs was done by the Institute independently of the manufacturer's surveys, according to the following criteria:

Roof assessments: General condition of roofing, roof assembly, flashings, welded seams, construction technology aspects.

Material samples: Thickness, tensile strength, elongation at break, low-temperature flexibility, peel strength and shearing tensile strength of site-welded seams, and microscopic investigation of the membrane surface.

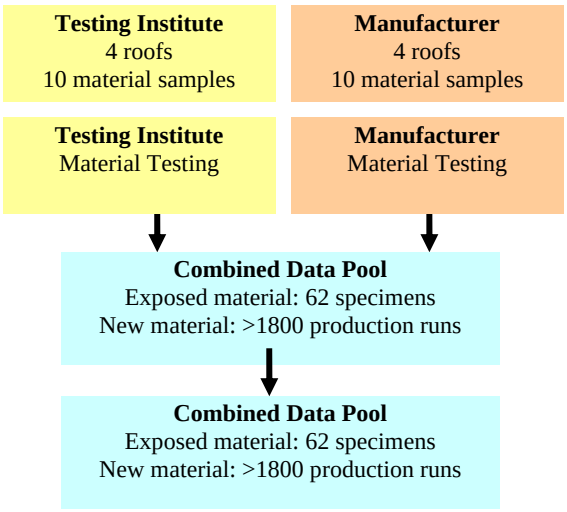

Figure 1. Data structure.

These properties are essential for predicting the durability of polymeric waterproofing membranes. By merging the data of the Institute and the manufacturer the long-term stability and durability of TPO roofing membranes of types G and S can be predicted, supported by a broad base of data and using methods of accelerated artificial weathering. The longer the observation period and the larger the number of investigated roofs, the more reliable the data obtained through field investigation is for predicting service life. A more detailed discussion on providing a forecast in the product and system development phase and subsequent reviews of the forecast in the utilisation phase has been presented by Beer and Keiser (2000).

3 RESULTS

3.1 Roof Assessments

All four examined roofs were found to be in good general condition (Fig. 2). The edge securement (Fig. 2) and the flashings at penetrations such as curbs (Fig. 3) were intact. All seams probed with a screwdriver were tight. All sampling locations (Fig. 4) could be patched without problem by welding using the standard methods described in the installation guidelines.

Figure 2. Two roofs investigated by Rieche [2004]. Left: Gravel ballasted industrial roof at Flawil, Switzerland (a typical application of G-type membranes). Right: Mechanically attached industrial roof at Ehingen, Germany (a typical application of S-type membranes).

Figure 3. Curb flashing detail, industrial building at Ehingen, Germany.

Figure 4. Sampling location on industrial building at Fellbach, Germany.

Comparing with the study conducted in 1999 [9], no changes to the technical or visual condition of the roofs were detected.

3.2 Mechanical Properties

To summarize the characteristics of various polymeric waterproofing membranes in uniform terms, one can express the change of properties over time in relation to the properties of new material. This method was used in this study. Mechanical properties of new material show a range of values, due to certain technical aspects of production and measuring. This distribution of values can be quantified using standard deviation methods. For the graphic display, a confidence interval of 99% was chosen. Of 100 measured values of new material, 99 are within the range of distribution.

If values measured on a sample from an exposed roof are within this confidence interval, the material properties have not changed significantly in comparison with the new condition.

3.2.1 S-type Membranes

Material investigations of S-type membranes showed that the mechanical values for elongation at break and tensile strength even after up to 15 years of exposure lie within the described distribution range for new material. Hence, there is no significant change of properties.

Figure 5 contains representative examples displaying the tensile strength of the S-type membrane specimens.

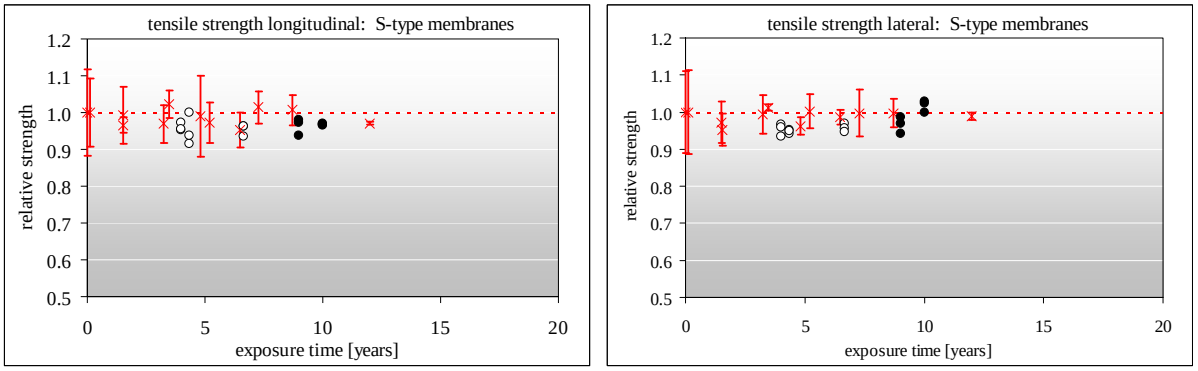

Figure 5. Relative tensile strength of S-type membranes after field exposure.
● data Rieche, 2004, ○ data Rieche, 1999, x manufacturer's continuous roof monitoring data.

3.2.2 G-type Membranes

Measured values of elongation at break for G-type membranes were similar to the results of S-type membranes; there was no significant change over time (Fig. 3: Elongation at break).

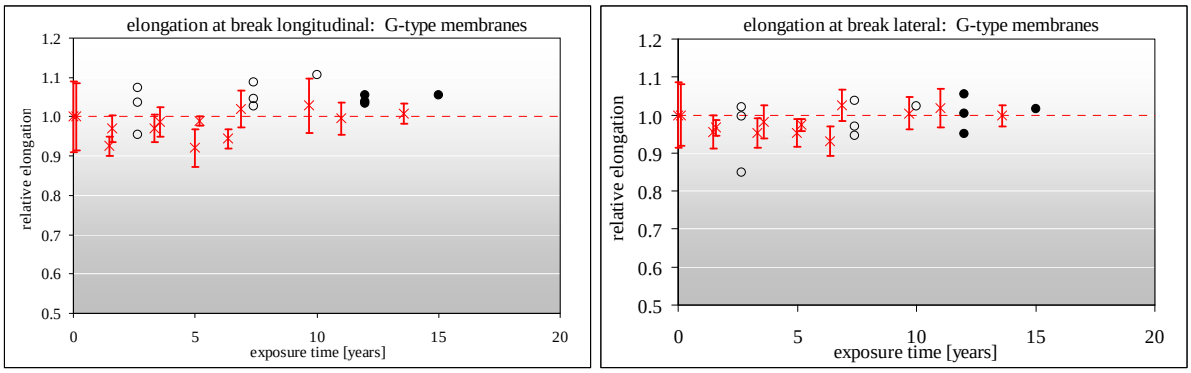

Figure 6. Relative elongation at break of G-type membranes after field exposure.
● data Rieche, 2004, ○ data Rieche, 1999, x manufacturer's
continuous roof monitoring data.

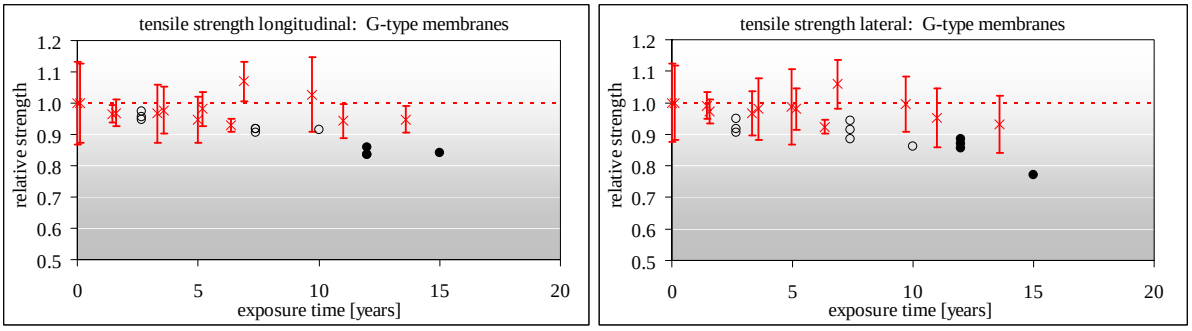

Figure 7. Relative tensile strength of G-type membranes after field exposure.
● data Rieche, 2004, ○ data Rieche, 1999, x manufacturer's
continuous roof monitoring data.

In the study conducted by Rieche [2004] the tensile strength of a G-type membrane showed a drop of 15% in machine direction (longitudinal) and 22% in cross direction (lateral) after 15 years of field exposure (see Fig. 7).

The manufacturer's continuous monitoring of field roofs reveals a decrease in tensile strength of G-type membranes as well, however, to a lower degree than Rieche's [2004] findings.

3.3 Other Properties

The thickness of aged membranes samples was measured according to standard methods (DIN 18531). Only the overall thickness was determined, but not the thickness of different membrane layers. For both G- and S-type membranes no change in material thickness due to exposure on the roof was found (Figure 7).

The low-temperature flexibility test produced no cracks in spite of using a testing temperature more stringent than that prescribed by standards (-35 °C instead of -20 °C) [DIN 18531, 2005], [SIA 280, 1996].

Optical microscope inspection at 30x enlargement showed no surface cracks. Seam strength of field samples was tested in shear mode and peel mode. All welded seams tested tore outside the seam area, as required by standards [DIN 18531, 2005], [SIA 280, 1996].

4 DISCUSSION AND ASSESSMENT OF DURABILITY

4.1 S-type Membranes

S-type membranes are designed for application in mechanically attached roof waterproofing. The prime requirement of these types of membranes is a high tensile strength in order to cope with the mechanical stresses induced by wind uplift forces. The polyester reinforcement scrim provides for the necessary mechanical strength.

Rieche's [2004] investigations of S-type membranes show that the results for specimens from roofs 9 to 10 years old lie within the distribution ranges of results obtained by the manufacturer's internal monitoring, or in other words, within the normal ranges encountered in production. To the extent that a comparison with specimens from that year's production (2004) was possible, the studies also show that after 9 years and 10 years no significant change in mechanical properties had occurred. Thus Rieche's [2004] investigation results confirm the data collected by the manufacturer for roofs up to 12 years old. The 1999 assessment [Rieche and Wehrle 1999] of the durability of S-type membranes (10 years old) is confirmed by the results of the update investigation [Rieche 2004] 5 years later (15 years old).

4.2 G-type Membranes

The roofs investigated with G-type membranes in Rieche's [2004] update study have been exposed for periods of 12 and 15 years. The properties tested, for example elongation at break, showed results similar to those of S-type membranes, i.e. no significant change over time could be detected.

A somewhat different behaviour was found for the G-type membranes' tensile strength: It dropped by 15% (longitudinal) and by 22% (lateral) after 12 years outdoor weathering. Considering the results from 1999, [Rieche and Wehrle] this shows a further reduction of tensile strength in comparison to the reduction during the first 7 and/or 10 years. However, the manufacturer's monitoring data with hundreds of data points indicate only a minor decrease of the G-membranes tensile strength. Most samples between exposure times between 2 and 14 years have tensile strength values whose scatter bands are still within the original values. An explanation for some lower strength data could lie in changes of the crystallinity degree of the polymers. However, a strength reduction by such an effect is not regarded as a damage to

the material since the relevant mechnical property of G-type materials is their elongation, which is virutally unaltered (cf. Fig. 6)

Nevertheless, the Rieche's observation of decreased tensile strength of G-membranes give rise to a deeper examination of the material durability. There are two ways to predict the service life of G-type membranes. The German standard DIN 18531 requires for new materials a value of at least 5 N/mm^2. Model calculations produce a period of time of 24 to 44 years before tensile strength drops to 5 N/mm^2. The requirement for tensile strength of at least 5 N/mm^2 applies to new material. For calculating the service life of G-type membranes the authors consider a requirement of 3 N/mm^2 for tensile strength reasonable and sufficient. Using the same considerations, this requirement of 3 N/mm^2 produces a time period of 40 to 64 years. Therefore all the data would indicate a service life of 40 to over 60 years for G-type membranes. Rieche's 1999 assessment of the durability of G-type membranes (10 years old) is confirmed by the results of this investigation 5 years later (15 years old).

The main application field of G-type membranes is in ballasted conditions, such as gravel or paver ballasted roofs or green roofs. The tensile strength is of far minor importance in these applications. Since all the other measured properties showed no deterioration during up to 15 years exposure duration the slight decrease of the g-type membranes' tensile strength is weighted low.

5 CONCLUSIONS

The studies the Institute for Building Materials [Rieche and Wehrle, 1999 and Rieche, 2004] as well as the manufacturer's continuous monitoring of 106 roofs (Figs. 3-6) support the previous assumption of a service life of the manufacturer's TPO membranes of several decades. The data give evidence that at least 20 years of service life are secured. An extension by one or two decades seems reachable, provided that proper maintenance of the roofs and the membranes are carried out.

ABSTRACT

Cellulose fibre has been used to substitute asbestos on Fibre Reinforced Cement (FRC) roof tiles, despite the fibre's deterioration caused by alkaline atack and intensified by wet-dry cycles resulting in embrittlement of composite. Mould growth is another problem in FRC because of its impact on the aesthetical and thermal performance of components. Mould Growth is largely influenced by the water absorption rates.

This paper investigates the effect of water-repellents on the accelerated aging of asbestos-free fibrecement sheets reinforced with PVA and cellulose fibres, under accelerated wet-dry aging cycles. Laboratory-scale produced fibrecement sheets were treated by foam roller brushing with different concentrations of a water-based silane/siloxane emulsion. After 28 days of curing both treated and untreated samples were submitted to up to 150 wet-dry cycles.

Composite deterioration was measured by water absorption kinetics, mechanical properties (MOR and specific energy) and thermogravimetric analysis (DSC).

The results show that: (i) the aging program causes important reduction in untreated fracture toughness and water intake results, (ii) for the treated samples, the higher the water repellent concentration, the lower the water absorption; (iii) the accelerated aging test did not cause any significant influence on the water repellency performance (iv) the silane/siloxane products prevented toughness degradation by aging and cellulose fibre degradation, (v) there is a correlation between cellulose degradation and fracture toughness.

1 INTRODUCTION

Cellulose fibre has been used to substitute asbestos on Fibre Reinforced Cement (FRC) roof tiles, despite the fibre's mineralization caused by wet-dry cycles resulting in embrittlement of the composite [Gran, 1983]. Mould growth is another problem caused by water absorption and it influences the FRC aesthetical and thermal performance.

Many alternatives has been used to prevent those degradation: a) low alkalinity cement [Savastano Jr 2001; Warden & Coutts 2001); b) pozzolanic addictions; c) increase the matrix carbonation rates [Tolêdo *et al.* 2003]; d) fibres treatment [Lin *et. al.* 1997] and ; e) water repellent products.

The last one, althouth the little information already published, has a potential advantage compared to the others because it could increase the FRC overall performance by reducing the soiling rate, mainly influenced by mould growth.

The water repellents most widely used for FRC are the silicone-based materials (mainly silane and siloxane). These products have good hydrophobic properties (by the apolar radical) and a potential long-term performance due to the Si-O and Si-C bond stability.

There are different ways to introduce the water repellent products in FRC plants. The first one is to treat the cellulose fibres (Abdelmowlett et. al, 2004), with the advantages of protecting only the fibres that show degradation and optimizing water repellent consumption.

The second is to add the water repellent during the mixing of raw materials, which may potentially reduce water absorption rates but may also influence the MOR and the sheet layer adhesion (Selley *et. al.*, 2006).

The third way is to protect the sheet surface as post-treatment application (Selley et. al,. 2006), which is the most used method in other building materials. The main factors that influence this method performance are: (i) application method (spray, paint or dipping), (ii) product concentration, and (iii) application moment (before or after curing).

Comparing the different methods is not easy, mainly because no complete published research has been identified in the literature. For industrial plants, the application as post-treatment is the easiest to put in action but its performance under service conditions is largely influenced by cracks (Lunk; Wittmann, 1998). The other application methods influence the FRC mechanical properties, and modify the flocculation process in the Hatcheck machine, thus requiring further researche before any industrial application.

This paper investigate the performance of one silicone water-repellent product applied as post-treatment in fibre cement sheets before and after accelerated aging.

2 EXPERIMENTAL DESIGN

The research was developed in laboratory. The water repellent performance were evaluated by means of the water absorption rates, modulus of rupture (MOR) and specific energy. In addiction changes in the chemical and mineralogical composition were evaluated using thermogravimetric analysis.

2.1 Materials and Specimens Preparation

Table 1 presents the main raw materials properties as well as the formulation of the composite used in the experiment. The formulation is similar to the commonly used for fibercement production and includes an ordinary Portland cement, densified silica fume, limestone filler, short bleached cellulose fibre and 6.0millimiters leght PVA fibres.

The following steps were used to produce the specimens: 1-mixing the raw materials and water to produce the pulp (Table 1) using a solid/water ratio of 0.20; 2-applying vacuum (300mmHg for two minutes); 3-compression using 3.2MPa dead load for one minute; 4-curing in a ventilated oven at 65^0C and 90%RH for 18 hours; 5-applying the water repellent as post-treatment; 6- curing in a plastic bag for 28 days; 7-cutting the specimens in the dimension 16 cm x 3.7 cm x 0.5 cm; 8- sealing the borders using liquid rubber; 9 - drying in an oven at 65^0C and 50% RH for two days.

The water repellent product used in the experiment was a silane/siloxane emulsion (table 2). It was used three different dilution rates: 3%, 5% and 10%. All of them based on the water weight. The first and the last concentration are the lowest and the highest recommended by the manufacturer. The untreated specimens were used as reference.

The hydrophobic agent was applied after curing using a foam roller in two coatings. After the application the specimens were cured in a plastic bag for 28 days.

Table 1. Properties of raw materials and formulation used in the research.

Materials	Density (g/cm^3)	BET Surface area (m^2/g)	Fraction (w/w%)
Portland cement	2.97	1.43	70.2
Limestone filler	2.69	1.50	20.0
Silica fume	2.18	18.18	5.0
Cellulose fibres	1.56	---	3.0
PVA fibres	1.35	---	1.8

Table 2. Properties of water repellent used in the experiments.

Active content	40 %
Color	Milky white
Density	1.01 g/cc
pH	6 to 8
Shelf life	720 days
Volatile organic content	< 200 g/L

2.2 Test Methods

Accelerated aging was performed in a laboratory at USP (University of São Paulo), in an automatic machine. Specimens were submitted to 150 wet-dry cycles, each of then lasting six hours: 2 hours and 50 minutes wetting, 2 hours and 50 minutes drying at 70^0C with a 10minute interval between these steps. During the cycles only one side of the specimens was wetted.

Water absorption was measured by immersion test in five different moments: after 30 seconds, 60 seconds, 3 minutes, 1 hour and 24 hours.

The modulus of rupture (MOR) and specific fracture energy were measured in an Instron Universal Machine 5569, with a load cell unit of 1kN. It consists in a four-point bending test, with 13.5cm bending spans, a load distance point of 5.0cm. Displacement ratio was controlled (5 mm/min) and deflection measured with a LVDT positioned under the specimens in the middle of the span. For each concentration of water repellent and reference a minimum of 5 specimens were evaluated.

Thermogravimetric analysis (TG) was conducted with a NETZSCH STA409PG on a 1.0 g sample mass in a nitrogen atmosphere (flow ratio = 60 ml/min), with a heating rate of 10°C/min from 10°C to 1000°C. Prior to the test, the specimens were first deep frozen in liquid nitrogen and then lyophilized for 16 hours to sublimate the absorbed water.

3 RESULTS AND DISCUSSION

3.1 Water Absorption

Figure 1 shows the water absorption results before and after aging. Continuous lines represent unaged specimens, while the dashed lines represent aged specimens. The higher the water repelant concentration the lower is the water absorption, for both aged and unaged samples.

Ageing caused a 23% of water absorption reduction (after 24h of immersion) for the untreated samples. This probably is a combined effect of increase of both, degree of hydration and carbonation [Dias 2005; Tonoli et al. 2006].

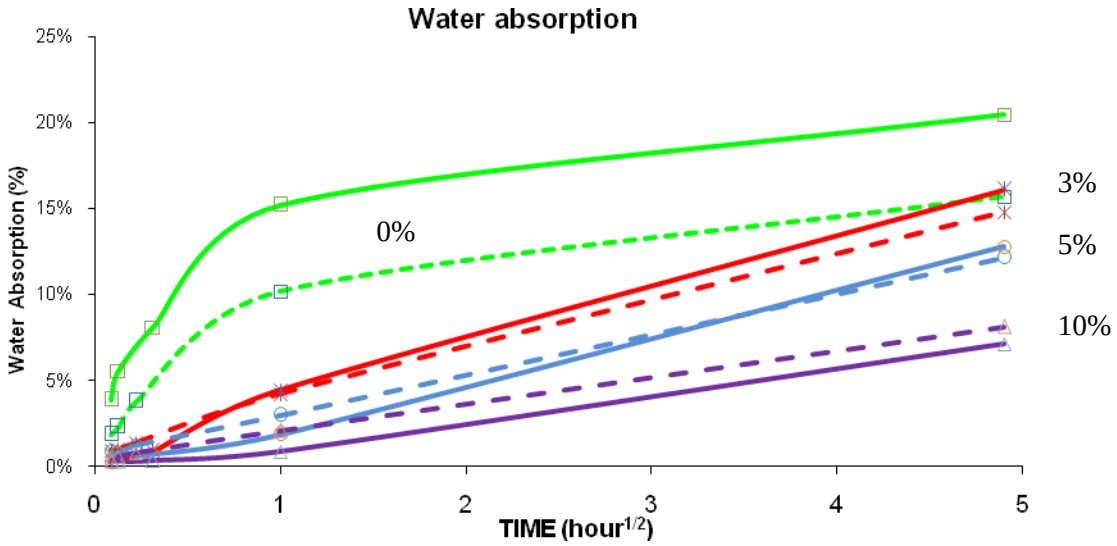

Figure 1. Water absorption kinetics before and after accelerated aging. Continuous line = unaged, dashed line = aged.

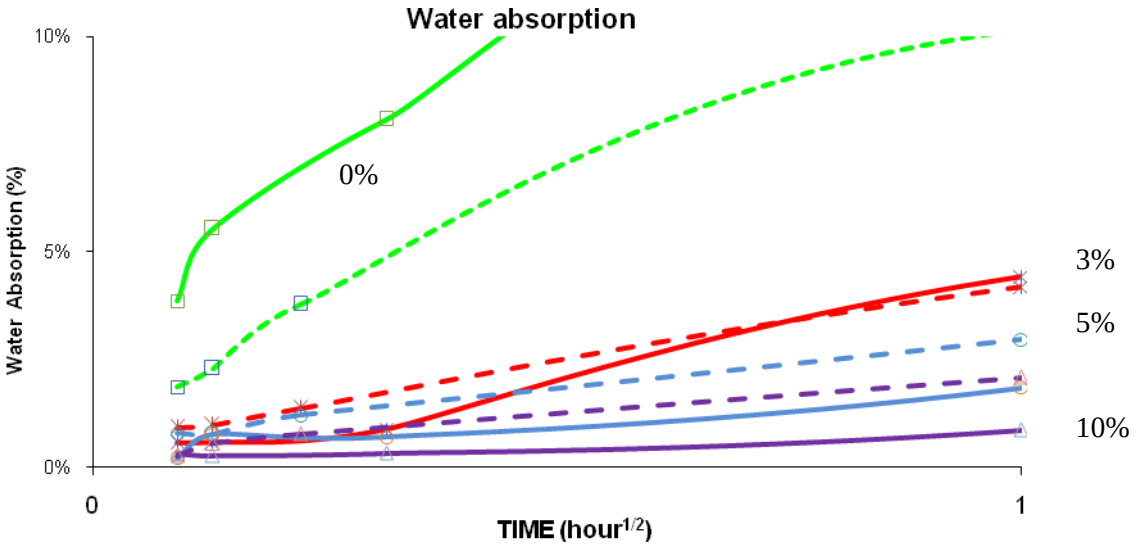

Figure 2. Water absorption kinetics along the first hour before and after accelerated aging. Continuous line= unaged, dashed line = aged.

For the treated samples, for all concentrations tested, artificial ageing showed only a slight influence on water absortion at 24 h. However, for shorter periods of immersion the aged treated specimens showed higher water absorption (Figure 2) than unaged ones. For instance, on the concentration of

10%, ageing caused water absorption to increase around 150% over unaged ones. This is problaly caused be an superficial degradation of the water repellent or composite cracking that enable water penetration.

3.2 Mechanical Properties

Figure 3 and Figure 4 show the MOR results. Figure 5 presents the typical curves for the highest water repellent concentration and for the reference (0%). The MOR of untreated samples was not influenced by accelerated aging (figure 4), while fracture toughness was reduced by around 70% (Figure 5). This conclusion and the absolut values are in accordance with other authors when a similar PVA fibre content was used [Dias, 2005; Caldas e Silva, 2002] and caused by cellulose sibre degradation by artificial ageing. This degradation cause the fibers to break during bending, therefore reducing fracture toughness. Another problem is the fibre mineralization (John et. al. 2005).

For the treated samples, on the other hand, aging caused reduction of MOR. The explanation of this unexpected result is not clear. One possibility is the reduction in water intake limited the increase the degree of hydration. In consequence, for samples with water repellant the increase of hydration wasn't enougth to counteract the other degradation mechanisms. By the other side, water repellant treatment was efficient to prevent fracture toughness reduction during ageing (Figure 5) because it protected fibers from degradation.

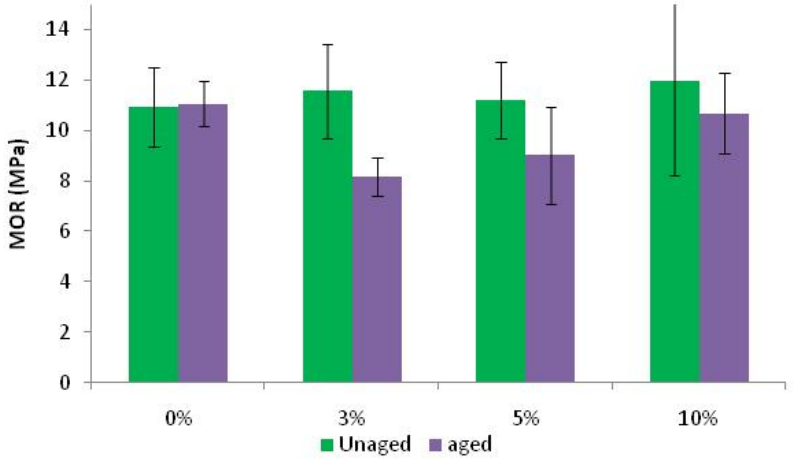

Figure 3. MOR results.

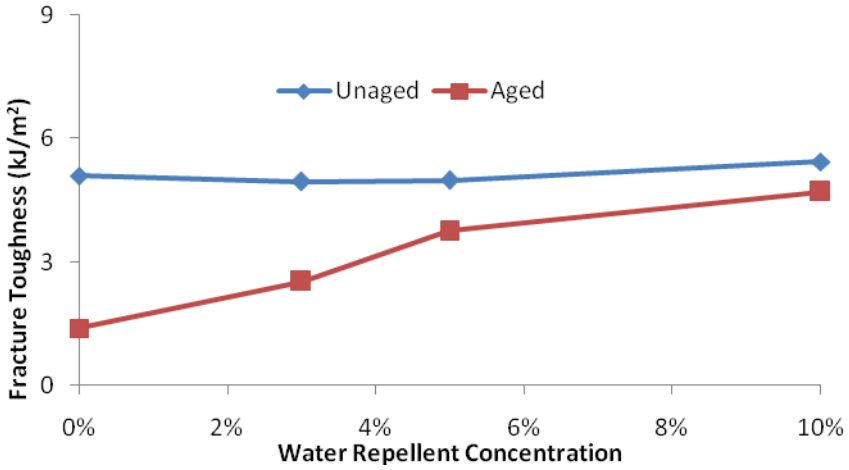

Figure 4. Fracture Toughness results.

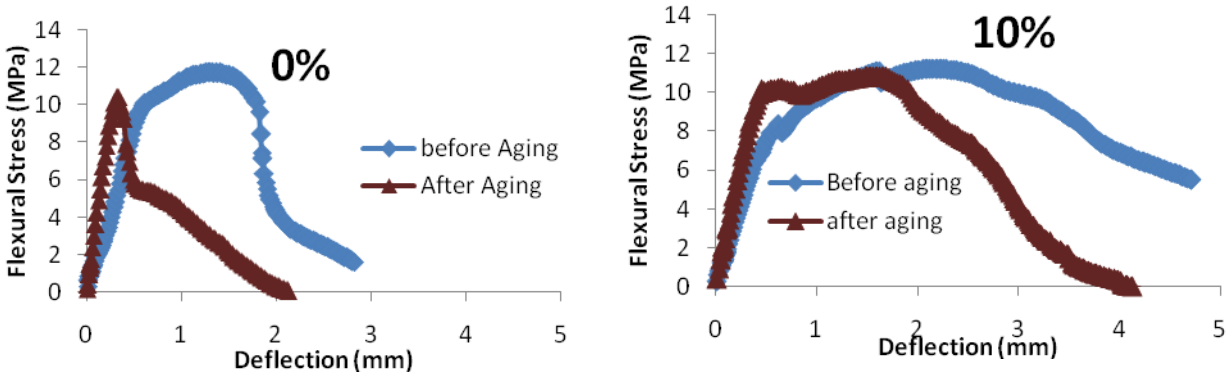

Figure 5. Typical curves of flexural stress versus deflection.

3.2 Thermogravimetric Analysis

In Figures 6 and 7 the thermal analysis results are presented. For the untreated samples (0%) ageing increased the CSH content and decreased the cellulose fibre peak. For the treated samples (10%) ageing increased the first carbonate peak and decreased Ca(OH)2. Comparing the thermal analysis results, it is clear that the water repellent treatment reduced cellulose fibre degradation and the matrix hydration. Figure 8 plots fracture toughness after aging and the cellulose fibre peak intensity ratio before and after aging as identified by the thermal analysis. The higher is this ratio (based in the composite non-volatil content) the higher is the cellulose mass loss intensity after aging compared to the unaged ones. The results shows an important correlation. However other researchers such as Dias (2005) did not identify differences in the cellulose peak by accelerated and natural aging, this must be confirmed by futher investigation.

CONCLUSIONS

The results show that: (i) the aging program causes an important reduction in the untreated samples' fracture toughness and water intake results; (ii) for the treated samples, the higher the water repellent concentration, the lower the water absorption; (iii) the accelerated aging test did not cause any significant influence on the water repellency performance; (iv) the silane/siloxane product prevents cellulose fibre degradation and toughness degradation by aging; (v) there is a correlation between cellulose degradation and fracture toughness.

ABSTRACT

In this work we study the effects of wet and dry cycles on the performance of asbestos-free fiber cement. Two accelerated ageing methods are analyzed, including the heat-rain ISO standard test and up to 500 scaled-down wet and dry cycles. Four-point bending tests were performed to evaluate the modulus of rupture (MOR), limit of proportionality (LOP), modulus of elasticity (MOE) and specific fracture energy of specimens. SEM with EDS analysis and mercury intrusion porosimetry (MIP) were used to evaluate the ageing effects on the microstructure. The results show that the effect of the heat-rain test and scaled-down wet and dry cycles on the mechanical performance of fiber cement results from a balance of positive and negative effects. Embrittlement of the composite was the main effect in both ageing tests as a result of cellulose fiber deterioration and enhancement of the bond between PVA fibers and the cementitious matrix.

1 INTRODUCTION

The introduction of asbestos-free fiber cement technology is relatively recent in developing countries, including Brazil, where fiber cement industries have used poly (vinyl alcohol) (PVA) or polypropylene fibers combined with cellulose fibers in the manufacture of building components.

Durability is an important parameter when developing and producing fiber cement components, because the expected service life of such products is usually high. Therefore a set of accelerated ageing tests has been developed to help to forecast long-term performance. Most of these tests are variations of wet and dry cycling or of carbonation combined with wet and dry cycling. ISO 9933 [ISO 1995], adopted in many countries, recommends 25 cycles of heat and rain test (or wet and dry test) on full-scale 10 m² samples. Many other small-scale wet and dry cycles have been used in several studies [Mohr et al. 2005; Mohr et al. 2006; Gram 1988; Agopyan 1991; Soroushian & Marikunte 1992] in which most researchers adopt modulus of rupture (MOR) and fracture toughness as deterioration indicators. Despite the fact that ISO 9933 controls only watertightness and the occurrence of visible cracking, variations in mechanical strength and fracture toughness are also relevant for such products. No work has been published so far comparing different accelerated ageing methods. Moreover, the number of wet-and-dry cycles deserves investigation.

In this paper we present two case studies. In the first case, full-scale industrially produced corrugated sheets available in the Brazilian market were submitted to heat-rain ISO 9933 test [ISO 1995]. These roof sheets were evaluated before and after 25 wet and dry cycles. In the second case, laboratory-produced fiber cement specimens were submitted to up to 500 scaled-down accelerated wet and dry cycles. In both case studies, the effects on microstructure and mechanical performance were evaluated.

2 EXPERIMENT

Results of a full-scale 10 m² roof submitted to ISO 9933 ageing heat-and-rain test were compared with those obtained with a scaled-down wet and dry test (up to 500 cycles). The corrugated sheets used in the ISO 9933 test were produced via Hatscheck method and presented a similar composition, except for the limestone content, to that of the laboratory-produced samples used in the wet and dry test (Table 1). Variation in LOP, MOE, MOR, fracture toughness and microstructure, due to accelerated ageing tests, were measured in selected samples.

2.1 Heat-Rain ISO Test on Asbestos-Free Industrial-Scale Produced Corrugated Sheets

The heat-rain ISO 9933 consists in submitting a 10 m² assembled 15° ± 5° sloped roof to twenty-five (25) wet and dry cycles. Rain is simulated by a water outflow of (2.5 ± 0.5) L/(min.m²) for 2 h and 50 min. Drying is performed by infra-red (IR) lamps capable of maintaining a surface temperature (black body) of (70 ± 5)°C for 2 h and 50 min. Between each heat and rain step there is an interval of ten (10) minutes, totalizing 6 h/cycle.

The roof used in the test was constituted of nine entire corrugated sheets with 6 mm nominal thickness, 1.10 m width and 1.20 m length, approximately 60 days after production. The standards require the examination of the roof for cracking, delamination, and other visible effects.

In addition to the ISO 9933 requirements, microstructure and mechanical performance were also characterized. For the mechanical tests, low-dimension specimens with approximately 35 mm width and 160 mm length were extracted from the straight regions of the corrugated sheets using a water-cooled rotary saw.

2.2 Wet and Dry Cycles on Asbestos-Free Laboratory-Produced Fiber Cement

This study was performed to evaluate the effects of up to 500 accelerated wet and dry cycles on the microstructure and mechanical performance of laboratory-produced asbestos-free specimens. The employed materials, formulations, and the methodology for the characterization of microstructure and mechanical performance are described below.

2.2.1 Materials, Formulation, and Preparation of Specimens

Table 1 presents the materials and the formulation that were used to prepare the specimens. Densified silica fume, ordinary Portland cement and limestone filler from the Brazilian market were also employed. Six-millimeter length PVA fibers and long unbleached cellulose fibers (average length of 1.24 mm) were employed as reinforcement. In this formulation, the cellulose volume fraction is 8.5% and the PVA volume fraction is 4.2%. The group of laboratory-produced specimens was labeled PVA_2.0%.

Fiber cement pads (~5 x 200 x 200 mm³) were laboratory-produced by using slurry vacuum dewatering method [Savastano Jr. et al. 2005]. Immediately after preparation, each green pad was pressed at 3.2 MPa for 5 min. Next, these sheets were maintained in plastic bags for one day, soaked in water for 5 days, and air-cured for up to 28 days. Low-dimension specimens with 40 mm width and 160 mm length were extracted from the pads using a water-cooled rotary saw. These specimens were submitted to the mechanical tests before and after the ageing tests.

Table 1. Materials and formulation of PVA_2.0%.

Materials	Portland cement	Limestone filler	Silica fume	PVA fibers	Cellulose fibers
Dry mass fraction (%)	75.20	12.72	6.08	2.0	4.0

2.2.2 Scaled-down Wet and Dry Cycles

Up to 500 scaled-down accelerated wet and dry cycles were performed with low-dimension specimens in automatic equipment. Fig. 1 shows a schematic drawing of the equipment. Wetting and drying times were similar to those previously described for the heat-rain test.

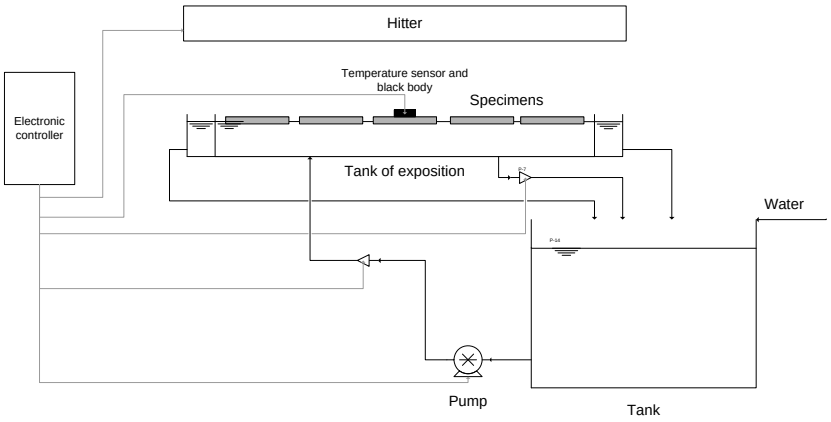

Figure 1. Schematic drawing of wet and dry cycle equipment.

2.3 Evaluation of Ageing Effects

The ageing effects were evaluated by microstructural analysis and mechanical tests. A high-vacuum LEO Leika S440 microscope with an acceleration voltage of 20 kV and current of 150 mA was used to examine a fractured section and a polished cross-section of the specimens. Samples for evaluation by secondary electron image (SEI) and backscattering electron image analysis (BSEI) were vacuum

(200 mbar) impregnated with epoxy resin and air cured for 24 h before grinding with silicon carbide and polishing with diamond paste (3, 1 and 1/4 mm grain size respectively). All samples received carbon coating before examination.

MIP tests were carried out using a Micromeritics Auto Pore III. For each treatment, three randomly selected 1 g specimens were cut with a precision rotary disk saw, subsequently dried at 70 + 5 °C with -60 kPa vacuum pressure and finally submitted to evaluation. The Washburn equation with a contact angle of 130° and mercury superficial tension of 0.485 N/m was employed to assess the pore size distribution.

Four-point bending tests were conducted with an INSTRON 5569 using bending span of 135 mm. Displacement ratio was controlled (1.5 mm/min) and deflection was measured with an LVDT positioned under the specimens in the middle of the span. Modulus of rupture (MOR), limit of proportionality (LOP), modulus of elasticity (MOE) and specific fracture energy of specimens were evaluated. All specimens, 15 specimens/group, were soaked in water for 24 h before the bending tests.

3 RESULTS AND DISCUSSIONS

3.1 Microstructural Changes

Accelerated ageing reduced the porosity of all samples. Significant reduction in porosity, from 30.7 to 27.5%, was observed in the corrugated sheet specimens that were submitted to heat-rain cycles. A similar effect was observed in laboratory-produced specimens (Fig. 2a), which presented lower porosity than corrugated sheets.

Fig. 2b shows that the reduction in porosity of corrugated sheets was expressive in the diameter range lower than 100 nm and higher than 10,000 nm. The large pores (>10,000 nm) are manufacturing defects and their volume is significantly higher than that observed in the laboratory-produced samples. Porosity reduction is a characteristic effect of hydration and matrix carbonation [Bier et al. 1987; Matsusato et al. 1992]. Both hydration and carbonation are positive effects that help to improve the mechanical strength of the composite matrix. However, they also cause densification of interface zones between fibers and matrix, thus resulting in embrittlement of the composite [Bentur and Mindess 1990].

The peak between 100 nm and 10,000 nm, present in all samples, is typical of fiber cement formulations that have cellulose fibers in their composition and it is probably associated with cellulose fiber lumens and with the fibers-matrix interface. This peak varied slightly with heat-rain cycles, as shown in Fig. 2.Wet and dry cycles also changed significantly the pore size distribution of laboratory-produced composites in a similar way to what was observed in corrugated sheets, except for the increase in the volume of pores with diameter lower than 10 nm (pore refinement) (Fig. 2c). Pore refinement is related with C-S-H formation by matrix hydration and by pozzolanic reaction.

In both cases a reduction in porosity was expected within the diameter range corresponding to the cellulose pores, as a result of the filling of cellulose lumens with cement products [Bentur & Akers 1989]. However, in both samples, the pore size distribution presented minor changes within this range after accelerated ageing.

Therefore, it is reasonable to suppose that wetting and drying times influence the filling rate of cellulose lumens.

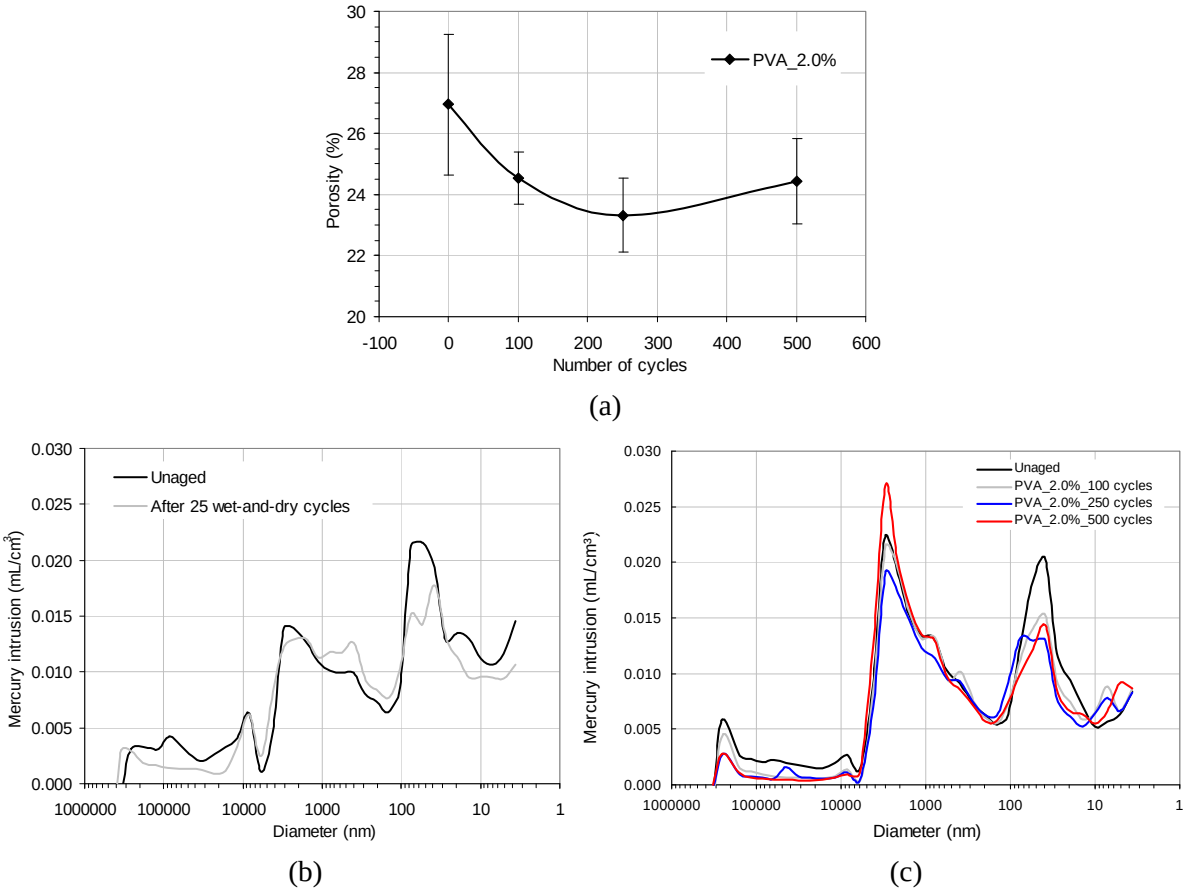

Figure 2. Porosity and pore size distribution of asbestos-free fiber cement corrugated sheets: a) porosity of specimens PVA_2.0%; b) small samples extracted from corrugated sheets and c) laboratory scale-produced specimens.

Images obtained by SEM of fracture and polished sections of laboratory-produced specimens show that, in the unaged PVA_2.0% samples (Fig. 3a), the fibers are predominantly pulled out of the matrix during the fracture process. However, accelerated aged samples presented predominantly broken cellulose fibers during fracture (Fig. 3b), which is a result of cellulose fiber degradation and interface densification. As a result, the composite suffered significant embrittllement. In addition, accelerated ageing did not fill the lumens of cellulose fibers.

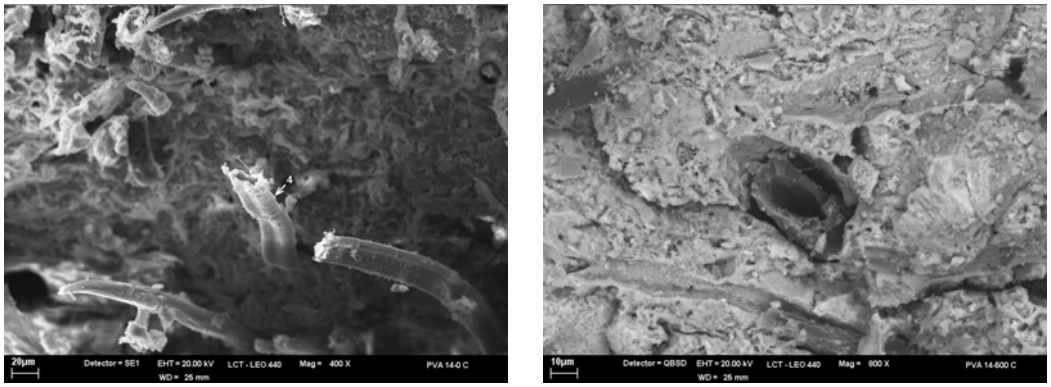

Figure 3. Images obtained by SEM of fracture and polished sections of laboratory-produced specimens: a) unaged and b) after 500 wet and dry cycles.

PVA fibers did not appear to undergo significant deterioration in the composites after wet and dry cycles and interface densification probably did not increase the pull-out force above the mechanical strength of the fibers, so they were predominantly pulled out both in aged and unaged specimens.

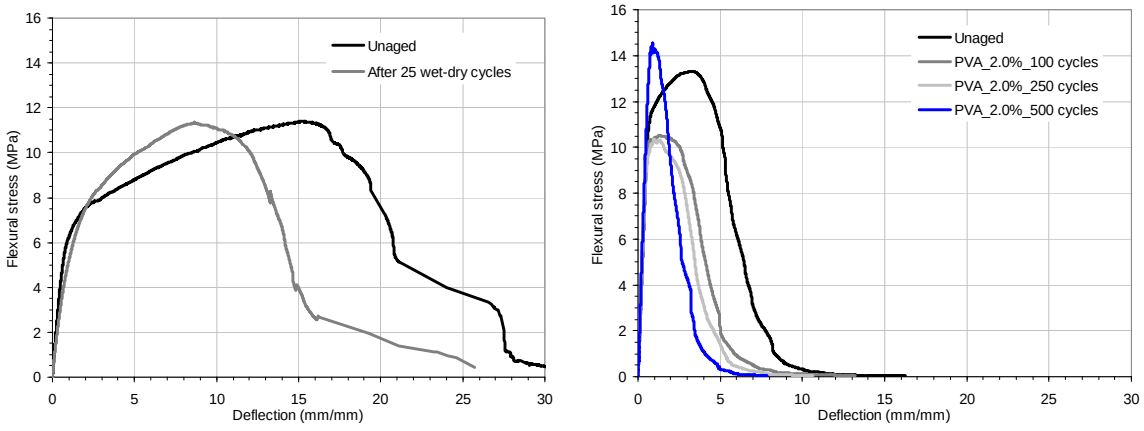
3.2 Effect of Ageing on Mechanical Properties

Fig. 4 shows the flexural stress versus deflection curves of both aged and unaged specimens and Table 2 summarizes their properties. Statistical analysis of data showed that, for the small specimens of corrugated sheets, embrittlement was the single significant effect (significance level of 0.05) of heat-rain cycles on the mechanical performance of the composite. Embrittlement means loss of toughness, which is proportional to the area under the flexural stress versus deflection curves. Both fiber deterioration and densification of the interface zone between fibers and matrix lead to the increase in the occurrence of fiber rupture instead of pull-out during the process of composite fracture, resulting in a decrease in the energy necessary to fracture the material [Bentur and Akers 1989].

The slope of the flexural stress versus deflection curve after the first crack on small specimens of corrugated sheets increased with heat-rain cycles, indicating the densification of the interface zone (Fig. 4a). Limited densification of the interface zone between PVA fibers and the matrix is a positive effect for MOR (maximum flexural stress). Cellulose fiber deterioration, on the other hand, contributes negatively to the mechanical strength. The balance of positive and negative effects can explain the maintenance of the modulus of rupture of small samples extracted from corrugated sheets.

Fig. 4b shows the flexural stress versus deflection curves of laboratory-produced specimens. The results show that MOR and specific energy are significantly changed after the first cycles, probably due to cellulose deterioration and deterioration of the interface zone. After 250 cycles the balance between the positive PVA fiber interface densification and the negative effect of cellulose degradation results in an increase in MOR. Thermogravimetric analysis showed that hydration, instead of matrix carbonation, predominated on the laboratory-produced specimens. In contrast, carbonation predominated on corrugated sheet specimens.

Results show that degradation is dependent on the number of cycles, and the exposure to a number of cycles above the ISO 9933 determination yields additional information. The large difference of toughness between laboratory and industrial products is at least partially due to fiber orientation on the Hatschek machines.



(a) (b)

Figure 4. Typical flexural stress – deflection curves of aged and unaged asbestos-free fiber cement: a) specimens extracted from corrugated roof sheets before and after ISO 9933 test (left) and b) laboratory-produced samples before and after up to 500 wet and dry cycles.

Table 2. Mechanical properties of industrially produced asbestos-free fiber cement small samples.

Properties	Unaged	25 heat-rain cycles
LOP (MPa)	5.6 ± 0.8*	6.6 ± 1.5
MOR (MPa)	11.7 ± 0.9	12.1 ± 1.1
MOE (GPa)	9.1 ± 2.1	6.8 ± 3.3
Specific fracture energy (kJ/m²)	6.8 ± 1.1	4.5 ± 1.1

* Average ± standard deviation.

Table 3. Mechanical properties of laboratory-produced asbestos-free fiber cement small samples.

Properties	Unaged	100 cycles	250 cycles	500 cycles
LOP (MPa)	9.29 ± 1.5*	9.4 ± 1.2	9.10 ± 1.47	13.8 ± 2.91
MOR (MPa)	13.8 ± 1.4	11.1 ± 0.9	10.6 ± 0.9	15.6 ± 2.4
MOE (GPa)	13.6 ± 1.5	14.6 ± 1.8	15.7 ± 1.3	15.8 ± 1.5
Specific fracture energy (kJ/m²)	2.8 ± 0.5	1.64 ± 0.6	1.4 ± 0.4	1.22 ± 0.2

* Average ± standard deviation.

3.3 Visual Inspetion

The samples did not present any visible damage in the performed tests. This was confirmed by many other full-scale heat and rain tests conducted by the team.

4 CONCLUSIONS

Changes in porosity and pore size distribution were evidenced after wet and dry cycles. Fiber cement porosity decreased after wet and dry cycles and this is mainly related with hydration and matrix carbonation. The effect of heat-rain and scaled-down wet and dry cycles on the mechanical performance of fiber cement is a result of a balance of positive and negative effects. Accelerated wet and dry cycles promoted significant changes in the mechanical properties of asbestos-free fiber cement and the main effect was embritlement of the composite. The number of wet and dry cycles influences degradation and there is an interest to increase this number above the minimum requirement specified by ISO 9933.

Polyolefin Roof Membranes on Site Durability Evaluation

Sergio Croce [1]
Matteo Fiori [2]

T 22

ABSTRACT

Thermoplastic polyolefins are a new generation of single-ply roofing. Polyolefin roof membranes were introduced to the international markets already from 1991 with the North American designation as TPO (Thermoplastic Polyolefins) or with the European as FPO (Flexible Polyolefins). Flexibility of such membranes depends on internal chemical structure: unlike other thermoplastic membranes, they do not contain plasticizers. This fact provides the membranes with the property of a pronounced longevity.

A special type of polyolefin is represented by TPO-FPA (Flexible Polypropylene Alloy), obtained from polypropylene semi-crystalline matrix (PP), in which is incorporated an high percentage of ethylene-propylene rubber (EPR), through a patented catalloy process. The aim of this paper is to present the results of a research commissioned by a company manufacturer, oriented to estimate the durability and the residual properties of TPO-FPA non-reinforced membranes, exposed in different latitudes directly to the solar radiation after 5/10 exposition year.

1 INTRODUCTION

Polyolefin membranes were introduced in Europe around 15 years ago. This time is sufficient to study their behaviour over time and therefore their reliability. The objective of the study was to check whether the main functional features of a mechanically-attached, polyolefin non-reinforced synthetic membrane are maintained.

The study was conducted by inspecting three flat roofs located in sites with different sun exposure and temperatures, by means of laboratory tests on samples taken in field. In the cases of Bourges (France) and Cordoba (Spain), the membrane had been laid more than 10 years before the inspection, in the case of Wattrelos (France) the membrane had been laid around 5 years before the inspection.

For the purposes of the study, the behaviour of membranes directly exposed to sunrays (UV) was compared with that regarding membranes in non-exposed areas (Fig.2). The data were then compared with those mentioned in the product technical specifications issued at the time of membrane production.

2 POLYOLEFINS

Polyolefins represent a large family of thermoplastic polymers. They can be formed by olefin monomers of the same type, such as, for example ethylene or propylene (homopolymer polyolefins) or result from a chain of monomers having different nature (copolymer polyolefins). In the case of polypropylene-based polyolefins (TPO-PP), like whose on which the experiment was carried out, materials have now become established which are generated by means of innovative polymerization processes: these are essentially ethylene-propylene copolymers that, upturning the conventional distinction between different homopolymers and their relevant packages of proprieties and performances, go beyond the behaviour profiles of the original polypropylene or polyethylene, somehow combining their features in one single polymer alloy whose architecture is directly obtained in the reactor. Precisely because of their structure, polypropylene-based membranes feature better hot mechanical properties in hot exposition: this is particularly important when membranes are applied on exposed roofs, without protection and with mechanical fasteners. Besides this, unlike polyethylene-based membranes, polypropylene based membranes can also be used without reinforcement.

3 INSPECTIONS

The inspections were performed on roofs located in Cordoba (Spain), Bourges (France) and Wattrelos (France). Eight samples were taken from each of the roofs, two with a size of 80x80 cm and six, with a size of 8x20 cm, on the overlaps. The areas where the samples were taken were repaired by means of new material, working on the inner side of the membrane without any welding problems. Inspections were performed in 2004 and 2005.

Table 1. Summary table of the main features of the analyzed roofs.

Description	*Bourges (France)*	*Cordoba (Spain)*	*Wattrelos (France)*
Type of building	industrial	industrial	industrial
Roof area	8800 m2	25000 m2	10000 m2
Year when the sealing membrane was laid	1994	1994	2000
Face thickness sealing membrane	1.2	1.14	1.2
Type of climate	Continental	Mediterranean	Continental
Latitude	47.50 N	37.53 N	50.42 N

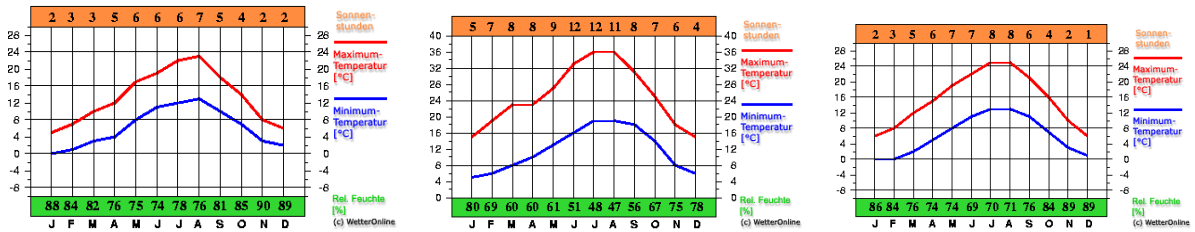

Figure 1. Average minimum and maximum temperatures in Bourges, Cordoba, Wattrelos.(Source WetterOnline).

4 IN SITU INSPECTIONS

Inspections were carried out on three flat roofs located in three different sites.

4.1 In situ Inspection of The Roof in Bourges (France)

The size of the roof is approx. 8800 m2 and it is characterized by six pitches, with little slope. The roof was re-built in 1994, with the presence of reliefs and skylights. Before it was rebuilt in 1994, the roof had been waterproofed by means of a bitumen membrane self-protected by aluminium foil. The waterproof membrane is of the polyolefin type with a polypropylene base, nominal thickness 1.2 mm, ply width of 1 m, homogeneous, fixed on the support by means of mechanical fasteners on the overlaps (Fig. 4); the distance between the fasteners is variable (16-20 cm). The membrane is laid crosswise with respect to the slope. No particular signs of decay were detected after a careful inspection of the waterproof membrane. The joints on the overlaps appeared efficient. No corrugations were detected on flat areas or on reliefs.

Fig. 1. General view

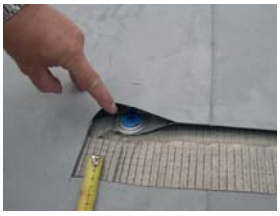

Fig.2. Non- exposed area

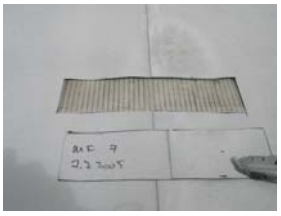

Fig.3. Sample extraction

Fig.4. Repair area

4.2 In situ Inspection of The Roof in Cordoba (Spain)

The size of the roof is approx. 25000 m2 and it was built in 1994. There are skylights and construction joints. The sealing membrane is of the polyolefin type, two-colours, nominal thickness 1.2 mm (required 1.14 mm on US standard), homogeneous, and is fixed to the support by means of mechanical fasteners in line on the overlaps; the distance between the fasteners is variable (16-20cm).

Fig.5. General wiev

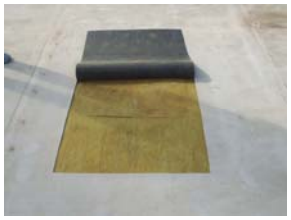

Fig.6. Sample extraction

Fig.7. Sample extractio in overlapping area

Fig.8. Non-exposed areas

No particular signs of decay were detected after a careful inspection of the waterproof membrane. The joints on the overlaps appeared efficient. No significant corrugations were detected on the flat areas or on overlaps and reliefs.

4.3 In situ Inspection of The Roof in Wattrelos (France)

The size of the roof is approx. 10000 m″. The roof is characterized by various pitches, each with a slope of around 25%. There are many skylights and system terminals. Water is collected on the roof flashings. The water is discharged through spouts at the ends of the flashings. The sealing membrane is fixed on the support along the overlaps at a distance of approx. 30 cm. The width of the plies is 210 cm. The nominal thickness of the membrane is 1.2 mm. The roof was rebuilt in 2000.

Fig.9. Skylight

Fig.10. General view

Fig.11. Old membrane before the renovation

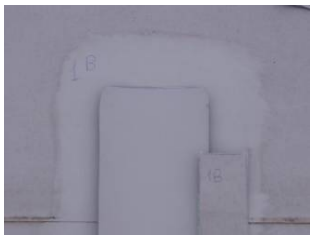

Fig. 12. Repair area

No particular signs of decay were detected after a careful inspection of the waterproof membrane. The joints on the overlaps appeared efficient. No corrugations were detected on flat areas or on reliefs.

5 ANALYSIS OF THE RESULTS OF LABORATORY TESTS

The samples were subject to experimental tests shown in Table 2. The table summarizes the results.

Table 2. Summary table of the features analysed.

Standard of reference	Results of the experimental tests
Thickness (UNI EN 1849-2)	The samples analyzed show a very similar behaviour. In all cases, there is an extremely low change in thickness, equal to maximum 5% between the area exposed and the area not exposed to sun radiation. This value is however comparable to membrane production tolerance, equal to 5%.
Crosswise and longitudinal tensile strength (UNI EN 12311-2, B Method: handlebar test strip)	Values obtained from the experimental test were similar to nominal values, without significant differences between exposed and unexposed samples.
Elongation (UNI EN 12311-2, B Method: handlebar test strip)	Values obtained from the experimental test were similar to, and sometimes higher than, the nominal value, without significant differences between exposed and unexposed samples.
Foldability at low temperature (UNI EN 495-5)	All tests performed, at a temperature of –30°C, had a positive outcome, without indications of damage or cracks.
Peel resistence of joints (UNI EN 12316-2)	Values obtained from the experimental tests were similar to or higher than nominal values.
Resistence to tearing (UNI EN 12310-1 and UNI EN 12310-2)	Values obtained from the experimental tests were similar to or higher than nominal values.
Dimensional stability (UNI EN 1107-2)	Tests performed, with an accuracy of 0.1 mm, proved that dimentional stability did not change over time.

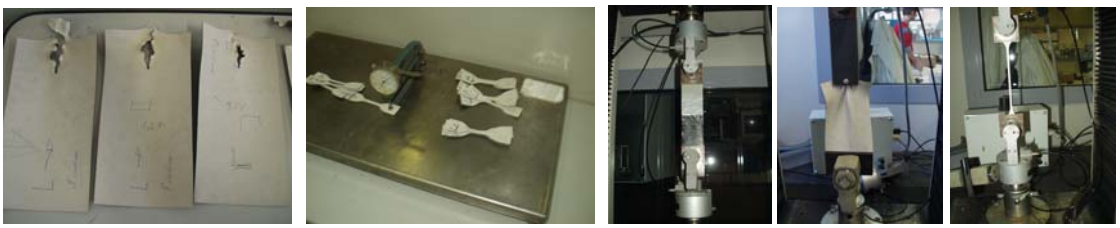

Figure 13. Pictures of laboratory tests.

Specifically, below are the diagrams of the results of the main experimental tests broken down by site. The values of the technical specifications at the moment of production are compared with the current values for the exposed and protected samples – and therefore not directly exposed to sun radiation.

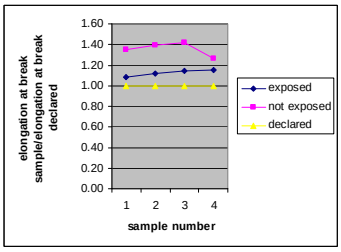
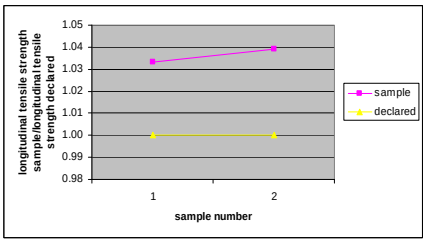
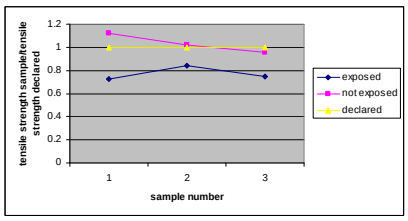


Graphic 2. Crosswise elongation at break

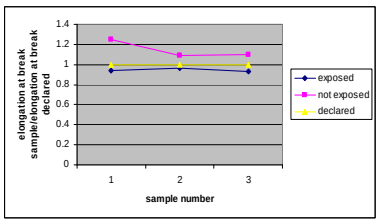


Graphic 3. Longitudinal tensile strength

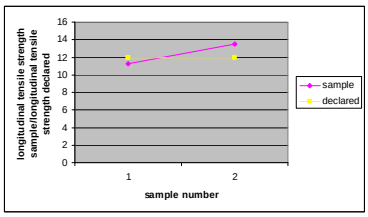
Cordoba (Sp)



Graphic 4. Crosswise tensile strength

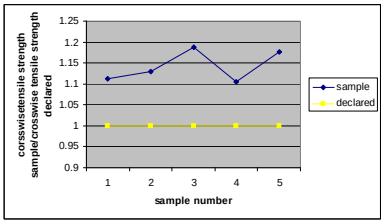


Graphic 5. Crosswise elongation at break

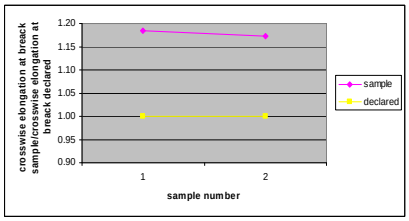


Graphic 6. Longitudinal tensile strength

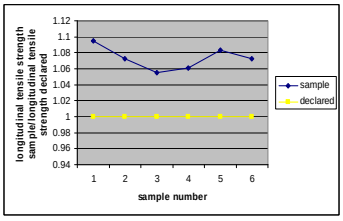
Wattrelos (Fr)



Graphic 7. Crosswise tensile strength



Graphic 8. Crosswise elongation at break



Graphic 9. Longitudinal tensile strength

6 SUMMARY RESULTS OF EXPERIMENTAL TESTS

Below are some figures that summarize the outcome of laboratory tests

Crosswise and longitudinal tensile strength (UNI EN 12311-2) B method (handlebar test strip):
The longitudinal tensile strength stated for the membranes were different: 12 N/mm2 for Bourges and Cordoba, 18 N/mm2 for Wattrelos. The values obtained from the experimental tests were similar to the ones stated. An additional indication is the comparison between the tests on exposed and non-exposed samples, performed for the Bourges and Cordoba test strips.

In this case, the difference between the two values was approximately 15%, while values were significantly different only in two cases (sample 3S1 and 3S6), of around 25%.

Elongation (UNI EN 12311-2) B (handlebar test strip):
The stated value of longitudinal tensile strength was different for the utilized membranes: 500% for Bourges and Cordoba, 700% for Wattrelos. The values obtained from the experimental tests were similar to the ones stated. An additional indication is the comparison between the tests on exposed and non-exposed samples, performed for the Bourges and Cordoba test strips. In this case, the difference between the two values was approximately 15%.

Peel resistance of joints (UNI EN 12316-2)
The values obtained from the experimental tests were similar to or higher than the ones stated.

Shear resistance of joints (UNI EN 12317-2)
The values obtained from the experimental tests were similar to or higher than the ones stated.

Longitudinal and crosswise resistance to tearing (UNI EN 12310-1 and UNI EN 12310-2)
The values obtained from the experimental tests were similar to or higher than the ones stated.

7 CONCLUSIONS

The objective of the research study was to analyse the behaviour over time of polyolefin membranes in TPO-FPA without reinforcement. Three flat roofs were examined, waterproofed with membranes having a nominal thickness of 1.2 mm, laid by means of mechanical fasteners, located in different climates, with operating times of 5, 10, and 12 years.

In all inspections the covers showed, on the flat areas section and in detail, an absence of visible signs of decay. The favourable overall assessment of the cover in place was confirmed by laboratory tests performed on the samples taken: measurements made showed similar behaviours in the three geographical sites.

Membranes had very different exposures to sun radiation, both in terms of intensity and duration: in Bourges (France) and Cordoba (Spain), the membrane had been laid more than 10 years before the inspection, in Wattrelos (France) the membrane had been laid 5 years before the inspection.

Sampling actions on the roofs showed the perfect weldability and therefore the full possibility to repair membranes, even after years of operating exposure, by working on the inner side of the existing membrane.

It should be noted that the assessments made refer exclusively to the specific experimented polyolefin material and therefore to membranes with a polypropylene base (TPO-PP), resulting from a particular polymerization processes.

Materials Used in Transparent Facades: an Approach Towards Building Maintenance

Geísa Gaiger de Oliveira [1]
Oliveira, Roberto de Oliveira [2]
Cláudio Renato de Camargo Mello [3]

T 24

ABSTRACT

Transparent facades have been widely used in construction as a way to promote user interaction with the external environment combined with an attractive and a modern appearance. Designing transparent facades, however, requires the understanding of intrinsic variables that, otherwise neglected, may result to user dissatisfaction. This work aims at identifying the main types of materials that are utilized in transparent facades in the city of Porto Alegre, Rio Grande do Sul State, as well as presenting a checklist for the evaluation of the maintenance process. The research method adopted for this work is composed of three main stages: a bibliographic search followed by the development of a checklist for evaluation purposes. The third stage was accomplished based on a checklist applied to a non-random sample of buildings located in Porto Alegre, Brazil. From the study of the sample, it was possible to observe a series of problems such as dirty stains, colour mismatch due to material replacement, and a series of complaints regarding the buildings' conditioning. It was also noticed that the solar orientation of some facades requires the use of internal shades, which, in turn, prevent integration with the external environment. In many cases, the lack of building details to facilitate maintenance was another noticeable problem. The most utilized materials in facades were reflective laminated glass and common tempered glass. Based on this study, it was possible to conclude that designers can count on a variety of materials available in the market. However, extra care should be taken when specifying a given material in order to avoid any mistakes that might later compromise the life cycle of the building.

1 INTRODUCTION

In the past few years, the use of natural light has become a trend in modern architecture as a design element for energy efficiency purposes and visual comfort. Optimization of natural light in buildings can significantly contribute to reduce energy consumption and to improve visual comfort and welfare of users. Natural daylight provides more pleasant and preferred atmospheres than artificial lighting (ABNT 02:135.02-001, 1998).

Appearance is the first thing to attract the attention of the client. But the task of designing a building requires the understanding of several variables that, if disregarded, may result in user dissatisfaction especially in terms of comfort. It is important to mention that comfort in this case means satisfaction and safety in a building.

Within this context, this work aims at identifying the main types of materials utilized in transparent facades, as well as proposing a checklist to evaluate facades with a view on maintenance process. The growing interest on this topic is due to the fact that a number of materials once employed as mere detail have become part of the facade itself.

2 TRANSPARENT FACADES

Major heat exchanges in a building usually occur through glazing devices such as windows, skylights, glass facades or any other transparent material employed in the architecture. Convection, conduction, and radiation are the three types of heat exchange. The radiation is the main aspect to be considered, since it is the amount of heat directly transmitted to the inside of the building and it depends on glass transmissivity (τ). When considering transparent glazing, the designer has many options of materials available such as glass and polycarbonates. However, employing these materials without a previous evaluation of their characteristics may cause a series of pathologic manifestations from aesthetic issues to more serious matters related to thermal comfort.

According to Alucci (1999), choosing a type of facade should take into account the activities for which the building was designed, as well as the weather conditions of the region.

The solar radiation transmitted to a building is either absorbed or reflected by the facade. A temperature increase implies higher infrared emission, which, in turn, is reflected back to the environment, resulting in air overheating and, consequently, the greenhouse effect. In architectural projects for facades, the main variables that may affect the heat input through glazing facades are: orientation and size, type of glass or transparent material, and use of internal and external solar protection. According to Silva (2001), for optimization of natural light, the glazing devices should be designed to allow a balance between the losses and gains that result from heat radiation transmission inward and outward the building and the light that comes inside the building.

The natural light available inside of a building depends on the amount of natural daylight available outside. The levels of natural light depend on cloudy sky conditions, on the period of the day and year, on the geometric characteristics of the building and compartments, on the dimensions and the spectrophotometric characteristics of glazed areas, on the level of external obstruction and, also, on the reflectometric characteristics of interior surface materials (SANTOS, 2000).

In the case of surface materials, the designer must evaluate the viability of the material that is being proposed – a material wrongly specified or a forgotten detail may compromise the whole performance of the building. In general, external sunshades with *brise soleil* or architectural details tend to be more efficient than internal protections.

3. MOST PREFERABLE MATERIALS FOR TRANSPARENT FACADES

Due to its transparency, the glass allows solar radiation to pass through, where it is converted to heat. Depending on the building location and position, the transparent facades should count on a shading device. It is important to mention that external shading devices are more effective than internal ones, since they reduce the amount of heat entering into the building and the consequent greenhouse effect.

The dark glass, whether laminated, normal or with some type of film, is designed to reduce solar radiation, but it also reduces the amount of natural light inside of a building. In this case, extra opening areas are often required. The use of reflective glass represents a good option to minimize the radiation. However, it is important to consider mobile elements to allow solar radiation and optimization of natural light.

Lamberts (1997) classifies glass for building purposes into simple, green glass, film and absorbing glass, film and reflective glass, and plastic. Although plastic (polymers) are not glass, they are entering the market as polycarbonates and acrylics for transparent shading elements.

Santos (2003) studied the main types of glass and materials used in transparent facades. They are presented below:

1)Coloured float glass or Absorbing glass - the main purpose of this glass is to reduce solar transmittance by absorbing a great amount of incident energy, reducing direct heat gain and glare inside of the building.
2) Laminated glass – is a type of safety glass composed of two or more layers of glass bonding together by up to four interlayers, usually made of polyvinyl butyral (PVB).
3) Reflective glass – based on colored or colorless float glass, the reflective glass receives a metallic coating (semi-conducted metal oxides) that is directly applied to one of its surfaces during production.
4) Polyester film with solar control layer – used for enhancing solar control. A solar control film is applied on the glass.
5) Polycarbonate – a material with outstanding impact resistance and transparency. Lighter than glass, it can be cold-moulded and it also provides UV protection.
6) Acrylic – a linear thermoplastic polymer obtained from addition polymerization of Methyl Methacrylate.

4 MAINTENANCE CONSTRAINTS

Performance losses of a building or of one of its elements often require recovery maintenance, which, inevitably, results in costs for users. Although this is a known fact, maintenance planning for buildings does not seem to be of great concern to many designers. The problem becomes more serious when the damage is not repaired. According to Perez (1988, p.611), it is taken for granted that maintenance begins when construction ends, but the process actually starts on the drawing board. For Vasconcelos (1998), a change in mentality towards the builder/client relationship at the moment the product is delivered is crucial. Based on that, Vasconcelos (1998) provides some guidance on how to prepare a program for periodical building maintenance and on how to turn maintenance into a facilitator component in the building/client relationship.

A building process with integrated stages (planning, project, execution) results in better quality product (building). In this case, the decision making process will not be based on a single stage, but on all stages. This type of procedure may minimize problems and costs of future maintenance. It is possible to perceive that for building matters, maintenance is seen as a cost when, in reality, it should be considered as an investment on the property. This investment not only increases users satisfaction, but it also adds value to the property.

The principle that maintenance adds value to a property is not often exercised by users, since they are usually unaware of how to perform maintenance and the advantages of doing so.
Many users mistakenly believe that once a building is finished it will remain in favourable conditions for a long period of time.

The interest in maintenance is based on the fact that, every year, condominiums are forced to spend great sums of money on this activity. Many problems that require maintenance could be avoided if only the materials and the architectural details received more attention during the project phase.

Performance requirements, however, are not officially in place yet. This fact makes Calmon and Grilo (2000) to affirm that the absence of crucial requirements throughout the decision making process in construction – associated with the lack of indicators to evaluate conformity of product and processes to the quality required during the production phase – favours pathologic manifestations and contributes to consolidate inadequate and counterproductive building techniques. This type of procedure procedure leads to the need of more frequent maintenance and, consequently, higher cots to users.

5 RESEARCH METHOD

The research method adopted in this work comprises four main stages. Figure 1 presents the research design. According to figure 1, the stages were divided into bibliographic search, checklist development, checklist application, and data analysis.

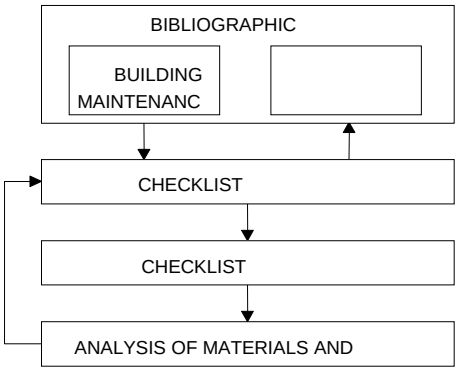

Figure 1. Research design.

During the bibliographic search an attempt was made to collect the theoretical framework related to building maintenance and transparent facades. The aim of this stage was to identify types of facades, materials as well as considerations and procedures for building maintenance. Once the theoretical review was concluded, a proposal of a checklist (Table 1) was developed and applied in a sample of buildings located in the city of Porto Alegre/RS – Brazil. The checklist was based on the topics approached in the theoretical framework and it was developed in order to facilitate the data collection process. The checklist was applied to a **non-random** sample of buildings. The authors decided to contemplate those neighbourhoods that are known for aggregating buildings with transparent facades. For this study, the authors decided not to classify the age or the cost of maintenance processes of the buildings in the sample, since the study aimed at developing a data collection instrument (the checklist) that may be used for a broader classification to be conducted in the future. A study of materials and typologies of facades was thus conducted. The data was analyzed with the aim at identifying – in the sample – the types of facades and the materials of which they were composed. During this stage, the authors attempted to raise considerations regarding ease of maintenance execution. After the analysis, some changes in the original checklist – to be used in further researches – were suggested.

6. ANALYSIS AND DISCUSSION

Based on the non-random sample, composed of 15 buildings located in the city of Porto Alegre, Brazil, it was possible to observe that in commercial buildings there is a predominance of reflective glass skin facades combined or not with architectural details in masonry and concrete or, in some cases, with aluminum sheets (Figure 2). In residential buildings, it was observed a predominance of laminated glass in the composition of the facades. In this case, the laminated glass was employed as frames, as shown in Figure 3

Figure 2. Transparent facade with aluminum sheets.

Figure 3. Laminated with frames.

Table 2 presents the most used types of glass observed during the study.

Table 2. Most preferable types of glass.

	Reflective Glass	Laminated glass	Tempered Glass
Commercial building	8	1	1
Residential Building	0	4	1

Polycarbonates and Acrylics were only observed in architectural details, such as skylights. But even in those cases the maintenance process should be performed with care in order to avoid major problems, as shown in Figure 4. From Figure 4, it is possible to observe a build up of dirt on the left lower portion of the window frame. It reveals a lack of maintenance or faulty assembly without adequate devices to prevent this kind of problem.

Figure 4. Glazing with alveolar polycarbonate with build up of dust.

The typology of the facade does not significantly interfere with maintenance. However, the majority of the inspected buildings lacked the necessary devices – scaffolds, safety belt d-rings, platforms, among others – to perform or facilitate this task:

None of the buildings presented specific construction details for maintenance or, at least, elements to facilitate the procedure. It is possible to perceive that, in the buildings with skin glass, the maintenance process, the replacement of a component or even a simple cleaning procedure often require external scaffolds. In one of the buildings, the facade was away from the structure (Figure 5). In this case, an internal scaffold was necessary. Glass with architectural detail or frame pyramidal shape of the upper floor would not allow any kind of device or scaffold for external cleaning.

Figura 5. Transparent facade displaced from the structure.

The dirt that builds up on the illuminating surfaces, that is, on the transparent facades reduces transmittance e reflectance. This dust that accumulates on the facade will interfere with the illuminance calculation, which depend on the measures of the room and on the natural light that can be lateral or zenithal. Transparent facades should be free from any kind of dirt; they require extra care since its differential lies exactly on their transparency. Cleaning products should be suitable for each material, otherwise they may cause damage to the facade.

Facades that are made of transparent or translucid material require more frequent maintenance; for that reason, the project for those facades should include devices to facilitate maintenance procedures. Those devices vary from structures to adapt scaffolds or similar devices to internal devices for fixing safety belts.

A great number of commercial buildings are located on streets or avenues of intense traffic of buses and cars a fact that considerably increases the amount of dirt. It is important to mention that, in some of the buildings, it was not possible to conduct an internal inspection. For these cases, it is not possible to affirm if the buildings with reflective glass facade had some kind of internal shading, except in a few buildings where it was possible to identify the use of curtains. With respect to solar orientation of the facades, it was not observed any significant predominance that could or could not justify the choice for transparent facades, taking into account thermal comfort, as shown in Table 3. This fact may lead to the conclusion that, in some cases, the solar orientation is directly related to the choice of facade. This issue, however, should be the topic for a further study.

7 FINAL CONSIDERATIONS AND RECOMMENDATIONS

As final consideration, the authors are able to affirm that: i) the project for buildings with transparent facades did not include any specific device to facilitate maintenance procedures; ii) the projects should specify materials and procedures as well as construction details that could facilitate maintenance procedures; iii) nowadays, with a variety of materials available, architectural designers are able to fully express their creativity; but it is important to be cautious when specifying a given material in order to avoid mistakes that may compromise the project.

The technology employed in new materials or in the improvement of existing ones offers a number of options available in the market, which, in turn, helps the architect or the engineer to design and specify materials. This availability, however, demands a much deeper understanding of a great number of different materials. Knowing the types and specifications of the desired materials will avoid future problems, such as pathologic manifestations and unplanned maintenance procedures.

The understanding of these facts and a sense of responsibility result in human comfort and promotes a harmonic relationship among people, their home and the environment, with less effort, lower energy costs, and fewer equipment.

The checklist not only aids the identification of tendencies in the use of certain materials, but it also helps in the classification of the state-of-art of the maintenance process performed in the city of Porto Alegre, Rio Grande do Sul State

As recommendation for further works, it is possible to highlight:

- Analysis – with professionals of the field – of the level of maintenance easiness of some facades;
- Interview with designers to identify tendencies of project;
- Analysis of the use of materials for transparent facades

Use of a Peltier Element to Increase Time of Wetness of Unglazed Solar Collector Specimens in a Natural Field Exposure Test

Bojan Stojanović [1]
Jan Akander [2]

T 24

ABSTRACT

In accelerated testing, material specimens are exposed to completely artificial environments, where exposure to individual degradation agents is enhanced. In contrast, field-testing exposes specimens to multiple degradation agents. When performing a semi-natural test, the influence of a selected degradation agent may be increased while the specimen is still situated in its natural environment. Moisture is such an agent. In an experimental set-up for evaluating long-term optical performance of an building integrated Unglazed Solar Collector, a sub-task was to increase Time of Wetness (TOW) for several collector specimens for two reasons: to "simulate" an active cooling of the component as is the case for solar collectors; and to assess the role of TOW on optical degradation of the solar collector. Specimen cooling and increase in TOW was achieved by utilisation of a Direct-Air Peltier Element. TOW was estimated through measurements with WETCORR sensors (monitoring surface temperatures and moisture) and climate parameters (temperature and relative humidity) at site. At this particular test site in Gävle, Sweden, TOW was more than doubled in comparison to non-cooled surfaces. The Peltier Element proved to be inexpensive and flexible for this purpose.

1 INTRODUCTION

The durability issues of solar collectors are in general related to a number of problems: erroneous manufacturing, installation or freezing [Wennerholm 2003]. Other durability issues are the exposure to various strains (solar radiation, wind, rain/humidity, snow and airborne pollutants) as a result of outdoor placing and in-service use. These contribute to a degradation process and contamination of the collector material (surface) that affects its energy performance due to change in optical properties (e.g. see Carlsson et al. [1994]). These changes will in turn be transposed throughout the system, lowering its degree of efficiency, which directly relates to the economical and environmental aspects of the system. As a result of these types of changes, a performance-over-time assessment is needed, so that the progression and effects of the performance lowering degradation processes can be assessed. This paper presents a study on optical surfaces degradation of a building (roof) integrated Unglazed Solar Collector (USC), by exposing USC specimens to a field test consisting of a natural and semi-natural test set-up. When performing a semi-natural test, the influence of a selected degradation agent is increased while the specimen is still situated in its natural environment; moisture is such an agent. The paper specifically presents the semi-natural test set-up procedure and its proficiency evaluation, in order to increase Time of Wetness (TOW) and highlights USC humidity exposure and its accompanying effects. The exposed USC was developed and used in the EU project Endohousing (Endothermic Technology for Energy Efficient Housing in the EU, Project No: NNE5-2001-00565). The project used solar-assisted heat pumps (e.g. see Ozgener & Hepbasli [2007] and Kjellsson [2004]) to provide the thermal energy to meet space heating, cooling and hot water requirements for domestic houses in different regions of the EU throughout the year. Five demonstration sites (Endosites) were established, equipped and evaluated across the EU; one of which was located in the central parts of Sweden (Sandviken), Fig. 1. The USC is made of extruded aluminium 6060, where the ends and in/outlet pipes are welded to the extruded profile. The USC surface is zinc chromate yellow etched prior to coating application, in which a polyester powder coating is used, in this case with colour RAL 7022; see Fig. 1.

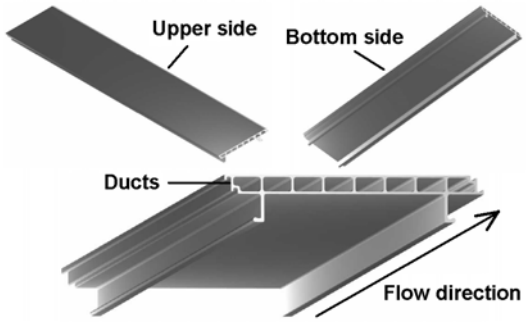

Figure 1. The Swedish demonstration site (Endosite) in Sandviken, showing the roof integrated USC. A drawing showing a top and bottom isometric view of the roof integrated USC used in the Swedish demonstration site (Sandviken).

A major degradation agent acting on all outdoor exposed building materials and components is humidity, whether it is in the form of rain, moist air or condensation. A roof-integrated USC is not merely a component in an energy system, it also has accompanying building technology functions and criteria, e.g. rain protection etc, which makes it highly exposed to the outdoor weather due to its function and placing.

An USC does not solely work as a solar collector since it also works as a convective heat-transfer surface, by absorbing heat from the ambient air. During this operating mode, there will be occasions when air is cooled at the USC surface to the extent that condensation occurs. Roofs also have the tendency for condensation due to night sky radiation (emitting long wave radiation), as these have a large view factor towards the sky. All of these scenarios demonstrate the USC humidity exposure and necessity of endurance. The evaluation and assessment of USC surface response to outdoor humidity exposure, is an important part in the field exposure testing (semi-natural test). In order to highlight humidity exposure and its accompanying effects, a number of USC samples were cut into rectangular shape and mounted onto a Direct-Air Peltier-Element (PE), which cools the samples to increase TOW. One of the main questions is, as the roof-integrated USC being an active energy system component (experiencing different temperatures and surface wetness), if it will have a different durability and Service Life (SL) in comparison to regular architectural surfaces. As the metallic USC is a regular outdoor surface (not as the absorber coating of a glazed solar collector), the coating applied on to the USC component will most likely be of the same type as for regular architectural surfaces (e.g. tin roofs), and have the same durability requirements. These requirements usually do not express optical durability related to the radiation energy transfer parameters: solar absorptance (α) and IR emittance (ε), which are vital for solar collector performance [Duffie & Beckman 2006], or regard the possibly harsher degradation environment as a result of the USC being an active component. This raises the question if current coating requirements and durability tests are adequate for this type of application.

2 FIELD EXPOSURE TESTING

In order to test the optical durability of the USC due to outdoor strain and in-service use at a pre-testing stage [ISO 15686-2], a natural and semi-natural field exposure test was set-up; see Fig. 2 and 3. The main idea behind the division into these two test procedures is to have a field test set-up that assesses in-service use and highlights the extremes of outdoor strain, without having a full USC test component in operation (in-use exposure [ISO 15686-2]). One extreme being a surface (component) absorbing as much as possible solar radiation, hence experiencing high surface temperatures and UV radiation (this is related to the natural test set-up), the other being rain and humidity – humidity due to that an USC in operation can/will convectively absorb heat from the ambient air to the extent that condensation occurs and condensation due to long wave radiation towards a clear night sky. In order to facilitate the collection of test sample specimens from the exposed USCs, pieces were beforehand cut out from the collector and exposed to the outdoor environment. This was achieved by first separating the upper side of the USC and thereafter cutting this aluminium sheet to smaller pieces. The necessity of doing so is due to the USC material thickness of $2 * 10^{-3}$ m, which makes it difficult to cut the test samples on site without damaging or contaminating the test and USC surface. The prepared specimens were then assembled into larger homogenous surfaces (see Fig. 2 and 3) in attempt to reduce the size effect of having smaller material test specimens [Marteinsson 2004]. Size effect implies that small specimens will statistically have fewer faults than is common for a larger surface. Small specimens are also more likely to behave as points in space rather than continuous component surfaces, e.g. experiencing different wind patterns, surface temperatures and moistures due to area and mass. The natural test set-up consists of USC specimens mounted onto a Plexiglas panel (see Fig. 2). The attachment is realised as holes were drilled through the Plexiglas panel. The USC specimens were placed over these holes, which thereafter were filled with silicone from the backside, thereby attaching the specimens with silicone fillings. This approach enables an easy detachment of test specimens and replacement with an aluminium dummy, in order to preserve the homogenous panel surface. The main purpose of this procedure is the ability to expose entire test panels as opposed to single small specimens (see discussion above). A total of five test panels were mounted onto a rack facing south which is inclined 45° (see Fig. 2). Each test panel holds 16 pre-cut specimens, 0.05 * 0.05 m².

In order to assess and characterize the exposure environment and its degradation agents, local and microenvironment monitoring was conducted during the exposure testing. The monitored local meteorological parameters used in the study (at a pretesting stage [ISO 15686-2]) were: air

temperature (°C), relative humidity (%), global- and diffuse solar-, and UV- (0.295-0.385 µm) irradiance at a horizontal surface ($W \cdot m^{-2}$). The microclimate (temperature and TOW) was monitored on the surface of the exposed test specimens with a WETCORR measuring equipment (see Fig. 2, 3 and 4). A WETCORR sensor consists of a ceramic plate with a grid of gold [Norberg 1998] that is connected to an adapter which provides a 100 mV DC excitation voltage, with a polarity reversal every 30 seconds. The resulting current flow, which is proportional to moisture on the grid, is sampled continuously and the average over one minute is logged and (in this study) set to be stored as a 30-minute average value. In addition to moisture, the sensor is also sensitive to pollutants, which may accumulate and thereby modify the electric conductivity of the moisture film on the gold grid [Norberg 1998]. An embedded PT-1000 element samples the surface temperature simultaneously. For further description of the WETCORR equipment, see Norberg [1993] and Norberg [1998]. WETCORR sensors were placed on two separate panels in the natural field exposure test and one on the semi-natural field exposure test. The mean of the two measured values in the natural field exposure testing is considered to be representative for the microclimate for these test surfaces. As for the semi-natural test, only one sensor is used as a representative measure. The USC test samples in this study were placed outdoors at the natural and semi-natural field exposure-testing site on the first of November in 2005. Measurements started simultaneously in order to monitor the exposure environment. The test site is located on the roof of the Centre for Built Environment at the University of Gävle, Gävle, Sweden.

Figure 2. The natural field exposure set-up of the USC optical durability test. 5 test panels mounted onto a rack facing south and having an incline of 45°.

2.1 Semi-Natural Field Exposure Testing

When performing a semi-natural test, the influence of a selected degradation agent may be increased while the specimen is still situated in its natural environment [Jernberg et al. 2004]; moisture is such an agent. Moisture is often a major degradation agent that acts on all outdoor exposed building materials and components, whether it is in the form of rain, moist air or condensation. The evaluation and assessment of USC surface response to outdoor humidity exposure, is an important part in the field exposure testing. In order to highlight humidity exposure and its accompanying effects, a number of USC samples were cut into rectangular shape and mounted onto a PE, which cools the samples to increase TOW, see Fig. 3 and 4. The PE unit used in the study for accomplishing this task is a Direct-Air system, which absorbs heat through a cold plate and "*pumps*" it through the PE, emitting the heat to the air (cooling fins) by an air heat sink at the backside. The used PE (DA-160-24-02) [Supercool 2007] is a product from the company Supercool. It has an active cold plate of 0.18 * 0.13 m² and a maximum cooling power of 160 W at $\Delta T = 0$ (cold plate – ambient temperature). The PE is assembled into a box (see Fig. 3), which incorporates the PE cold plate with the box front.
The exposed plate has a larger aluminium surface onto which USC specimens are mounted, thereby isothermally cooling hence increasing USC TOW while being situated in a natural environment.

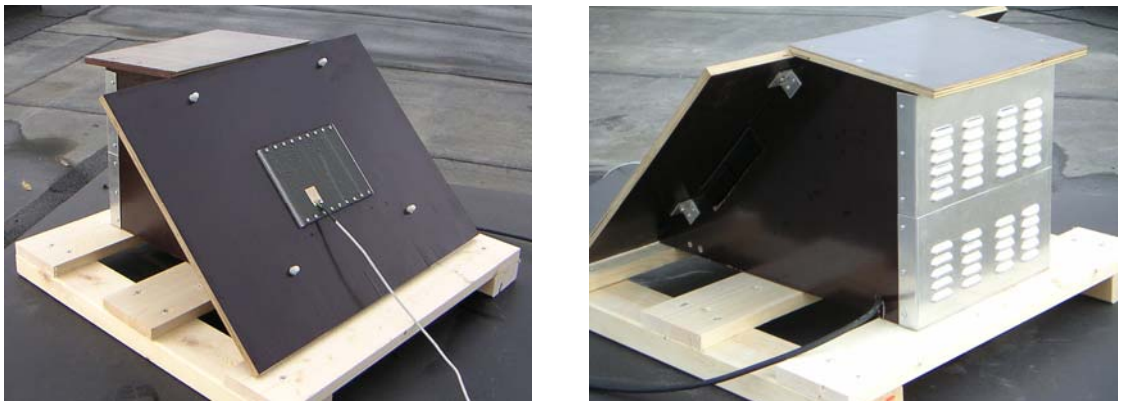

Figure 3. The Peltier Element test set-up in the semi-natural field exposure testing. *To the right*: box front side with exposed specimens. *To the left*: box back side with slots for removal of absorbed heat.

The specimens in the so-called semi-natural field exposure testing have the size of 0.14 * 0.02 m² and are screwed onto a lager cooled aluminium surface of 0.14 * 0.19 m², which is attached onto the PE cold plate. The 9 specimens make up a larger test panel (see Fig. 3). The test set-up has an inclination of 45° facing north. The sides of the PE set-up are also shaded to assure that no direct solar radiation reaches the PE cooled surfaces. This set-up is chosen in order to avoid surface heating and drying up, thereby increasing humidity exposure. The control strategy of the PE was to set a fixed temperature difference between the surface and ambient air, such as to obtain continuous visible surface condensation. As the PE is a Direct-Air type, the directly cooled aluminium surface (USC specimens) temperature will follow the outdoor temperature variations with a fixed cooling temperature difference. The set point temperature is chosen by guidance of monthly outdoor mean air temperature and humidity of a reference year of the test site. This rough and simple control strategy can in combination with time-to-time visual checkups and adjustments render a significant overall TOW increase. The convenience of using a PE is the simplicity of only being dependent on electricity. Other set-ups for cooling, usual require some circulating brine or other cooling fluid, in combination with a refrigerator unit. The semi-natural test set-up proved to cool the exposed USC test specimens in en proficient way, by actively maintaining a homogenous surface temperature lower than the ambient (see Fig. 4); making the assumption that all semi-natural USC test specimens are exposed to equivalent conditions, fair.

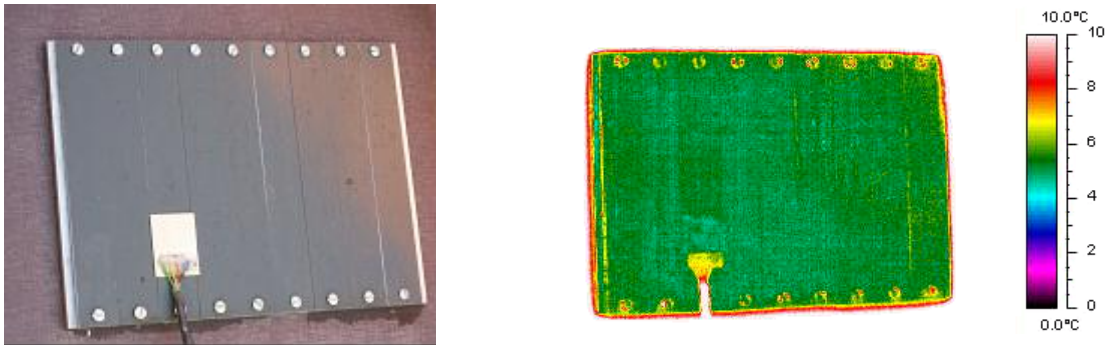

Figure 4. A Close-up picture of the cooled test surfaces in the semi-natural field exposure testing and a thermograph picture of the Peltier Element cooled USC specimens exposed in the field test, showing that the cooled specimens are isothermal.

3 MICRO AND LOCAL CLIMATE MEASUREMENTS

Compiling the monitored exposure environment attained a lucid view of the USC test surface conditions. The quantified surface exposure parameters presented within the scope of this paper is surface temperature and TOW; as the objective of the paper is to present the TOW increase proficiency of the semi-natural field exposure test set-up.

The processed data presented below range for approximately 21 months, from November 2005 to September 2007. Measured surface temperatures (sampled by the WETCORR PT-1000 sensor) are presented in cumulative graphs in Fig. 5, for the total exposure time. In these figures N and SN denote natural and semi-natural.

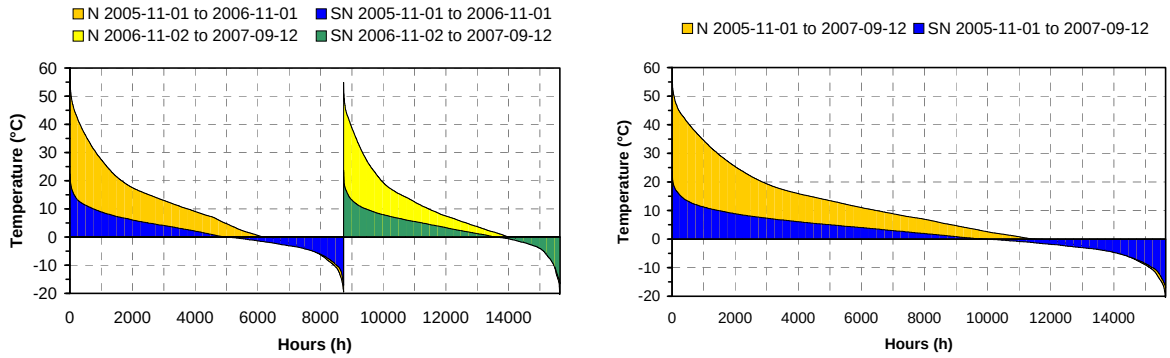

Figure 5. Cumulative graphs of the measured test surface temperature of the natural (N) and semi-natural (SN) exposure for the test period.

In order to estimate TOW of the USC surface, a WETCORR sensor signal limit was identified to indicate the wetness status of the surface (wet/not wet). The limit of 10 nA was found adequate, as can be observed in Fig. 6, which represents a period in July 2006 that was used as limit guidance. The limit of 10 nA, was also found adequate and used by Norberg [1993] in an earlier study, performed at the same test site.

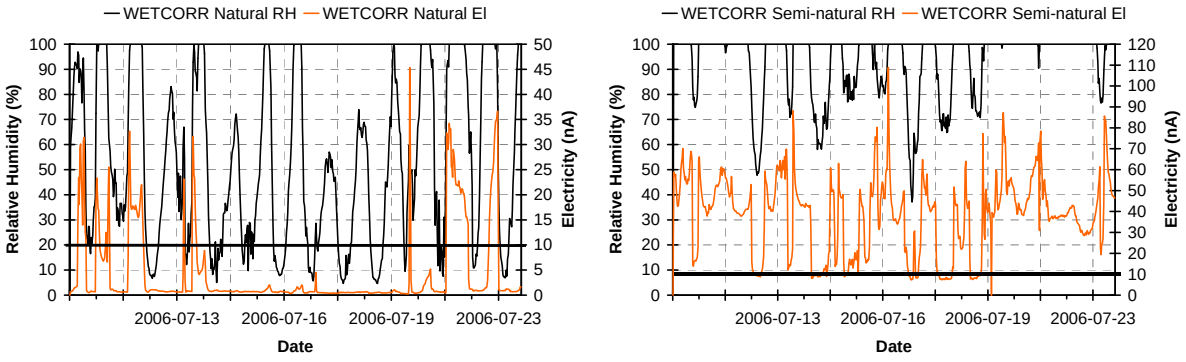

Figure 6. *To the left:* Calculated relative humidity at the natural exposed test sample surface (*surface temperature vs. ambient humidity*), and electrical signal from the WETCORR sensor. *To the right:* Calculated relative humidity at the semi-natural exposed test sample surface, and electrical signal from the WETCORR sensor. Note that the 10 nA limit is marked.

The estimated TOW is presented in Fig. 7 for the USC specimen exposure time. Fig. 7 shows duration time of the electric signals from the WETCORR sensors, with the electrical current criteria of >10 nA

when the surface temperature is >0 °C. The surface in question is considered wet when the electric current and temperature criteria is fulfilled.

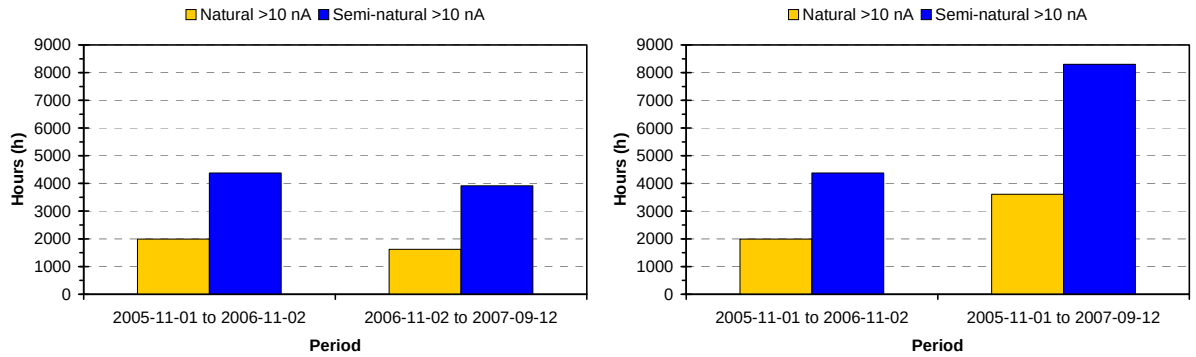

Figure 7. Cumulated measured (estimated) TOW for the natural and semi-natural exposure with the electrical current criteria of >10 nA (from the WETCORR sensor) when the surface temperature is >0 °C, for the presented periods. These periods represent the exposure time.

4 DISCUSSION AND CONCLUSIONS

The semi-natural test set-up showed a considerable increase in USC test surface TOW in comparison to the natural test set-up (~2.3 times longer TOW), due to lower surface temperatures; see Fig. 5 and 7. This shows that it is possible to achieve a significantly increased moisture exposure, through a relatively simple cooling device (PE) and rough control strategy. The test set-up also proved to be cost effective, as well as convenient for attaining a prolonged surface TOW and highlight humidity exposure, as the PE is only dependent on electricity. Other set-ups for cooling usual require some circulating brine or other cooling fluid in combination with a refrigerator unit. The down side of PE units is the difficulty of homogeneously cooling larger specimens or a number of specimens, as commercially available PE units usually have a limited cooling surfaces size. An optical (solar absorptance (α) and IR emittance (ε) [Duffie & Beckman 2006]) USC surface coating durability evaluation [Stojanović et al. 2007] performed after about 11 months of exposure, showed (at time) no significant optical degradation induced by the natural or semi-natural field exposure testing, at this particular test site. However, measurements revealed a significant impact on the specular reflectance due to surface pollution (predominantly quarts in this case). The natural and semi-natural test procedures present an approach for field testing and assessing the optical durability of solar thermal active building envelope components, acting in an energy system. Future work will be conducted and contain a continued USC test specimen exposure and monitoring, as well as additional optical and material durability evaluations.

Minimum Required Performance Level for Rendered Facades

Pedro Lima Gaspar [1]
Jorge de Brito [2]

T 24

ABSTRACT

Service life ends when buildings and components fail to meet a predefined minimum required performance level. However, performance levels are relative concepts that vary according to time, place, available budget, building regulations, existing and expected comfort standards or even the pressure to keep up with the neighbours.

This paper focuses on minimum required performance levels for cement-rendered facades, based on an on-going field research. First, field data on the condition of in-service residential buildings is used to identify a degradation pattern for rendered facades. Different condition levels for rendered facades are then discussed, according to varying building ownership status (public owned, private owned or rented), previously identified as paramount for the durability of rendered facades.

The final aim of the paper is to identify a set of criteria that can be adapted to different building and social contexts and used in service life prediction methodologies, most notably those relying on degradation curves. In practice, for each situation, a combination of criteria should be identified and the minimum required performance level accordingly adjusted in order to obtain the predicted service life. The emphasis is placed on the decision maker, for experience shows that most refurbishing decisions are made due to subjective criteria – before the actual physical degradation threshold of buildings and components is reached.

1 INTRODUCTION

All building and building parts go through a deterioration process from the moment they are finished, during which they increasingly lose their ability to fulfil their users' needs and expectations. Loss of performance manifests itself through construction defects – or failures – that occur due to design problems, lack of construction quality or wrong choice of materials, under the specific maintenance, in-use and environmental conditions, for any given construction [Burati *et al.*, 1992].

Degradation of a building part can be plotted in scatter diagrams, expressing *Condition* (that is, the deterioration level of the part considered) as the dependent variable versus *Time* (as the independent variable). Degradation paths are hence obtained through simple linear regression techniques, best suited to express continual degradation mechanisms, such as environmental actions that affect a facade [Shohet *et al.* 2002]. Once the minimum required performance level for the sample studied is known, it is possible to establish the estimated service of the building part considered.

Building facades are particularly sensitive to the effects of environmental agents for they present a large exposed surface (under the direct influence of rain, wind, sunlight and atmospheric pollutants) but a relatively thin thickness. Visual degradation and disfigurement of the facade are therefore often pointed out as a widespread problem, which has a strong impact on the aesthetic performance of a building envelope and on the quality of the urban environment. [Parnham 1997, Flores & de Brito 2003]. It also generally implies high maintenance costs associated with cleaning and repair actions [Watt 1999, Chew & Ping 2003].

In this paper, fieldwork data relative to the condition of cement-rendered facades of residential buildings are used to identify the deterioration path of the sample studied. Different condition levels for rendered facades are discussed, according to varying ownership status, in order to identify different thresholds of the required performance of rendered facades that can be adapted to different building and social contexts.

2 MINIMUM REQUIRED PERFORMANCE LEVEL OF A BUILDING PART

The minimum required performance (MRPL) of any building or building part is a changing, relative (and often a subjective) concept. In fact, one has just to remember past comfort standards (such as available room area per person, protection against heat, humidity or noise) to realize the changing nature of minimum required performance levels. Evidence of evolving performance standards can also be gathered through the increased performance demands on building legislation and codes, in such distinct areas as structural and fire safety, cost and maintainability, environmental protection, energy consumption, waste control and recycling, access to disabled users or durability.

Finally, even when performance levels can be clearly and objectively defined, previous research demonstrates that changes in buildings occur mostly due to subjective reasons [Aikivuori 1999, Sarja 2005] according to time, place, budget available, building regulations, existing and expected quality standards or the pressure to "keep up with the neighbours". As far as exterior building surfaces are concerned, Balaras *et al.* [2005] have shown that "owners tend to decide on exterior renovation actions on the basis of the general appearance of the building", that is, on its aesthetic appearance.

2.1 Defining Varying Minimum Required Performance Levels for Render Facades

In this research, different performance levels for rendered facades are identified based on a fieldwork survey of 50 residential buildings in real-life service conditions, located in Lisbon, Portugal. First, data collected are measured and computed into one single degradation indicator: overall degradation level (ODL). The latter is then plotted against time in order to identify a degradation path that can model the typical deterioration process of rendered facades. Finally, different deterioration stages are

described and related to the respective case studies (and most notably to their ownership status) so that different 'profiles' associated with distinct minimum reference levels can be identified.

3 FIELDWORK DATA

3.1 Fieldwork Data Collection

A sample of buildings was randomly chosen and filtered in order to select case studies matching the following criteria: a) buildings with cement-rendered facade, b) no known records of deterioration as a result of accidental actions, and c) with known records of past maintenance actions or the date of construction. The last condition was regarded as indispensable so that the pattern of variation in time of the ODL could be identified.

Fieldwork surveys were performed between July 2006 and July 2007. Each facade was visually assessed and photographed. Defects were registered and classified based on a discrete level classification system – from "0" (no degradation) to "4" (immediate action required) [Balaras *et al.* 2005]. Finally, each photograph was converted into drawn elevations in which deteriorated areas were measured, according to their condition level, for each of the three main defect categories: "staining", "cracking" and "detachment" of render. After completing the fieldwork, it was possible to quantify ODL of each facade, improving on earlier research [Gaspar & de Brito 2005].

3.2 Overall Degradation Level

The overall degradation level of a facade (ODL) represents the severity of degradation (area and depth of defects) relative to a reference degradation area that corresponds to the total exposed rendered area of the facade, affected by the most unfavourable condition for all possible defects, see equation (1).

$$ODL = \sum (A_n \,.\, k_n \,.\, k_{a,\,n}) \,/\, (A_r \,.\, k \,.\, k_{a,\,n}) \qquad (1)$$

where,

ODL	overall degradation level, in percentage;
A_n	area of a facade affected by defect n, in square meters;
k_n	condition level for defect n, where $k_n \in K$;
k	constant, equivalent to the value of the worst condition level within K;
$k_{a,\,n}$	relative importance of the defects detected, where $k_{a,\,n} \in]\,0, +\infty\,[$;
A_r	exposed rendered area of a facade, in square meters;
$K = \{0, 1, 2, 3, 4\}$	space with all condition levels.

To obtain the value of ODL for the cases studied, defects are weighted according to their hazard level. Such distinction is based on empirical evidence that suggests that, for normal ageing processes, light degradation (associated to staining, soot and dust deposition) occurs before heavy degradation (cracking and detachment of render) [Parnham 1997]. Furthermore, as deterioration progresses situations of simultaneous action of different degradation agents tend to occur more frequently. The combined effects of different degradation types (such as cracking and water penetration) also lead to increasingly hazardous defects (such as salt attack or freeze-thaw cycles that penetrate deeper in the render thickness) [Henriques 1992].

Different scenarios for $k_{a,\,n}$ (see equation 1) were therefore studied and the best-fitting combination of values was selected: staining, cracking and detachment defects are affected by $k_{a,\,n}$ indexes of 0.67, 1.00 and 1.50 respectively.

3.3 Modelling Loss of Performance Over Time

The ODL indicators obtained for the cases surveyed can be plotted in scatter diagrams, expressing Condition (as the dependent variable) versus Time (as the independent variable), as shown in A degradation path for the sample studied - obtained through linear regression - is also plotted in Fig. 1.

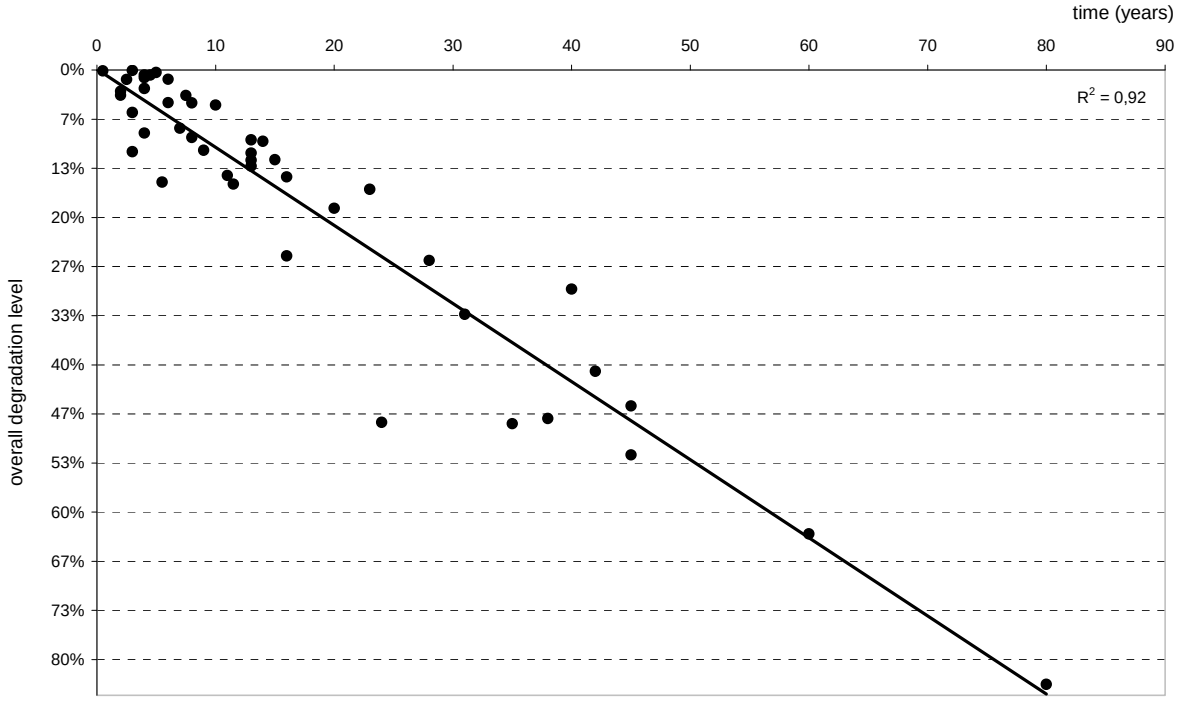

Figure 1. Overall degradation path for 50 cement-rendered facades, expressing loss of performance over time.

Analysis of figure 1 shows that degradation of cement-rendered facades tends to increase over time, according to a linear pattern. ODL seems also to provide a good correspondence between results and a linear regression pattern (Pearson R^2 of 0.92) for the 50 facades surveyed.

3.4 Analysis of Fieldwork Results

Analysis of fieldwork results suggest that the cases surveyed can be classified according to five groups corresponding to different ODL levels:

a) Renders with ODL ≤ 5%, corresponding to cases with no signs of degradation or to cases with very small areas of very light staining (condition levels of "1" or "2") and no cracking nor detachment of render; with no exceptions, all of these renders are less than five years of age;

b) Renders with ODL between 6 and 10%, corresponding to situations of staining (levels "1" to "3") and cracking (levels "1" and "2"); most staining corresponds to light soot and dirt deposition; all of these renders are less than 10 years of age;

c) Renders with ODL between 11 and 20%, corresponding to extensive areas of staining (levels "1" to "4"), including early manifestations of algae and moss, and broader areas affected by cracking (of all condition levels); all cases with ODL higher than 14% show signs of small detached areas as well; within this group, age of render tends to group around 10 to 15 years, although two cases studied correspond to renders with less than five years of age (suggesting a defective intervention) and two cases correspond to renders of about 20 years of age (that is, cases with above standard quality levels);

d) Renders with ODL between 21 and 30%, corresponding to just three situations of heavily stained facades with significant parts of render cracked and some detachment (especially in corners and below balconies); age of render in this group is also scattered (from 16 to 40 years);

e) Finally, renders with ODL above 30%, corresponding to extensive degradation of all three type of defects: heavy staining (all condition levels), significant areas of render cracked (levels "3" and "4") and sometimes large portions of detached render; these situations correspond to the older renders of the sample – although it is quite difficult to confirm the age of renders with more than 40 years.

Data collected show that there is some correlation between the ODL of cement-renders and the age of the latter (older renders tend to present higher deterioration levels, as expected) that makes it possible to identify groups of renders with similar degradation patterns.

Furthermore, the results obtained seem to confirm the empirical view that deterioration of renders progresses from light staining defects (soot and dirt deposition), to more significant forms of disfigurement (runoff marks on the facade due to defective or non-existent drips in ledges and window sills). Over time, more hazardous types of defects tend to occur, such as cracking and detachment. For the most deteriorated situations (high values of ODL), all types of defects occur simultaneously leading to increasingly higher degradation levels (for instance, cracked areas allow runoff water to penetrate into the render and deposit salts that destroy the matrix of the render and originate efflorescence, more extensive cracking and even the detachment of the render).

4 IDENTIFYING MINIMUM PERFORMANCE REFERENCE LEVELS

As a facade progresses in its deterioration path (and reveals increasing levels of disfigurement as well as diminishing performance levels) owners and users are also increasingly confronted with the need to correct such process. At an early stage, deterioration may remain unnoticed for some time. When defects are consciously considered, the decision to repair may be affected by considerations of cost, opportunity and difficulty of intervention. MPRL therefore correspond to different acceptance levels from end users and owners – and to accordingly different demands for repair work to be scheduled.

Previous research [Balaras *et al.* 2005] has shown that more affluent owners (private companies that strongly rely on their perceived image – such as hotels or banks – or private owned condos) will maintain and repair the facade even at earlier stages of deterioration, whilst in rented or state-owned residential houses the decision to repair may tend to be postponed until unacceptable or dangerous levels of degradation occur. Finally, if no intervention is performed, the building may enter a stage of neglect and decay [Wyatt 1999].

To test these assumptions, data on the ownership status of the building surveyed were collected and crossed with the degradation level of the latter and the time of intervention.

4.1 Minimum Performance Reference Levels for Private Owned Buildings

Analysis of fieldwork data reveals that all cases with ODL less than 5% (condition level "0") are privately owned buildings that have had recent interventions on the facade, despite the age of the building. In such situations, interventions at facade level may result from a desire to improve recently acquired buildings – perhaps due to a keep-up-with-the-neighbour attitude – or from the will to sell for a better price, for indeed many buildings correspond to constructions with more than 50 years of age that are experiencing a renovation of dwellers. Two company-owned buildings were actually subjected to repair work despite the fact that their ODL was no higher than 10%.

Privately owned buildings are still dominant in groups of condition level "1" and "2", although there are some situations of rented buildings (town-owned) with somewhat recent interventions. Noteworthy is the fact that repair work was actually initiated in private owned buildings with ODL of less than 15% and age of render of 13 years.

With two exceptions, rented buildings correspond to the majority of cases with ODL more than 20%. Within these cases, no major distinction can be identified between buildings that belong to a private landlord or town-owned dwellings. However, renovation work does eventually occur in the latter group – especially under specific programs that finance such interventions in low rent dwellings – whilst the former may undergo a process of neglect and decay, as described.

4.2 Degradation Patterns Associated With Ownership Status

To better visualize the correspondence between ownership status and ODL, all cases studied were grouped according to four ownership categories (company owned, private owned, town-owned, and rented buildings). Although the available data prevents the sample from being statistically significant, cases studied and their regression lines are plotted in figure 2.

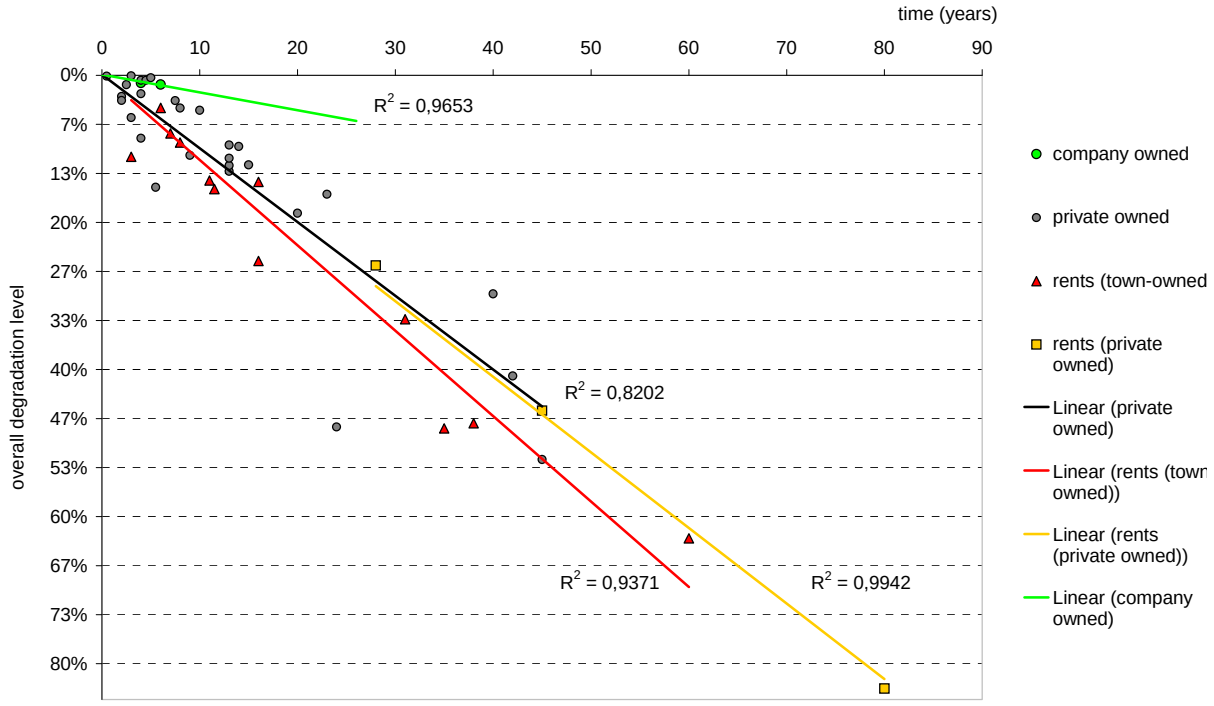

Figure 2. Overall degradation path for 50 cement-rendered facades, grouped by ownership status.

Not surprisingly, analysis of Fig. 2 reveals that the majority of the situations accessed corresponds to privately owned buildings, which can be explained by the specificity of the Portuguese real estate context: scarce rental market (due to the compulsory maintenance of the values of existing rents, which led to very low age-old rents and only a small percentage of market-value rents) and widespread purchase of private dwellings (especially fostered by low interest rates).

Further analysis of figure 2 also shows a clear distinction of the degradation pattern for town owned, privately owned and company owned dwellings. Each of these groups seems to have increasingly demanding performance reference levels inasmuch as they show slower degradation patterns. Distinction of the degradation pattern between 'privately owned' and 'rented (to a private landlord) dwellings' is not so clear, except that the latter show higher deterioration levels and older renders

whilst the former tend to display more recent renders. This may be an indication that facades of privately owned buildings tend to be repaired sooner, as indicated during the fieldwork phase.

5 DISCUSSION OF RESULTS

Despite the scarce sample of renders assessed that prevent the results obtained from being statistically significant, some conclusions can be drawn:

a) Fieldwork data seems to confirm a deterioration pattern for cement-render facades, from light staining due to dirt and soot deposition to increasingly hazardous defects (water runoff stains, cracking and detachment of render) and simultaneous effects of the latter;
b) Renders can be classified according to their degradation level into five broad categories that illustrate the deterioration pattern of this type of cladding;
c) In accordance to the work of other authors [Balaras *et al.* 2005], age and ownership status seem to influence the condition level of the renders;
d) Older renders tend to show higher levels of degradation over time, according to a linear pattern with a rather good correspondence of results, especially as data have been gathered in buildings in real-life service conditions;
e) Ownership status influences the perceived degradation level: privately owned cases of the sample reveal better performances than town-owned (rented) buildings;
f) Rented buildings have been found to have lower performances than private owned condos: not only do the latter undergo repair work sooner, but also the former tend to remain unattended for longer periods and eventually experience a process of neglect and decay [Wyatt 1999] (ODL higher than 60%); this situation can be explained by the very low rents associated with much of these dwellings due to the Portuguese real-estate context;
g) Town-owned buildings tend to deteriorate considerably before repair work is scheduled, perhaps due to financial constraints, but also on account of the low lobbying power of their tenants; when finally repair work is performed these buildings seldom return to very high performance levels, especially when compared to privately owned condos that have been recently repaired as well;
h) Finally, different minimum performance levels can be proposed, based on the degradation level of the cases studied before repair work on the facade is scheduled: thus a pattern was identified in which company owned buildings were repaired before they reached 10% of ODL; as a rule, privately owned and town owned were repaired before they reached 15 and 20% of ODL respectively.

6 CONCLUSIONS

In this paper a methodology is proposed to identify minimum performance reference levels according to the ownership status of buildings, based on a sample of 50 rendered facade buildings located in Lisbon, Portugal. The results obtained confirm the strong correlation between ownership status and degradation and suggest that buildings can be grouped according to their degradation level, following a linear pattern of degradation.

The degradation level of the sample is then used as an indicator of performance or, indeed, of loss of performance. Through analysis of fieldwork data it is possible to identify different degradation patterns associated with ownership status and thus deduce the minimum performance level for each group. Although minimum accepted performance is a relative (and changing) concept and the decision to repair highly subjective, the methodology presented is able to propose distinct minimum performance levels in relation to the ownership type, for the Portuguese context. It also provides benchmark information concerning the expected service life time of cement-renders for life-cycle analysis and service life estimation methodologies.

Durability of Sandwich Panels

Çiğdem Çelik Tekin [1]
Ülger Bulut [2]

T 24

ABSTRACT

Durability of a material is its ability to resist changes of its properties. In design process of a building or system or component cannot be considered rationally except in the context of that material in service and the environment in which it must function since it is the interaction of elements of environment with a material that determines its durability.

In this context, durability and performance characteristics might require modification or innovation in process of choosing material and compound design. Necessity of more durable and high performance building materials causes to development of composite materials. In this study composite sandwich panels which are used for industrial buildings, prefabricated buildings, sport buildings, hypermarkets, except housing, are researched

Distributed load bearing capacity, wind load, indoor comfort criteria, heat and sound insulations, fire load effect, expansion, durability of environmental conditions affect sandwich panel compounds. All above mentioned factors determine service life of sandwich panels.
In this study, it is explained how the different selection of paint, metal and layer of heat insulation affects servis life and durability of panels and indoor comfort level. Additionally to this, the faults in transportation, storage and the application of sandwich panels are examined.

1 INTRODUCTION

All buildings are aimed to be durable and comfortable during their service life. Durability which also effects the comfort conditions-criteria, is the ability of resistance and tolerance of the features of materials and systems against negative factors in the buildings. Besides the production, storage, transportation, application and use features, durability is also closely related to avoiding from the radiation, temperature, water, freeze and chemicals that affect-ruin-damage the materials when exposed and the environmental conditions.

Sandwich panels also have a wide range of possibility of use with compatiblity-applicablity for many kinds of buildings such as industrial buildings, prefabricated buildings, gym centers, supermarket buildings and shopping malls, but excluding residences. Same as the buildings, sandwich panels also have service lives. In general they might be considered having long service lives like 30-40 years. However, the durability term of the panels might decrease owing to the choice of types of panels, production, transportation, storage or adjustment-mountage, and a discomfort of inner space conditions and service quality might be observed.

Most of the mistakes on choosing the component combinations forming the sandwich panels, made by the consumers, mainly depend on economical worries. On the other hand, most of the mistakes on the production, transportation, storage, mountage and application of the sandwich panels are caused by inexperience and lack of knowledge.

2. SANDWICH PANELS

Sandwich panels are multi-layered/laminated composite materials used for roofing and wall systems that are formed of metal panels on both sides and certain thickness of isolation material in between. The metal panels are usually aluminum, galvanized plate, pvc membrane or craft paper, and the coating paints are polyester, plastisol or PVdf, and the isolation fill material might be polyurethane, rockwool, glasswool or expanded polystren. The optimum result solutions choosing the sandwich panels, are determined according to the function, the physical features of the panel components, the environmental conditions and the fulfilling of certain needs.

One of the main parts of the panels; galvanized plate, should be galvanized with “hot-immersion” method, be in TS EN 10142 standarts and 100-275gr/ m^2 zinc plated. As the proportion of the galvanize determines the durability of the plate, this proportion should be determined according to the environmental conditions where the sandwich panels will be used. Aluminum is used straight or after crimping. Although, aluminum, is a corosion-resistant, conductive material, its coefficient of expansion is much higher compared to galvanized plate. (for carbon steel-galvanized plate = 10,8x10-6 /C; for aluminum = 23 X 10-6 /C)

Depending on these features, it is preffered for asidic conditions and / or heavy industry conditions. Galvanized and aluminum plates are painted with coil coating technique. Within this coil coating technique, a painted metal with homogenious paint thickness for continuous production line and metal surfaces is obtained. In this technique, galvanize or aluminum roll is opened on the continuous painting line and surface cleaning is first applied. The surface to be painted, is purified from grease and unwanted substances which is followed by the chromate coating process for a convenient surface before painting. Then, first both sides of the metal is primed and kiln-dried. As the last process, the chosen color and type from the RAL catalogue is applied then kiln-dried again and covered with folio.

2.1 The Effect of Panel Combination on Durability

The low costs while constructing a building does not mean that it is an economical building. The criteria of an economical building are; the ability of energy saving during the presumed service life,

low costs of maintenance and the qualification to reduce the environmental effects to the least both inside and outside the building.

Sandwich panels are composed of multi-layers with different mechanical features. Depending on the paint, metal and isolation features, many different panel combinations can be obtained and closely related with the comfort, cost of maintenance and long service life of the building. Each component has different and limited rigidity and one alone cannot resist the load as they can compositely. As a whole, the bending momentum is met by the metal panels, and the shear momentum is met by the filling layer. The choice of insufficient thickness of panels and fillings caused by economical worries may result as stated below.

a. Type, thickness, dimension of trapeze form of metal plate for sandviç panel, determined results of statical analyses. According to the carcasse system, purlin span and the distributed load, suitable galvanized or aluminum plate should be used. Under constant load, the filling material of roof panels are deformed more slowly. For this reason, under constant load, the panel deformation would increase gradationally. But, there is not constant load on wall panels. Thus, especially for roof panels, the calculations should be made according to the type of load and the type of filling to be used. The calculations should be made considering the effects of climatical conditions, snow, wind, temperature, dead and live loads, and the components like construction and the purlin spans of the building should be calculated each alone then together considering the worst scenario the convenient filling and metal plate thicknesses should be chosen. The thickness of the metal panels is different; the carrier upper plate is thicker. Galvanized carrier plates should be at least 0, 50 mm; and for aluminum plain and trapeze plates 0, 70 mm. The load capacity of the panel can be increased with a better metal and filling adherency. The adhered surface between metal plates and filling reinforces the endurance of the sandvich panel. The "in situ application" systems where the metal panels are not adhered to the fillings are less endurant to torsion than the sandwich panels. As there should be a good adherency between the metals and the filling, the filling itself should also be able to meet the flexibility. Metal panels meet the bending momentum and the filling the shear momentum. Especially, the mineral fillings should be adhered carefully. Sandwich panels should definetely be tested for resistance and long-term effects. Before choosing the panels, the applicator and the consumer should demand TSEK and production proficiency certificates from the producer. The adherent surface of filling should be tested against aging and loss of strength. With these tests, the effects of water steam and temperature on stress strength should be determined.

b. Places where the day-night, summer-winter temperature flactuations are observed, the final coating material should be chosen carefully. Besides the atmospheric temperature effects, radiation also affects the buildings. Direct and spread radiation, causes a higher temperature than the atmospheric temperature on surfaces relevant with the color and texture of the wall. In winter, especially during nighttime, again relevant with the radiation effects and depending on the features of the wall, a temperature lower than the atmospheric temperature appears. As a result of these thermal changes, the expansion causes contractions or extensions on the building. If the thermal expansion coefficiencts of the panels and fillings are different, this effect causes damage and disintegration. Choosing different metals for the upper and lower panels of a sandwich might be unpreferrable since the expansion coefficient of metals may vary. Even the reaction of the same metal may vary for the thermal expansion inside and outside are different. So, the choice of metals for the panels should be made considering the inner and outer weather conditions and changes. In summer, the temperature of the outer panel depends on the coating color and the reflectivity of the panel surface. For this reason, the determination of the color of coating should be made considering the temperature changes, like in hot climates, use of dark colors should be avoided. High temperatures usually accelerate the deformation-decomposition of materials. For example, in the Mediterranean Region, while the surface heat of light color panels are 55°C, the dark color panels might increase until 80°C. Using light colors or reflective elements on the roofs, the expansion activities caused by the thermal changes might be reduced.

c.The thickness and density of the fillings of sandwich panels should be determined according to the climatical data of the location of the building. The thickness of the filling is calculated according to the thermal conductivity coefficient of the substance used. Mainly, polyurethane, glasswool, rockwool or EPS are used as fillings. The thermal conductivity coefficients and densities of the substances are important for the rigidity and load-bearing features of the panels. The necessary features for the isolated sandwich panel fillings are shown below on Table 1. As shown on Table 1, the thermal conductivity coefficient of polyurethane between 10-20°C is around <0,025 W/mK. But, for lower temperatures, the thermal conductivity coefficient value also decreases and a better heat isolation is provided. Because of this feature, polyurethane is convenient for cold storage spaces. For hygiene-must spaces, the panels should be produced with folios on both sides.

Table 1. The technical features of the filling materials

	Polyurethane	Rockwool	Glasswool	EPS
Thermal conductivity coefficient (W/Mk)	≤ 0,025	≤ 0,040	≤ 0,040	≤ 0,040
Density (kg/m3)	40 kg/m3	100-110kg/m3		20kg/m3
Thermal endurance of filling material °C	-50/+110 °C	-50/+700-750°C	-50/+250°C	-50/+75°C
Fire classification	B1-B2	A1	A1	B1-B2
Location & use in the building	Roof-wall systems, cold storage buildings	Roof-wall systems	Roof-wall systems	Roof-wall systems
The contribution of the material to isolation	Only thermal isolation	Thermal-sound and fire isolation	Thermal-sound and fire isolation	Only thermal isolation

d. The metal and the filling material of the sandwich panels used as roof or wall systems effect the extension of the fire and the damage that might be caused on panels. When the filling materials of the sandwich panels, which generally are used on industrial buildings, are being determined, the features should be evaluated considering the function of the building, the materials used and the risk of fire. Polyurethane and polysiyanurat, which are thermosets, become liquidified during fire and move in between the panels dropping. EPS in the thermoplastic category is 1,5 times flammable than polyurethane. EPS when exposed to high temperatures, before flaming it softens and shrivels (Eren, 2005). The shrinkage, softening or the melting of the filling materials cause the continuous and non-cavity structure sandwich panel to loose its strength. Plastic originated filling materials have the disadvantages such as causing high heat and toxic gases during fires and hinder the intervention, cause gas-affected deaths and accelerate the extension of the fire. The behaviors of metal panels during fire are also important. Steel materials are 2 or 3 times stronger than aluminum and affected by temperature at 585°C. Aluminum is affected from about 100-225 °C. While a 10 mm. steel beam at 500°C expands 600 mm., under same circumstances, an aluminum beam expands double and melts at 660°C (url. 1). Polyisocyanurat are resembled to polyurethane but different indeed. Polyisocyanurat, when exposed to a source of heat, does not soften but gets parched in limits. When parched, might melt and flammation might occur if the steam comes out. But, if a certain amount of parching occurs and then the heat source is stopped, the material loses isolation features. Normally, in low flame heat source might not cause flaring and shows a fire-resistant behavior; but in big scale fires, might combust and cause the fire to extend quickly. Polyurethane exhales a dense smoke, toxic gases, hydrogen cyanid and carbon monoxide (url. 2). For fire safety priority buildings, A class, non-flammable, mineral wool filled panels should be preferred. These panels do not increase the fire load, exhale toxic gases, drop, soften or shrink in case of fire. The melting point of rockwol and glasswool is 1000°C. According to the building fire instructions, use of A class filling materials are necessary relevant with the type of building.

e. The metal plates of the sandwich panel should be protected against corosion, ultraviolet rays and sufiric acids. For this reason, the galvanized plates or aluminum plates are painted on the continuous production line with coil coating technique. With the last layer, the preferred color is given and a homogenious paint thickness is obtained on each and every point of the plate. According to the climatical and environmental conditions where the sandwich panel would be located, metal plates are coated with epoxy prime followed by polyester and PVdf or plastisol paint. These paints with different feature have the common point to be wet paints. Paint helpsthe metal to longlast. Metals coated with coil coating technique can easily be processed. Painted surfaces are not affected by trapeze shaping processes. And another important feature of painted metal is the prime layer applied to the isolated side of the metal (Karasu 2006). With this layer, isolation filling is adhered to the metal and isolated panel gains a composite structure. The last coating layer of the metal panels should be determined not considering the type of the metal, but the location and environmental data. Standart polyester paint is applied 20 microns on 5-7 microns of prime on the metal surface. Sandwich panels possible to be exposed to chemical materials, plastisol paint should be preferred. But, in 2007, according to ISO14001 Environmental Management Systems instructions, production of plastisol paint is forbidden. Paints widely used and features are given on Table 2. According to this, the best UV resistant paint is PVdF and the worst is plastisol.

Table 2. Technical features of paints.

UV resistance	*thermal resistance*	*corrosion resistance*	*Hardness*	*flexibility*
PVdF	*PVdF*	*Plastisol*	*Polyester*	*Plastisol*
Polyester	*Polyester*	*PVdF*	*PVdF*	*PVdF*
Plastisol	*Plastisol*	*Polyester*	*Plastisol*	*Polyester*

f. There are alternative roof and wall systems to the prefabricated sandwich panels composed of two panels and filling in between. These systems do not cause any changes on the inner space physical comfort features, but only production, application and constructional needs are different; such as “cast-in-situ”, “waffle system” and “clamp system”. The preferred roof and wall systems should be decided in design state, not after the building is constructed. Before the construction starts, the necessary details should be designated; the thickness for thermal isolation, filling for water and sound isolations and loadbearing system should be decided.

g. The main purpose and function of roof and wall systems are to protect the inner space comfort from the outer conditions. This function can be provided by waterproof materials. The risk of a roof to leak, especially from horizontal connections, is higher than the walls. The risk of leak for roofs changes according to the roof plans. The risk increases for low pitches. Materials and connection elements used for plain or low pitch roofs should be 100 % waterproof. To prevent deformations caused by humidity, the formation of humidity on the surfaces of elements and the inner building should be prevented. If humidity and dampening are inevitable, the dampening time should be tried to be kept minimum. Moreover, the quantity of galvanize to be used on the plates of the sandwich panels should be increased and the type of paint should be decided upon the corosion-resistance listed on Table 2. Water caused by the intensification of damp, especially causes the mineral wool fillings to get wet and its thermal conductivity increases and as a result, a loss of energy occurs. Mineral wool (glasswool, rockwool) filling panels should be kept away from water and damp during storage and transportation.

2.2. The Effects of Production Defects on Durability

The metal plates to be used as panels, painted or unpainted, are brought to the factory in rolls. The rolls are opened by the quality control department to be checked for **TS EN 10143**; “continuously hot-dip coated steel sheet and strip-tolerances on dimensions and shape” for plate tolerance limits. The tolerance limits changes depending on the thickness of the plate, such as, the tolerance for a 0.40 mm. plate is 18 mm. Otherwise, the undulating panels especially when used on walls with “cast-in-situ” systems show the defects very clearly.

The polyurethane filled panels used for roof and wall system should have constant mechanical features. (in accordance with **TS EN 13165**, density tolerance limits: 40 kg/m³ ± 2 kg/m³). The polyurethane filling in the sandwich panels should have a homogeneous density and with no pores to change the porosity. While production, the amounts of polyol, isocyanate and pentane gas mixtures should be proportioned correctly. The effectiveness of polyurethane can be provided with only correct amounts of mixtures. Also, the temperatures of the upper and lower plates, raw materials and the kiln are important. If the amounts of polyol, isocyanate and pentan gas mixtures in the polyurethane filling are not well-proportioned, the defects are only seen after production as deformations on the panels. This problem can partially be solved with re-settling the polyurethane with some tools. The deformations usually occur on the sun-seeing façade, not the North façade. This problem can be reduced by considering the precautions stated above. When such a problem is faced, first, only the swollen part of the upper plate should be drilled with 1-2 mm bit, and so the swelling would be stopped. But if it is not drilled on time, the plate would have been deformed and drilling would only stop the progression, the physical deformation would still remain. As removing the sandwich panel and mounting another would be costy, another solution might be mounting a trapeze plate or some other material directly on the panel. On the extraordinary dark painted plates, a protective polyetilen folio should definetely be used to avoid scrathes or other damage.

In mineral wool filled sandwich panels, polyol and isocyanate mixture is used to adhere the wool to the metal. But the mixture used for mineral wool is different than the one for polyurethane. There occurs no deformation of damage on the mineral wool panels. Sometimes as a production defect, there might be insufficient adherence and for this reason the panels and the filling material might detach. The adherent mixture should be homogeneous and spread effectively.

Epoxy prime paint is smeared on the inner side of the aluminum or galvanized plate to adhere it to the filling material. If the outer side of the metal panel is not painted, prime paint is applied to the inside. Before the prime, a chemical process is applied on the plate. This chemical process and prime on the bottom may cause the upper part lose resistance to corosion and deformation and an unwanted appearance. For these reasons, the manufacturer to prevent these problems in short-term, produces the panels without the prime paint, which causes the the fillings to detach from the panels. As aluminum is a soft material, there appears stains on the plate if past from the pulley thick and unpainted. Before and after the production of the sandwich panels, the quality control department should control the dimensional stability, type and color of the paint, the convenience of the raw polyurethane material and the deformation risks.

2.3. The Effects of Storage and Transportation Defects on Durability

To adhere the metal panels to the mineral wool filling, polyol and isocyanate mixture, which is also used for polyurethane production, is sprayed on the mineral wool filling. So, the adherence is enstrengthened to let the sandwich panel carry, hold itself up and down while mounting without detaching. For mineral filling sandwich panels are flexible, if they are longer than 8-9 m., might break apart when carried by two people from both sides. So, even if the break on the plate is repaired, it never looks like before. It then might be used as a roof according to the will of the customer, but not on the walls. The weight should be considered when forming the dimensions of the mineral wool panels, as well as the transportation to the place and mounting it. These factors are not valid for the polyurethane panels as they are much lighter than the mineral panels. Moreover, polyurethane filling adheres to the panels much better than the mineral ones.

Mineral filling materials are easily affected from water and damp. Mineral panels for this reason, should definetely be covered before and after transportation. In the construction site, the panels should be stored in an inclined position so that the rain or snow would not stay on. If the mineral panels are damaged, they will not be recovered; within the visuality, it will also lose its thermal conductivity. So, they should not be piled on the others while kept waiting to be mounted. Usually panels are

transported by long vehicles. For the panels longer than the damper of the truck, the damper might be opened and 1,5 mt max might go out.

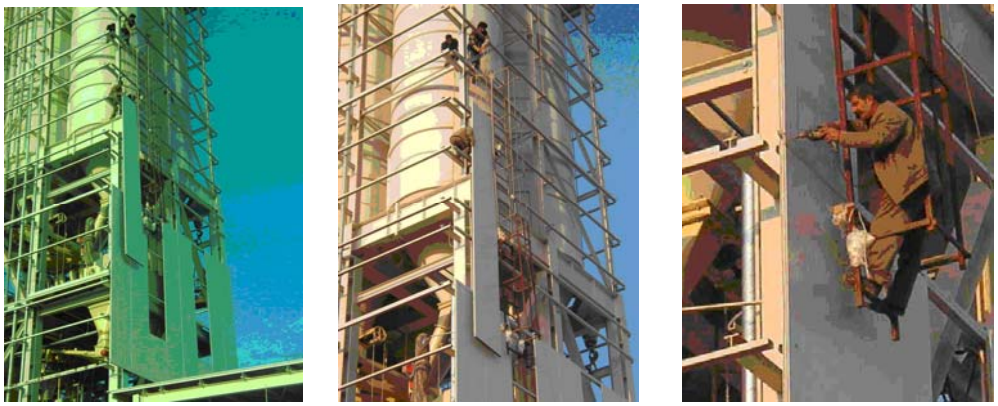

Figure 1 a, b, c Mountage of the panels.

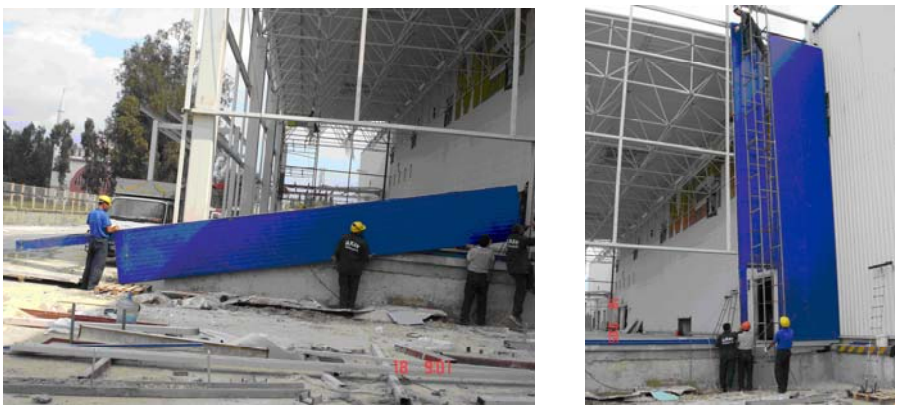

Figure 2 a and b. Transportation and mountage of the panels in the construction site

2.4. Effects of Application Errors on Durability

The main principle of the application is that the details should be mounted waterproof, airproof and not forming a cold bridge. The roof and wall panels cannot tolerate or cover the construction mistakes, but also causes the defects of the construction seem more clearly. So, before the mountage, the defects of the carcasse should be re-checked, and if there happens to be a problem, it should be corrected before mountage.

The folio adhered to protect the panels should be torn out before mountage because after being exposed to sunlights, it might be harder to tear it or might look unaesthetic.
The construction site should be cleaned after work hours every day. Otherwise, with rain, the small pieces of metals might cause corosion on the panels.

The panels should not be mounted in snowy or foggy weather, or when the wind speed is more than 9m/s. The mountage should start on the opposite direction to the wind, in order to prevent the joint surfaces be exposed to wind.

Panels should not be spread around randomly on the roof where they are being mounted, but be piled as a point load. The parts to remain under the panels like accessories for ridge, eaves, and valley should be mounted before the panels. And then, finishing accessories such as corner profil, ridge profile should be mounted.

The roof panels should be screwed from on the top of the undulating panel untill the construction. The screw should have an EPDM gasket. The gasket should be checked from time to time as long as the construction is used, because the damage of the gasket causes the risk to leak. The screw should be chosen as at least three threads longer.

Figure 3. Roof panel montage

Figure 4. Mineral wool filling wall panels

Mineral wool panels, if to be mounted on the concrete purlins on a reinforced concrete carcasse construction roof, the concrete screws should be used over the top of the undulating panel **(Figure 3)**. As the concrete screws don not have threads on their bottoms, upper panel plate and screw cannot join as strong as to bear the load, so, because of the thermal changes and the load on the flexible roof, there happens deformations on the bottoms of the screws, which may again cause the roof to leak. **(Url. 3)** For these reasons, the mountage of the mineral panels on the roofs should be on the concrete purlins with metal profiles, gaskets and screws with threads.

For the isolation filling not to get wet, on roofs, eaves and ridge profiles and on walls, wall coping profiles should be mounted on the same day with mineral wool filling panels **(Figure 4)**. Especially on wall panels, if isolation filling gets wet, it may yield because of gravity.

Sandvich panels which are used for valley on roofing, getting a 10 cm overlapping, before mountage, bottom metal plate should be cut 10 cm and fillings in it should be emptied and then, bottom plate should be twisted. Thus leak of water is prevented. This detail solution should be applied especially for mineral wool panels. Throughout ridge, between the panels which are come from two different surfaces of a roof exist uncovered gap.

Througout ridge, on the upper and bottom surfaces of panels, ridge profile should be mounted and isolation filling should be put in to between these two ridge profiles. In addition ısolation band should be used to prevent of condensation or cold bridge between ridge profile and panels. Frequency of mountage screw determined according to geographical conditions. Overlapping between the consecutive panels should be minimum 15 cm.

According to horizontal or vertical mountage of wall panels mountgage starts up to down or down to up. Choosing convenient screw for wall panels, it is consider, screw should be aable to transfer the loads, which are beared by panels, through carcasse.

In mineral wool panels with hidden screw **(Figure 5)**, excess driving of screw cause to deformation of metal plate of panel. To prevent this kind of deformation “screw inferior plate” should be used. Details for valley, lateral side profile, ridge, wall coping, dilatation, inner-outer corners, door, window and water drip, metal bending profile is used which is the same kind of metal with panels.

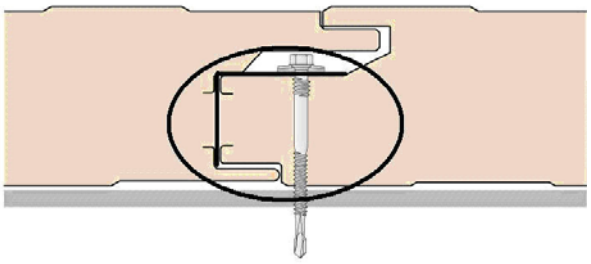

Figure 5. Hidden screw detail

3. CONCLUSION

Sandwich panels, having accelerated the construction speed, been a significant step in prefabrication. The durability of the sandwich panels depend on the production features, the correct combination of components, transportation on determined conditions, storage conditions and a detail design, as well as the performance features.

Experimental Programme to Assess ETICS Cladding Durability

Bruno Daniotti [1]
Riccardo Paolini [2]

T 24

ABSTRACT

The paper reports on the experimental evaluation of the durability of ETICS cladding through accelerated laboratory ageing, which is now being developed by BEST – Polytechnic of Milan. The experimental programme as a whole includes accelerated laboratory ageing, long-term outdoor exposure, comparison and analysis of results. Four types of specimens have been built with masonry wall acting substrate EPS as insulation and polymeric additives incorporated in the base coat mortar. Of the additives included in the mortar, two were prepared with acrylic resin and two with vinyl resin. Additionally, for each type of specimen, one included a typical finishing coat and another one an acrylic painting. For each series of ETICS specimens, a one set will be aged and the other remains as the (cladding system reference set). There are also four pairs of sets of smaller scale samples on which disruptive tests are to be completed. The ageing cycle consists of 125 UV cycles, 125 summer thermal shock cycles and 50 winter thermal shock and freeze-thaw cycles. In order to assess performance decay on the reference specimen and on the aged specimens at the end of their service life, several disruptive tests will be carried out, including: water absorption, water vapour permeability, tensile bond strength of adhesive and of base coat to insulation, render strip tensile tests, and pull off tests. Non-disruptive tests (e.g. record of T [°C], RH [%] and heat flow) are being conducted throughout the ageing process and, at every end of test cycle, characterization tests are carried out to assess changes in thermal conductance, moisture transfer properties, dynamic effects and thermal inertia. Infrared thermography and capillarity tests are also being carried out and photos are taken in order to survey evolution of cladding degradation.

1 INTRODUCTION

This paper portrays structure and methodology of ETICS experimental programme, which has been developed by Durability of building components group (BEST Department – Polytechnic of Milan) since November 2003. The research programme concerns the durability assessment of ETICS (External Thermal Insulation Composite Systems with rendering) also well known as EIFS (Exterior Insulation and Finish System). This building component has been chosen due to its widespread distribution across Europe and North America and the problems concerning its durability. The study has two types of objectives: general and specific ones. General objectives are methodological ones and include: the search for innovative tools useful for Service Life assessment test design, design of methods for estimating service life, design of methods for forecasting degradation and performances decay. On the other hand, specific objectives, more closely related to the performance assessment of ETICS cladding are also sought, and include: observation and measurement of performance decay, qualitative degradation models (for ETICS), and knowledge useful for technology improvement.

This work is linked to studies concerning durability of building components developed by other research units of the Italian Durability network and it's the development of methodologies set during the research activity brought on by BEST in collaboration with SUPSI (Italian Swiss Professional University School) about paintings durability. Main special features and innovations of ETICS experimental programme are:

- Usage of degradation factors and mechanisms analysis as a tool in designing accelerated ageing cycles (not only to find the agents to be reproduced and as preliminary analysis);
- Ageing cycles pre-design with climatic data analysis (not excluding re-scaling with outdoor specimens);
- Dynamic thermal performance decay measurement.

Future targets of research activity are outdoor exposure and time re-scaling got with degradation comparison of indoor and outdoor specimens, design of other specific tests suited for studying ETICS degradation mechanisms. First results are not to be considered as quantitative values, but as a first step in developing a method and a measurement technique suited for assess ETICS and building components durability generally. In particular, in results analysis should be considered errors and approximations due to:

- Ageing cycles not reproducing all agents (e.g. atmospheric pollution, wind and vibrations are not included);
- Limited dimensions and number of specimens;
- Limited number of sensors (iso-determined equation systems);
- Accuracy and measurement errors;
- Prototype research programme.

First results got with accelerated ageing tests concern degradation, water absorption and thermal insulation performance decay (related to water absorption).

2 SPECIMEN DESCRIPTIONS

Four kinds of specimen have been designed: two with acrylic additive in base coat (one with acrylic painting, one with finishing coat) and two with vinyl additive in base coat (one with acrylic painting, one with finishing coat). For each type one specimen to age and one not to (to test as reference for system characterization) are provided and for each type also are tested one big sample reproducing the complete wall (i.e. substrate and ETICS) and sets of small samples (only ETICS on polystyrene) suited for measuring single characteristics (thermophysical and mechanical ones). In order to study each

considered combination of ETICS, small samples are stored inside a climatic chamber and a big sample is used as door of the chamber.

Large-scale samples (100 x 100 x 22,45 cm) are comprised of three mechanically fixed and adhesively bound insulation panels (two panels 50 x 50 cm in the lower part, and one 100 x 50 cm in the upper part) are used in order to reproduce one T joint in the middle of the specimen. Polypropylene anchors are used are fixed in five positions (in four middle points and in coincidence with T joint) and aluminium profiles are used to reproduce boundary conditions and in coincidence with profiles there is a superposition for 10 cm of two sheets of glass fibre mesh. First ETICS kind tested is type A.1.

Table 1. Types of ETICS specimens and related components

Layer	s [m]	*Specimen type*			
INTERIOR		A. 1	A. 2	B. 1	B. 2
Interior finishing	0,005	Gypsum plaster

EXTERIOR					

2.1 Bed Mortar and Plasters

The bed mortar for the masonry brick substrate is pure cement mortar designed, according to proportions suggested by the EMPA (of Dübendorf), whereas the mix design for the lime cement plaster was carried out according to Italian National specifications for masonry construction (D.M. 20/11/87). On the other hand as binder for the polystyrene and as base coat, a pure cement mortar with polymeric additive was used.

Table 2. Mix Characteristics of Bed mortar, Plasters and Base Coat. (w/b: water – binder mix proportion, V/V_{CEM}: volume on cement volume)

Mortar	Bed mortar: w/b = 0.56		Plasters: w/b = 0.67		Adhesive and base coat	
Material	*Type*	*V/V_{CEM}*	*Type*	*V/V_{CEM}*	*Type*	*V/V_{CEM}*
Water		0.83		1.33		0.5
Cement	CEM II/A-L 32.5	1.00	CEM II/A-L 32.5	1.00	CEM II/A-L 32.5	1.00
Sand	EN 196-1 normalized	2.84	EN 196-1 normalized	4.00	0/1 [mm] EN 13139	3.00
Lime	No	-	Hydraulic	0.50	No	-
Additive	No	-	No		Vinyl / acrylic	0.05

2.2 Finishings

Two kinds of finishing systems, characterized by PVC (Powder Volumetric Concentration), are compared: an acrylic painting with PVC 40 and a 1.5 mm thick finishing coat with PVC 80, that

consists of sand (0/1 mm) and an acrylic resin binder plus additives. Both finishings are red, with solar absorbance $\alpha = 0.6$. Surface emissivity is measured as $\varepsilon = 0.82$.

2.3 Construction and Curing Time

Specimens were fabricated inside the laboratory (spraying plaster and base coat to avoid shrinkage) and were allowed a minimum curing time of three months after the installation was completed (five months after construction of substrate) before ageing the first sample. This was done to ensure that the same initial water content for all specimens (reducing the construction water) was maintained.

Figure 1. Sample A.1, Base coat with vinyl additive and finishing coat with acrylic resin.

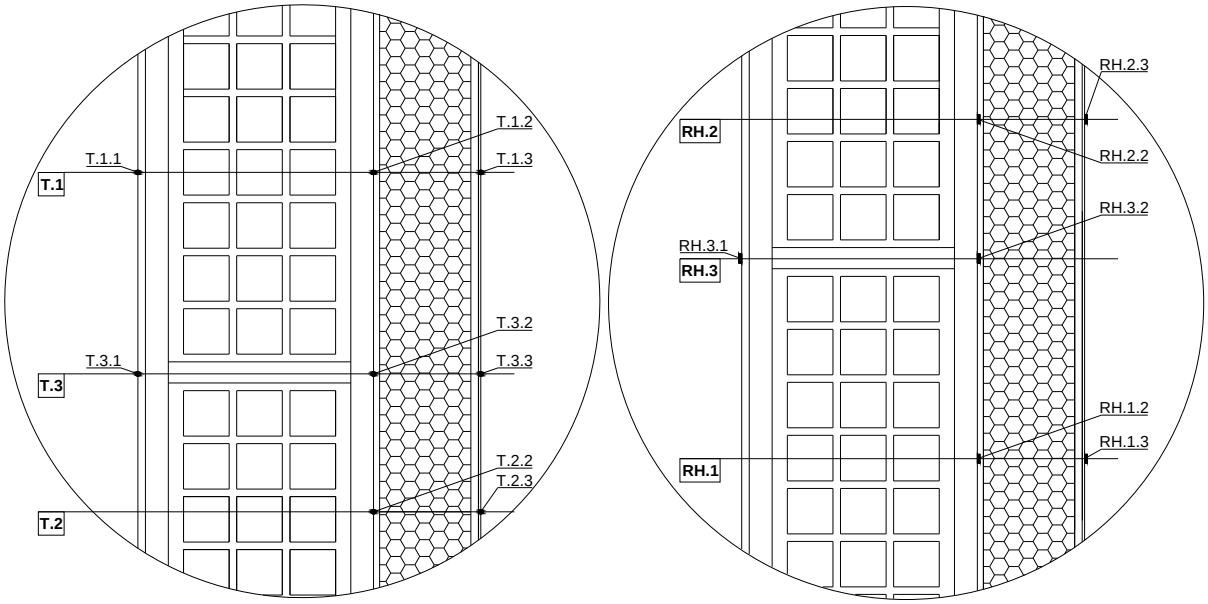

Figure 2. Location of sensors in section RH sensors are placed in the lower part of the sample.

2.3 Measurement Apparatus

For large-scale samples (100 x 100 cm) during the cladding fabrication process, relative humidity (RH) and temperature (T) sensors were placed in the assembly such that three T and RH data profiles could be obtained (one in section, one coincident with EPS panel joints, and one coincident with bed mortar joint). In each profile, sensors were positioned on the interior and exterior surface of the

specimen and between the insulation and the plaster. A heat flow meter was also placed on the interior surface of the main section.

The specimen to age is placed is binded as door of the climatic chamber with a steel frame (separated from it by XPS panels) and it is insulated at boundaries (in order to get a one-dimensional heat flow). Temperature and relative humidity are recorded on the inside of the climate chamber and in the laboratory.

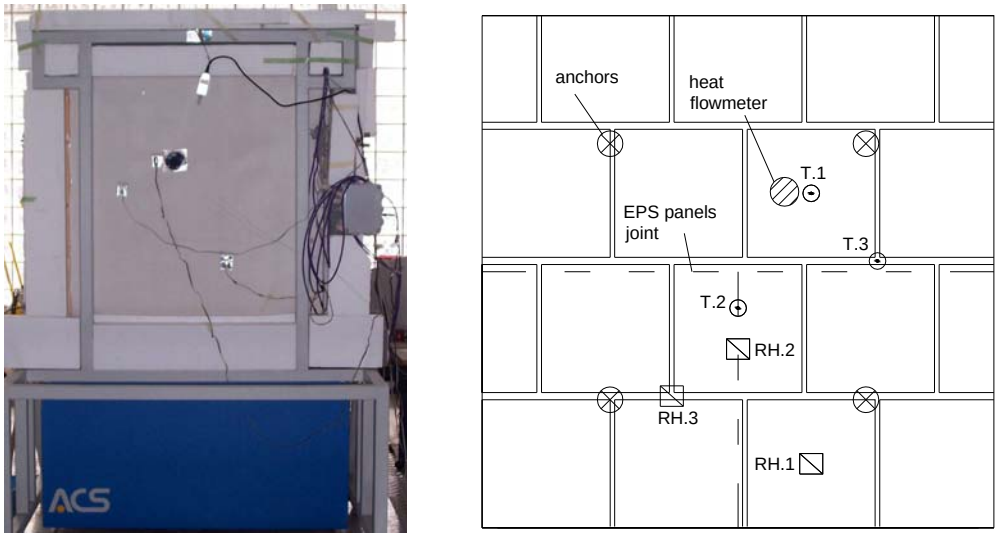

Figure 3. On the left the sample linked to the climatic chamber; on the right sensors profiles position.

3 PREPARATION PHASE

3.1 Degradation Factors

A wide analysis concerning degradation factors and mechanisms (see Daniotti & Paolini [2005]) has been brought on throughout the experimental programme in order to assess which environmental agents must be reproduced and their related intensity, and as well, on which characteristics of the building component are important, that means what to observe to identify the degradation and the performance decay evolution.

3.2 Ageing Cycle

In order to design the accelerated cycles and assess the proportion between its parts, two ways have been pursued: standard reference (ETAG 004) and analysis of climatic data of Milan context (Test Reference Year and UNI 10349). Thanks to this study, three ageing cycles (UV cycle, winter thermal shock + freeze-thaw cycle and summer cycle) have been planned and the proportion between the summer cycles and the winter one set to 2,5. However the correct proportion between summer and winter ones must be determined with time re-scaling, studying the comparison between the degradation of the outdoor exposition specimens and the indoor accelerated ones. The value here proposed has the only intent to be a pre-design value.

Ageing sub-cycles are repeated in order to maintain the proportion 2.5. So in each complete cycle CX there are 25 UV cycles, 10 winter cycles and 25 summer cycles. Complete ageing cycles CX therefore are assembled in groups of five so to get a macro-cycle TX (its overall duration is about one month).

Table 3. Agents included and not included in the ageing cycle. Agents not included cannot be reproduced in laboratory tests or can be reproduced, but not included into an accelerated cycle.

Agent – type of solicitation		*Layer / component of most interest*
Included in the ageing cycle	**Summer and winter thermal shock**	Base coat and finishing
	Freeze - thaw	Base coat and finishing
	Rain	Base coat and finishing
	UV radiation	Finishing
	Cyclic variations in T [°C] and RH [%]	Base coat and finishing, insulation
Not included in the ageing cycle	Pollution	Base coat and finishing
	Mould	Base coat and finishing
	Vibrations	Whole system
	Impacts	Base coat and finishing
	Wind	Anchors, whole system

Table 4. Basic Ageing or Ageing sub-cycles (Note: set point values in bold type).

Basic Cycle	Repeat	N°	Phase	Climatic chamber				Laboratory		
				T_{air} [°C]	T_{sup} [°C]	T_{H20} [°C]	RH [%]	$T_{op,i}$ [°C]	RH [%]	Duration [min]
UV	25	1.1	UV	***35***	-	-	15 ± 2	26 ± 3	60 ± 5	60
Winter	10	2.1	Rain: 1 [lt/m^2]	***5 ± 1***	-	5 ± 1	100	19 ± 2	60 ± 5	60
		2.2	Freeze	***-20 ± 2***	-	-	-	19 ± 2	60 ± 5	180
		2.3	Winter heat	***30 ± 2***	-	-	50 ± 2	19 ± 2	50 ± 5	60
Summer	25	3.1	Dry heat	***70 ± 5***	70 ± 5	-	15 ± 2	26 ± 3	60 ± 5	60
		3.2	Rain	*20*	-	20	100	26 ± 3	60 ± 5	60

4 DEGRADATION AND PERFORMANCE DECAY MEASUREMENTS

In order to observe the decay in performance and the evolution of degradation, two main types of tests are taken into account: disruptive and non-disruptive.

4.1 Non-disruptive Tests

Non-disruptive tests are brought on big specimens before the accelerated exposition (not aged sample) and throughout ageing time every macro-cycle TX (that means every 5 complete cycles = 5 x (25 UV cycles + 10 winter cycles + 25 summer cycles). Two kinds of non-disruptive tests are performed (in this order):

- Qualitative degradation evolution assessment:
- Photographic degradation survey in six fixed positions (one point in the centre, four points in the half of the half of diagonals and one under the centre in coincidence with vertical joint between insulation panels). Degradation evolution is checked according to ISO 4628;
- Non-disruptive capillary absorption test (Karsten's method according to NORMal 44-93) measurement of low-pressure absorption of water volume (in [ml]) by the surface of a porous material at fixed time steps. Results report absorption [lt/m^2] versus square root of time [s^{-1}]
- Hygrothermal performances characterization cycles (record of T [°C], RH [%] and heat flow):
- SINa – Summer dynamic conditions – low wave

Simulation of 21 July outdoor temperature variation in Milan context (according to UNI 10349) without solar radiation influence
Duration: 48 hours (2 sine curves with period of 24 h)
Conditions: T [°C] sine curve: max = 31.9 [°C], min = 20 [°C], amplitude = 12 [°C]

RH [%] = 50 constant

- SINb – Summer dynamic conditions – high wave

Simulation of 21 July outdoor temperature variation in Milan context (according to UNI 10349) with solar radiation influence: air – sun temperature with solar absorbance $\alpha = 0.6$

Duration: 48 hours (2 sine curves with period of 24 h)

Conditions: T [°C] sine curve: max = 65.5 [°C], min = 20 [°C], amplitude = 45.5 [°C]

RH [%] = 50 constant

- TI – Thermal Inertia

Assessment of time constants and thermal capacities.

Duration: 72 hours (3 sine phases of 24 h)

Conditions: T [°C] 24 h at 20 [°C], 24 h at 70 [°C], 24 h at 20 [°C]

RH [%] = 50 constant

- CON – Thermal Conductance in steady thermal state

Assessment of thermal insulation performance decay

Duration: 96 hours

Conditions: T [°C] = – 20 constant

RH [%] = 0 constant (inside the climatic chamber below 0°C must not be water or humid air for technical reasons)

- Infrared thermography

To capture the response of surface temperature gradients on the specimen surfaces during the CON cycle, an infrared thermographic camera is positioned for 24 hours outside the climate chamber, pointing towards the interior surface of the specimen (gypsum plaster),. At the end of ageing time (end of Service Life declared) the specimen is turned round of 180° and another thermography is executed for 24 hours (T = - 20 [°C] inside the climatic chamber) in order to assess the evolution of thermal bridges in coincidence with joints between insulation panels.

- RHst – Relative Humidity stabilization

Assessment of stabilization time of relative humidity (and so water content) only for the exterior layers (base coat and finishing).

Duration: 8 hours (4 phases of 2 hours each)

Conditions: T [°C] = 35 [°C] constant

RH [%]: 2 h at 20 [%], 2 h at 50 [%], 2 h at 80 [%], 2 h rain 1 [Lt/m^2]

A longer exposition (to assess moisture changes inside the whole sample) could influence the overall thermal capacity and alter ageing tests storing an excessive moisture amount.

4.2 Disruptive Tests

Disruptive tests are performed both on non-aged samples (characterization tests) and on aged samples when the end of Service Life is reached. Disruptive tests prepared for this experimental programme are: water absorption, water vapour permeability, tensile bond strength of adhesive and of base coat to insulation, render strip tensile test.

Other disruptive tests, such as resistance to hard body impact or resistance to perforation, could be executed, but the analysis of test methods highlighted that they do not offer numeric results and they are have to be evaluated without a precise scale.

Disruptive tests are so performed both on large samples (1m^2) and on sets of selected smaller scale samples (as prescribed by the specific standards), that incorporate only the ETICS cladding component and not the masonry substrate. A set of small specimens (for all disruptive tests) is stored inside the climatic chamber and a comparison between results obtained by tests on these small aged samples and the ones obtained by tests carried on cores taken from large-scale aged samples are compared in order to help understand the influence on degradation of different position inside the chamber, different dimensions of samples and of constraints given by substrate and plastic anchors.

Table 4. Disruptive tests, dimension and number of samples and standard test method chosen.

Test	*Sample dimensions*	*N°*	*Standard*
Water absorption (capillarity test)	200 x 200 mm	3	ETAG 004 - § 5.1.3.1
Water vapour permeability	Round samples: A > 5000 mm^2	5	EN 12086
Render strip tensile test	600 x 100 mm. Mesh length: 800 mm, (100 mm leaning out at boundaries)	3	ETAG 004 - § 5.5.4.1
Tensile bond strength of adhesive and base coat to insulation	200 x 200 mm	3	EN 13494

5 CONCLUDING REMARKS

Ageing tests are in progress on specimen Type A.1 that includes a vinyl resin base coat and finishing coat, the preliminary results being given in Daniotti & Paolini [2008]. Other tests related to improving knowledge of the evolution in performance decay and degradation are now being studied, whereas specific tests suited for understanding degradation mechanisms are now being designed. For example, tests methods are being devised for determining if capillary absorption properties vary more significantly in the base coat or finish coat and the phenomena that cause such variations). On the other hand, ageing tests on all specimen types in an on-going process and outdoor exposure tests will also be performed in the future.

Defacement of ETICS Cladding Due to Hygrothermal Behaviour

Eva Barreira [1]
Vasco Peixoto de Freitas [2]

T 24

ABSTRACT

External thermal insulation systems for walls (expanded polystyrene insulation faced with a thin rendering) – ETICS – have been used in Portugal since the nineties. Despite the thermal advantages, Portuguese buildings covered with ETICS are faced with a huge and yet unsolved problem: the system's defacement caused by microbiological growth.

In recent years, although several studies have been carried out to solve this problem, the practical conclusions are not very satisfactory: so far the only feasible solution is to use biocides. These chemical products are not environmentally friendly and are considerably expensive because of their short-term effectiveness.

To obtain a less expensive solution to this problem, it is essential to first understand the hygrothermal behaviour of façades covered with ETICS, namely, the dynamic heat exchange between the ETICS exterior layer and the atmosphere. It is also very important to study the influence of the surface's orientation and the local climate.

This paper presents the results of an experimental characterization of ETICS' hygrothermal behaviour performed by the Building Physics Laboratory (LFC) of the Faculty of Engineering of Porto University (FEUP). "In-situ" tests are being carried out on a building covered with ETICS located in Portugal's northwest region.

1 INTRODUCTION

External thermal insulation composite systems (ETICS) have been applied on a somewhat regular basis in European buildings since the 70's. The systems' main advantages are guaranteed continued thermal insulation, thinner exterior walls, greater thermal comfort due to the higher interior thermal inertia and ease of application. The latter is particularly important in refurbishment since it may be applied without disturbing the building's dwellers [Freitas 2002].

However, past applications of ETICS have revealed some problems, particularly low impact resistance and diminished long-term durability. The scientific community has performed various studies to fully characterise these systems, to measure the properties of the respective materials, to identify the main problems and, in some cases, to develop solutions [Hens & Carmeliet 2002].

One of the problems not yet solved is the cladding defacement due to accumulated dirt and, in particular, microbiological growth (Fig. 1). Studies already performed in this field were not very satisfactory since, although the phenomenon is known, the only feasible solution is to use biocides which imply economic and, in particular, environmental drawbacks.

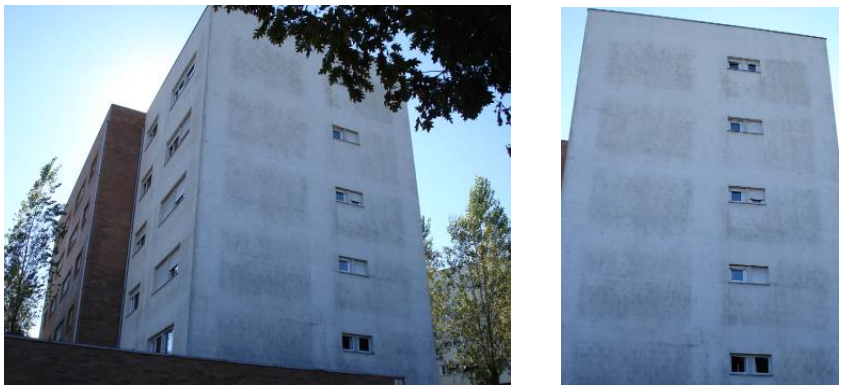

Figure 1. Building covered with ETICS showing microbiological growth.

During the last decade, studies have been performed about the physical phenomenon that promotes microbiological growth on the surface of ETICS [Kunzel & Sedlbauer 2001; Becker 2003]. It is known that the longwave radiation exchange between the exterior surface and the atmosphere during the night causes the ETICS' surface temperature to drop [Kunzel & Sedlbauer 2001; Zillig *et al.* 2003; Holm *et al.* 2004]. Condensation forms when the exterior surface temperature is lower than the dew point temperature. If the drying process is not sufficiently fast, the surface moisture content remains high for long periods and consequently increases the risk of microbiological growth [Krus *et al.* 2006].

Knowledge of this physical phenomenon made it possible to develop mathematical models simulating heat and moisture transfer between the system's exterior surface and the atmosphere [Kunzel *et al.* 2002; Becker 2003]. However, no simple process has yet been developed to foresee the degradation of exterior thermal insulation systems and which may be used by designers and by ETICS application companies.

It is therefore essential to study the causes underlying the degradation of ETICS. This is the only way to develop rules that will guarantee its durability.

2 DEFACEMENT OF ETICS CLADDING

ETICS cladding represent a substantial market share of external thermal insulation systems for façades. Its growing popularity was, however, undermined by some pathologies [Freitas 2002].

Although no statistical studies are available, we may presume that there are a relatively high percentage of cases where algae and fungi have grown on the façades of Portuguese buildings coated with ETICS, particularly when located in coastal zones. Portugal's climate aggravates the problem, particularly in the west coast, which has relatively mild temperatures and very high relative humidity year-round (Fig. 2).

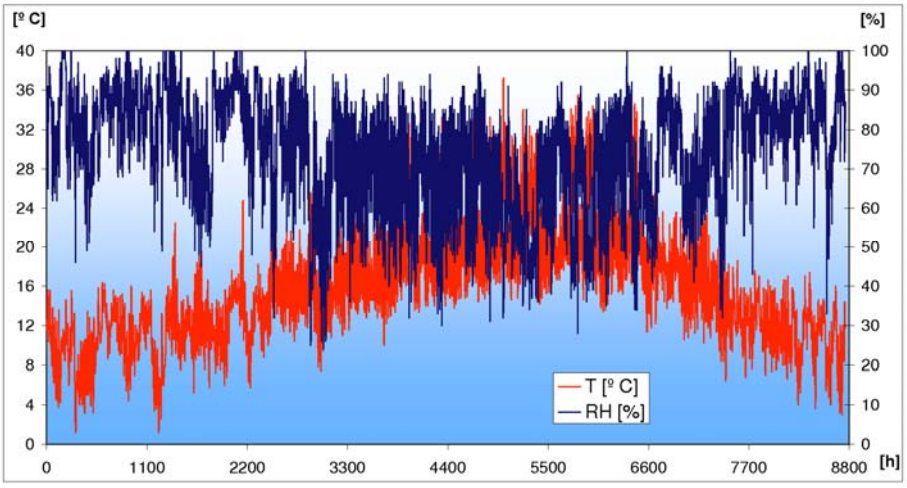

Figure 2. Annual outdoor temperature and relative humidity variations in Lisbon (TRY)

Degradation due to microbiological growth occurs, in particular, on façades facing north and west, since their coating's high surface moisture content is maintained for longer periods.

3 LONGWAVE RADIATION EXCHANGE

Superficial condensation, which takes place predominantly during the night, is caused by a longwave radiation exchange between the exterior surface and the atmosphere. Although radiant exchange occurs on all exterior surfaces, it has more serious consequences on components with substantial thermal insulation – which reduces the flow of heat through the construction element practically to zero – and on components whose thin exterior layer has a very low thermal inertia, as in the case of ETICS [Kunzel & Sedlbauer 2001].

The radiant balance of the building's façade is affected by three parameters: the building's radiation, the sky's radiation and radiation emitted by terrestrial surfaces located near the building (Fig. 3).

A building emits longwave radiation with a total intensity, E_b, calculated according to the Stefan--Boltzmann Law:

$$E_b = \varepsilon_b \cdot \sigma \cdot T_b^4 \qquad (1)$$

T_b Surface temperature

$\sigma = 5{,}6704 \cdot 10^{-8} \quad W \cdot m^{-2} \cdot K^{-4}$ Stefan-Boltzmann constant

ε_b Surface emissivity

On the other hand, the façade absorbs part of the longwave radiation emitted by surrounding objects (terrestrial radiation) and by the sky (atmospheric radiation) [Holm *et al.* 2004]. Terrestrial radiation is caused by the sum of longwave radiation emitted by the different terrestrial surfaces whose temperature is similar to the building's temperature. Since the temperatures are identical, the radiation exchanges between the building's surface and the surrounding surfaces are somewhat balanced.

Figure 3. Radiant balance of a building's façade.

Atmospheric radiation depends mostly on what comprises the atmosphere and may behave in two distinct manners. If the sky is cloudy, the atmosphere behaves like a grey body whose temperature is the same as the building's, and emits radiation in a continuous spectrum at an intensity similar to that of terrestrial surfaces. If the sky is clear, the atmosphere stops emitting continuously for all wavelengths. In wavelengths between 8 and 13 μm, the atmosphere's emitted radiation is decreased considerably mostly due to the influence of molecules of water, carbon dioxide and ozone. Since the maximum intensity emitted by all terrestrial surfaces occurs for 10 μm, there is a loss of radiation to the sky which is not compensated by atmospheric radiation.

This negative balance that is not compensated by solar radiation during the night causes the building's superficial temperature to decrease, which is maintained until heat transport by convection and by conduction compensate for the loss by radiation [Holm *et al.* 2004]. Condensation takes place whenever the superficial temperature is lower than the dew point temperature. The accumulation of condensed water creates favourable conditions for algae and fungi growth.

Algae is able to grow when the relative humidity on the façade's surface is greater than 70%-80%, within a temperature range between 0º and 40º C. Algae can withstand long dry periods and then begin to flourish again when enough humidity is available. Consequently, a dry surface during the day is not sufficient to prevent algae growth [Zillig *et al.* 2003]. Fungi require a minimum relative humidity of 80% to grow. However, and unlike algae, fungi need nutrients to grow, a factor which depends on the finishing layer's materials [Zillig *et al.* 2003].

4 EXPERIMENTAL STUDY

4.1 Setting Up the Test

To evaluate exterior superficial temperature variations on the ETICS, instruments were set up on the façades of a low building in the Northwest of Portugal whose walls face the four cardinal directions (Figs. 4 and 5).

While the system was being applied, in April 2007, T-type thermocouples (copper constantan) were placed inside the system on the four façades, at about 1 m from the ground, as shown in Fig. 5. Three thermocouples were placed on each façade wall (on the interior side of the thermal insulation, between the thermal insulation and the rendering and on the rendering's exterior surface). A second thermocouple was placed on the North and West façades, on the exterior surface of the rendering next to the North/East and West/South corners, respectively. Two temperature and relative humidity sensors were also installed, coupled to a data acquisition system, to monitor the hygrothermal conditions (temperature and relative humidity) inside and outside the building.

Figure 4. Building where the measurements are being taken.

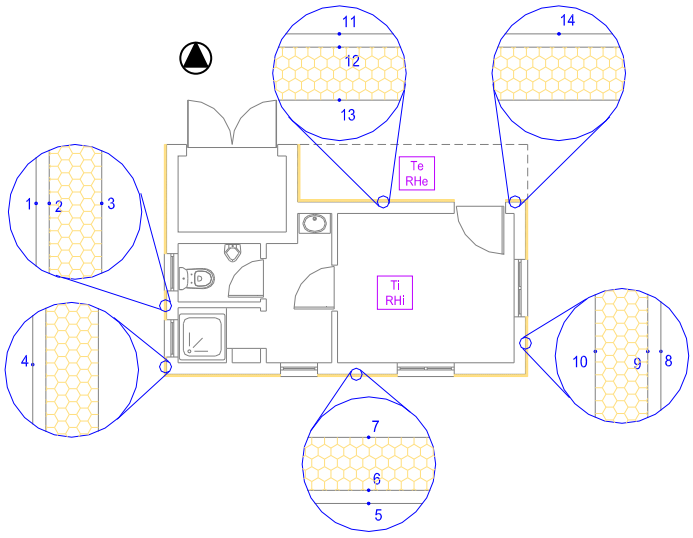

Figure 5. Layout showing thermocouple locations.

4.2 Results

The temperature and relative humidity measurements inside and outside the building (Fig. 6), between 17/05/2007 and 14//06/2007, reveal that:

- The exterior temperature varies from 11º C to 31º C;
- The exterior relative humidity is relatively high, on average about 76%;
- The interior temperature is somewhat constant and of about 24º C;
- The interior relative humidity is, on average, of about 64%.

In the same period, the temperature variation in the ETICS of the West façade's wall is indicated in Fig. 7 and 8. These graphs also indicate the dew point temperature (Tdp), witch is dependant on the exterior temperature and relative humidity. An analysis of the data measured in the façade wall reveals that:

- The temperatures measured by the T1 and T2 thermocouples are very similar: remain somewhat constant during the night, increase progressively at dawn and morning and reach their maximum at about 18:00 h;
- The maximum temperatures measured by the T1 and T2 thermocouples varied from 23º C to 52º C, and the temperatures measured during the night varied from 10º C to 18º C;
- The temperatures measured by thermocouple T3 ranged from 17º C to 29º C, and the maximum temperature occurred at about 19:00 h. Note that the temperature measured by the T3 thermocouple differed, on average, by about 2º C from the interior temperature.

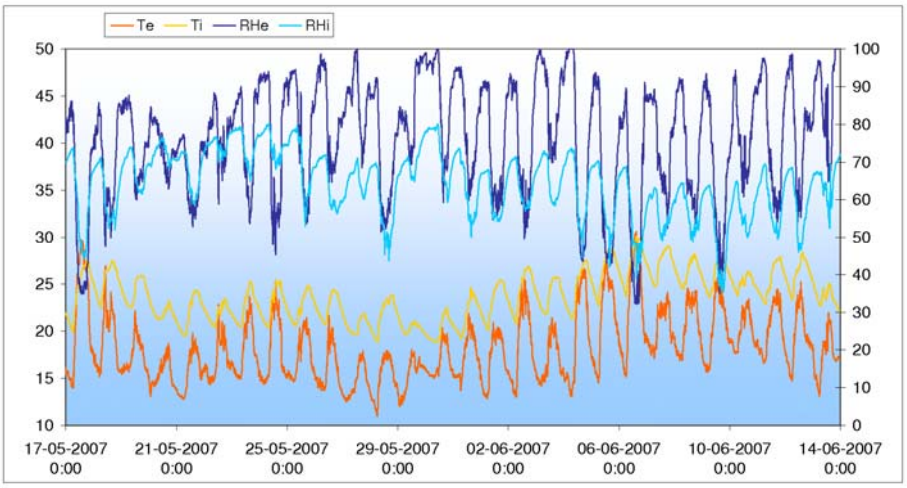

Figure 6. Interior and exterior temperature and relative humidity (17/05/2007 to 14/06/2007).

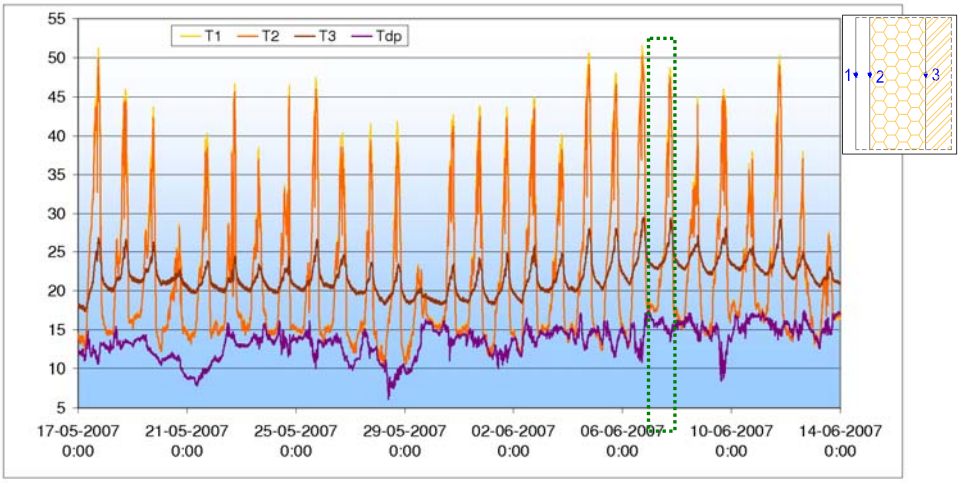

Figure 7. Temperature variation in the ETICS and of the dew point temperature (17/05/2007 to 14/06/2007).

By comparing the exterior superficial temperatures of the ETICS, obtained by the T1 thermocouple, with the dew point temperature (Tdp), we were able to determine the differences between the two temperatures. The graph in Fig. 9 shows only the negative temperature differences (superficial temperature lower than the dew point temperature), whereby the positive temperature differences were taken as equal to zero. The graph in Fig. 10 defines the total daily time during which superficial condensation takes place in the west façade's wall.

4.3 Review of Results

An analysis of the results obtained until now reveals that:

- The thermal resistance of the ETICS' exterior layer is practically nil, since the temperatures on the two sides are very similar. This result was foreseeable because of the thin exterior layer.
- The temperature on the inner side of the thermal insulation varied about 5º C during the day and is relatively similar to the temperature inside the building.
- Condensation takes place whenever the surface temperature is lower than the dew point temperature. In the period under analysis, surface condensation took place during less than 10% of the time.

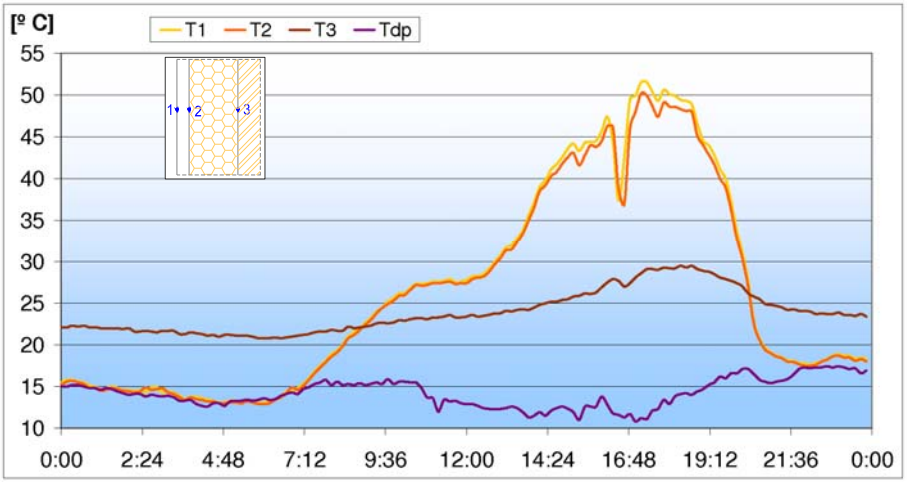

Figure 8. Temperature variation in the ETICS and of the dew point temperature on 06/06/2007.

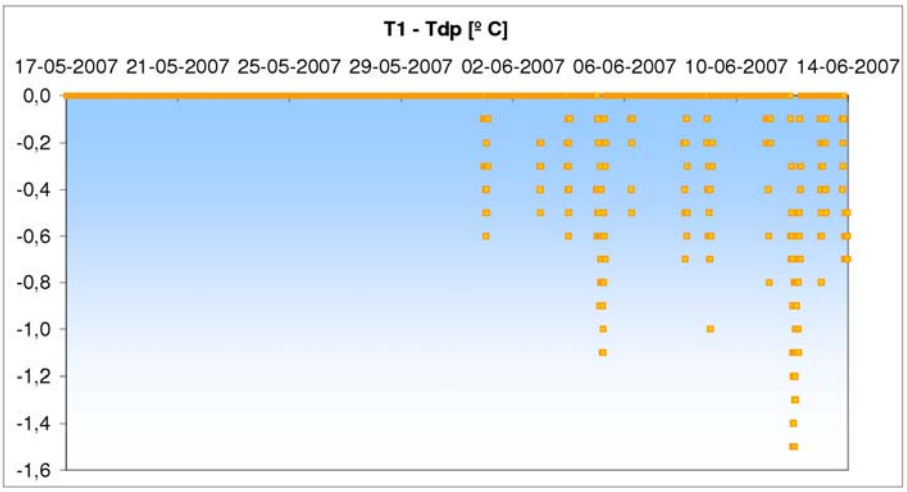

Figure 9. Difference between the superficial temperature of the ETICS and the dew point temperature (17/05/2007 to 14/06/2007). Positive temperature differences were taken as equal to zero.

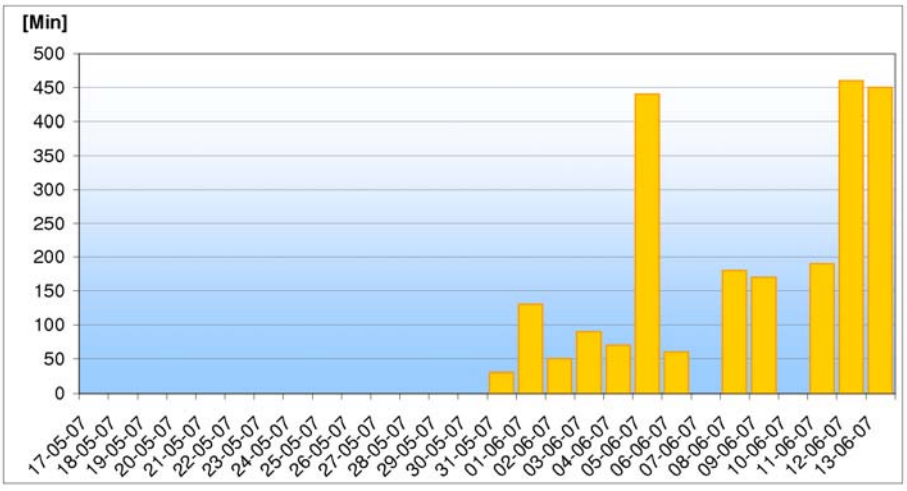

Figure 10. Period during which superficial condensation took place (17/05/2007 to 14/06/2007).

4 CONCLUSIONS

ETICS have been applied regularly in Portuguese buildings. However, despite their advantages, the cladding defacement is a very worrisome pathology. Increased suface moisture content, caused by nighttime condensation, is one of the factors that influence this aeshetical degradation. Superficial condensation is caused by radiative cooling of the surface, which is more detrimental during the night due to the lack of incident solar radiation. ETICS are highly susceptible to superficial condensation.

Instruments were placed on a small building in the Ovar zone to evaluate superficial temperature variations in ETICS. Measuredata is being collect since May 2007, making it possible to evaluate the period during which superficial condensation takes place and the difference between the superficial temperature and the dew point temperature.

In the future, the authors wish to maintain this experimental program by continuing to collect data during autumn and winter. Superficial temperature variations according to the orientation will also be evaluated.

ACKNOWLEDGMENTS

The authors would like to thank Iberfibran – Poliestireno Extrudido, SA for having created the necessary conditions to carry out this experimental campaign.

Durability of External Wall Insulation Systems with Extruded Polystyrene Insulation Boards

Durmus Topcu [1]
Holger Merkel [2]

T 24

ABSTRACT

External wall insulation systems (ETICS = External Thermal Insulation Composite Systems) are one of the most common insulation systems in Europe. The systems are designed to provide the appropriate thermal insulation of the wall.

An ETICS comprises the thermal insulation product and a reinforced render. The insulation boards are bonded onto the wall either by an adhesive or a mechanical fixation or a combination of both. External thermal insulation systems with extruded polystyrene boards (XPS) are widely used in Turkey and other European countries.

The paper shows results of durability tests done at laboratory scale as well as results and findings from building projects.

The durability tests were carried out using hygrothermal test facilities to simulate heat, rain and frost conditions. The results show the high tensile bond strength between the render system and the XPS insulation boards after simulated ageing of the ETICS. Due to very low water absorption of the XPS type used there is no risk of moisture accumulation within the system. This is of high importance for the durability of thermal performance of the whole construction.

The test results are in good correlation with practical experience. Examples of ETICS with XPS insulation will be provided.

1 INTRODUCTION

Europe continues to waste at least 20% of its energy mainly due to thermal inefficiency of buildings [EC 2006].

The most cost and energy efficient measure to reduce energy consumption and CO_2-emmissions is thermal insulation of buildings, which in addition improves the indoor-air quality and the living comfort. It has a significant impact on the durability of a building by reduction of ageing of the building structure due to thermal and moisture impact.

The total ETICS (ETICS = External Thermal Insulation Composite System) market in Turkey has reached around 10MM m^2 in 2006 and expected to reach to 40MM m^2 in coming 5 years time. The average growth rate of ETICS market has been 35% in last 5 years. This growth is coming both from new buildings and also very strong renovation segment.

2 EXTRUDED POLYSTYRENE FOAM –XPS

XPS is produced by a continuous extrusion process which finally forms a homogenous closed cell foam structure.

Variations in the slot die allow board thicknesses between 20 mm and 200 mm. After passing through a cooling zone, the board edges are trimmed. The smooth foam skin resulting from the extrusion process remains on the boards or is removed mechanically (planed) for particular board types to achieve better adhesive strength in combination with e.g. concrete, mortar, or construction adhesives.

XPS foam is a standardized insulation product which complies with harmonized European Product Standard [EN 13164:2001] and the corresponding Turkish standard [TS 11989 EN 13164].

XPS insulation products have a closed-cell structure throughout the foam.

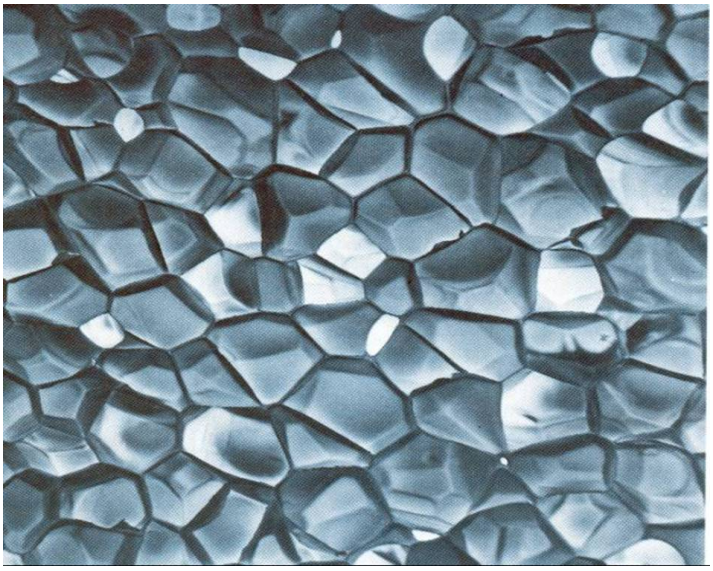

Figure 1. typical closed cell structure of XPS (Photo: Dow Building Solutions).

Extruded Polystyrene Boards, such as Styrofoam do not contain capillaries. This is important especially for exterior wall areas which are close to ground level. Liquid water cannot be transported within the foam behind plaster.

The typical water absorption characteristics are listed in Table 1.

Table 1. Requirements in terms of water absorption for XPS insulation products, in accordance with [EN 13164:2001].

Water absorption characteristics	Thickness [mm]	Limit value [Vol-%]	EN code (EN 13164)
by diffusion	50	≤ 3.0	WD(V)3
by diffusion	100	≤ 1.5	WD(V)3
by diffusion	200	≤ 0.5	WD(V)3
after freeze-thaw	40 – 200	≤ 1.0	FT2
by full immersion	40-200	≤ 0.7	WL(T)0.7

Extruded polystyrene is a thermoplastic material which demonstrates visco-elastic behaviour [Merkel 2004].

The homogeneous closed structure of XPS provides high mechanical resistance; e.g. tensile strength and shear strength [Strzepek 1990]. Additionally XPS exhibits a high resistance against forces pulling through mechanical fixations. These properties are important for the resistance of the ETICS against wind load. The robustness of an XPS product makes it ideal for handling under the tough conditions on a job-site.

The XPS products manufactured according EN 13164 are subjected to a continuous factory production control (FPC) of properties. In some European countries; e.g. France and Germany the application related product properties are certified by independent institutes (notified bodies). Thus quality and compliance of XPS products with the product standard is assured.

3 REQUIREMENTS FOR INSULATION PRODUCTS IN ETICS

The requirements for the insulation component of the system are specified in [ETAG004].
These are related to:

- Thermal resistance
- Water absorption
- Water vapour permeability
- Tensile strength
- Shear strength
- Reaction to fire

The XPS products are classified as reaction to fire class E according to the European Standard EN 13501-1. In Turkey, XPS products shall meet the requirements of German Fire Classification B1 [DIN 4102]; e.g. Styrofoam Shapemate IB.

The water absorption by partial immersion shall not exceed 1kg/m² after 24 hours.

The value has been established to cover also Mineral Wool and EPS products. For XPS the value is close to zero. Low water absorption means the performance is unaffected by moisture in this application.

The μ-value (water vapor diffusion resistance factor) shall be declared. There is however no requirement for a specific μ-value of the insulation. This is obvious, since the water vapour transport and the moisture behaviour of the wall is determined by the entire build-up with all layers and the internal and external climate conditions.
The minimum tensile strength shall not be lower than 80kPa. For XPS the declared tensile strength perpendicular to the surface is >100kPa. Actual values (provided by Dow Building Solutions) are

between 400kPa and 500kPa. The shear strength is well above the required value of ≥ 0,02 N/mm² (20kPa). Actual values are about 0,20 N/mm² (200kPa).

The shear strength is very important for the mechanical resistance of bonded systems to carry the permanent weight of the system.

The surface of XPS boards for ETICS application shall be planed which allows sufficient tensile bond strength between render and insulation. Products with a smooth skin type of surface are not appropriate.

The thermal conductivity of XPS boards is sufficiently low to meet the energy savings requirements. Typical values for XPS products; e.g. Styrofoam Shapemate IB are in the range of 0,030 W/(mK) up to 60mm thickness according to Turkish Standard.

4 TESTING OF ETIC-SYSTEMS WITH EXTRUDED POLYSTYRENE FOAM (XPS)

It is undisputable that the hygro-thermal wall-test is most important for the determination of the durability of an ETIC-System.

The results reported in this paper were obtained from tests performed in a test facility with two walls forming the envelop of a closed climatic chamber (see Fig. 3).The test conditions were more severe than required in [ETAG004].

The two completed test walls (after 28 days drying) were assembled into the test rig. The arrangement of the test rig is shown in Figs. 2 and 3.

Hot air at 70°C was circulated into the test chamber for a period of 3 hours. After this time, the supply of hot air was terminated and a water spray of at least, 1.0 liter per square meter of wall area per minute was applied to the rendered surface of the wall. The water spray was maintained for a period of 3 hours. These conditions were maintained over 140 cycles.

After the cycles, the walls were subjected to a series of twenty 24 hour cycles consisting of exposure to a temperature of 30°C for 8 hours and exposure to a temperature of minus 20°C for 16 hours.

The water flow rate to the spray head was calibrated before the test began, which confirmed a rate of 1.25 liter per square meter of wall area per minute. Measurements of the water temperature during the test indicated that the temperature varied between 15°C to 18°C.

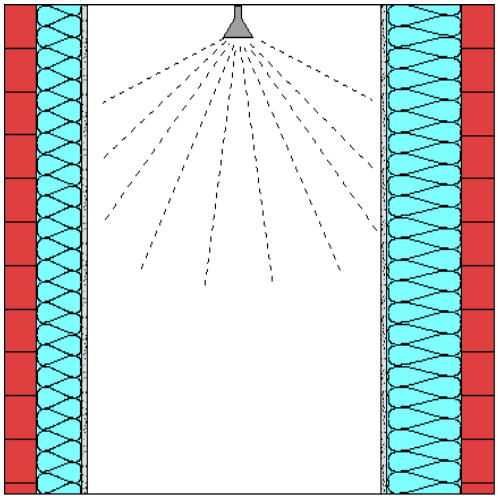

Figure 2. Schematic design of “two wall” test rig.

The test is halted briefly during the heating and moisture cycles for observation after 8, 20, 35, 49, 60, 81, 95, 107, 120 cycles.

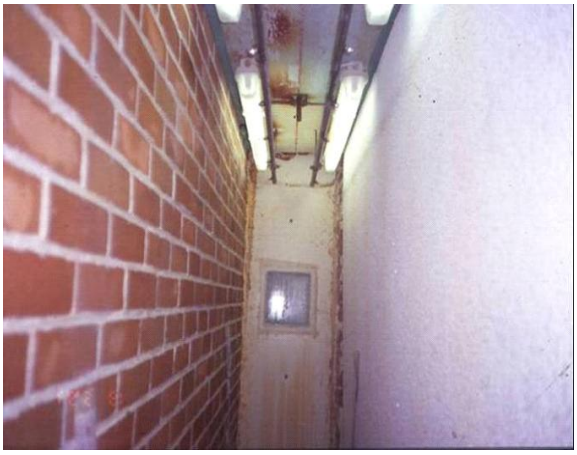

Figure 3. A look into the test chamber; two walls on the left and right side can be tested (Photo: Dow Building Solutions).

The durability of a system can be characterized by determining key parameters, e.g.

- Water absorption
- Tensile bond strength between base coat and insulation

after the hyrothermal test.

Figure 4 shows the water content of the insulation after hygro-thermal ageing of an ETIC-system under the above mentioned test conditions. In general the water content is rather low for the products tested. But it is obvious that the XPS insulation products contains only a negligible amount of water due to their high water resistance.

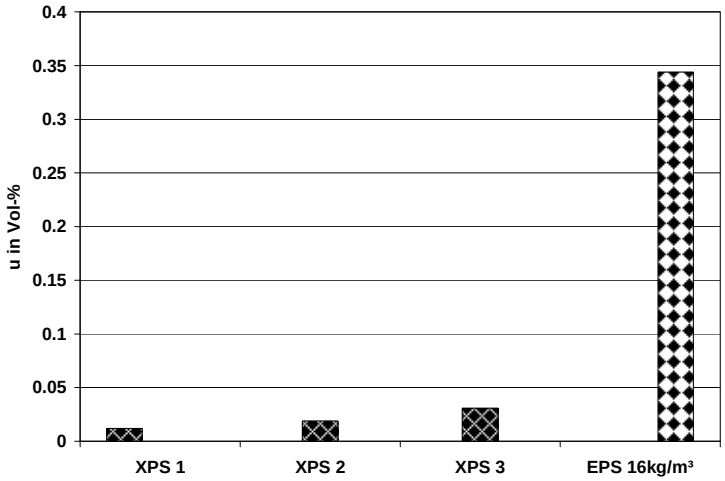

Figure. 4. water content of the insulation after hygro-thermal ageing for XPS and EPS products.

The water absorption by long-term fully immersion was tested separately according to [EN 120875]. Typical results are listed in table 2. Some values in the third column of this table were converted into kilogram water absorbed per square meter. This makes it possible to compare with water absorption values determined according EN 1609 [EN 1609]

Table 2. Water absorption (WA) after long-term (28 days) fully immersion for planed XPS.

Thickness in mm	WA in m³/m³ (Vol-%) acc.[EN 1609]	WA in kg/m²	WA in kg/m² acc. [ETAG004]
40	0,52	~ 0,07	~0,01
50	0,45		
50	0,58		
60	0,75	~0.14	
80	0,30		
80	0,61	~0,13	

When comparing the values it has to be taken into account that the test conditions of EN 12087 are much more severe than those of EN 1609. This is very important regarding the assessment of durability under moisture impact.

The tensile bond strength between the base coat and the XPS insulation depends on the composition of the base coat and the surface properties of the foam.

The durability of the tensile bond strength is exemplified by values given in Fig. 5. The test has been performed according to [ETAG004]. It is obvious that the adhesion between base coat and insulation significantly depends on the performance of the base coat itself, given that the surface of the insulation provides sufficient porosity.

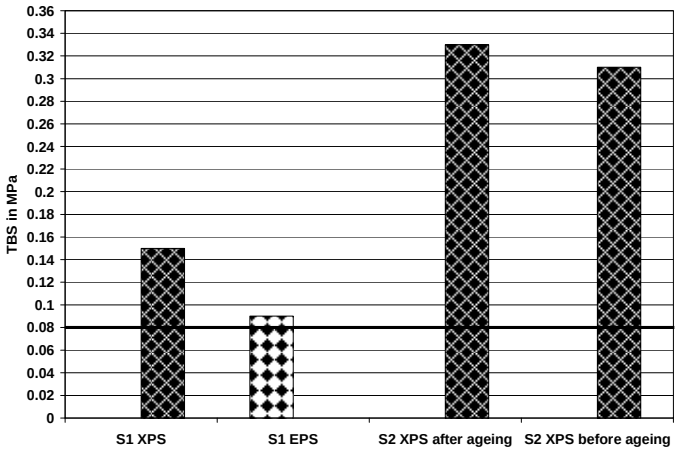

Figure 5. Tensile Bond Strength (TBS) after ageing between base coat and insulation for two different render Systems S1 and S2.

The impact of hygrothermal ageing on the tensile bond strength properties of systems with XPS is rather small as shown in Fig. 5. The required minimum tensile bond strength of 0,08 MPa [ETAG004] is sufficiently exceeded by both systems.

5 APPLICATION OF XPS IN ETICS

From a building physics point of view the external thermal insulation is the preferred solution for wall insulation. The problem of thermal bridges can be easily solved. There is no need for internal vapor retarder (barrier) like for internal thermal insulation solutions. The water vapor resistance is decreasing from inside to the outside of the construction. This means that the construction gets the more diffusion open the more externally the layer is located. Water vapor gets not blocked at the outer layer of the wall. There is no risk of interstitial condensation.

Extruded Polystyrene Foam does not contain capillaries due to the closed cell structure. Hence there is no capillary moisture transport through the foam. This prevents moisture absorbed by the render during a rain period from penetrating into the system. The moisture will dry out to the outside.

The improved moisture resistance of XPS over other insulation materials [Merkel 2002] is of great importance in areas where the ETICS is connected to other structural parts of the building, in particular to perimeter insulation. Moisture from the ground cannot penetrate behind the render via the insulation.

The durability of XPS makes the products applicable to wall construction of highly exposed multistory buildings as shown in Figs. 6 and 7. Even under warm climate conditions XPS based systems show good long-term performance [Concesion 189]

Figure 6. ETIC-system applied to multistory building in Istanbul/Turkey (Photo: MARDAV).

Figure 7. ETICS with XPS after ~15 years of service. No cracks nor blisters are detectable. (Photo: residential buildings in Guadalaraja/Spain).

6 SUMMARY

There is positive experience with XPS in external rendering applications for a long time. Millions of square meters were installed over the last 20 to 30 years in Europe.

The results of hygrothermal ageing tests and the practical experience demonstrate the durability of XPS based ETICS provided that the different building materials layers and their interaction were properly designed and tested.

Extruded Polystyrene Foam (XPS) is a standardized insulation product according EN 13164 and is widely and successfully used for external rendering applications in a number of countries for decades. The main advantages of XPS in ETIC-System are:

- high water resistance,
- closed cell structure of the entire foam, no capillaries, no gaps between cells,
- high shear strength, to carry the permanent load of the system,
- high tensile strength,
- high impact strength,
- appropriate vapor transport performance to avoid condensation risk in moderate and in warm climates.

Hence, extruded polystyrene foam manufactured according EN 13164 or TS 11989 EN 13164 is well suitable as insulation component in ETIC-Systems and meets the requirement of durability.

Durability of Repaired Concrete Facade Elements

Riccardo Nelva [1]
Roberto Vancetti [2]

T 24

ABSTRACT

This paper illustrates the major criteria for designing and performing repairs on reinforced concrete facade elements, as identified through experimental investigations of repair durability and work at a pilot site. A number of fundamental aspects of repair work are discussed, including the need to understand the causes of degradation and the condition and characteristics of the area to be repaired, the need to develop a correct design procedure that specifies each stage of repair, and the need to identify the methods for monitoring and inspecting repairs that are most appropriate from the standpoint of durability.

A series of experimental investigations have been carried out at the Politecnico di Torino Second School of Engineering in Vercelli, together with the LTS laboratory at DACD - SUPSI of Canobbio (CH), and with the cooperation of a number of manufacturers in the sector. Through this work, accelerated aging tests for repair mortars were developed, product behavior was analyzed, and comparative tests were carried out on the basis of recently issued European standards EN 13687-2 and 13687-4. The experience gained during work at the pilot site demonstrated the advisability of approaching repair projects case by case, analyzing the specific deterioration conditions, performing preliminary investigations, and planning repair work on an ad hoc basis for all stages, from selecting the products to be used to specifying application methods. To ensure durability, it is essential that the critical stages of repair work be monitored through on-site tests.

1 INTRODUCTION

The large number of buildings with reinforced concrete elements and structural members, the fact that many of these buildings are several decades old and some are now approaching the hundred-year mark, recent environmental changes that expose concrete to extremely aggressive conditions, and the poor quality of the construction techniques prevailing in the latter half of the 20th century have all combined to draw attention to the problem of degradation in concrete masonry units and products, and to their protection, maintenance and repair.The economic issues that these problems raise thus affect all kinds of buildings, including residential and non-residential civil construction as well as industrial construction.

Concrete's durability is affected by a number of factors. Essentially, these factors can be classified as either chemical, resulting from aggressive environmental pollutants, physical or mechanical. For building structures exposed to air, one of the major factors contributing to degradation is the action of carbon dioxide and the resulting phenomenon of carbonation. As is known, in fact, the durability of reinforced concrete structures is heavily dependent on the protection which the concrete affords to the metal reinforcement: the concrete creates a highly alkaline environment which blocks the onset of oxidation reactions on the part of the rebars. Cured concrete is permeable to gases to some extent, which allows carbon dioxide and other atmospheric pollutants to convert alkaline hydrates into carbonates, thus lowering the initial high pH and making it possible for the reinforcing steel to oxidize, giving rise to further concrete degradation phenomena such as spalling, etc..

The problems associated with concrete's durability in this connection have received extensive attention since the 1960s, with studies; a number of technical guides have also been published, including those produced by the ACI (1996, 2003) together with the BRE and ICRI. Recent experimental studies have addressed the durability of mortar repair techniques and the accelerated aging tests developed to assess them. As regards European standardization, a number of recent UNI EN standards have been issued for "Products and systems for the protection and repair of concrete structures". These standards specify reference concretes for testing (UNI EN 1766 - 2001) and types of mortars and resins (UNI EN 1504.1 - 2000), general principles for the protection and repair of concrete structures and the requirements and properties of the products and systems used (UNI EN 1504.3 – 2006), and accelerated aging test methods (UNI EN 13687-2, 13687- 4).

2 PHENOMENA AFFECTING THE DURABILITY OF REPAIR WORK

This paper illustrates the major criteria for designing and performing repairs on reinforced concrete facade elements, as identified through a series of experimental investigations of repair durability and the experience gained through work at a pilot site. In particular, a number of fundamental aspects of repair work are discussed, viz.: the need to determine the condition and characteristics of the area to be repaired, and identify the causes of degradation; the need to develop correct design procedures that take each stage of repair work into account; the need to identify the methods for monitoring and inspecting repairs that are most appropriate from the standpoint of durability.

A number of correlated phenomena take place when a repair mortar is applied to an existing concrete substrate, many of which depend on the mortar's properties. After mortar is applied, it contracts as it dries. This *drying shrinkage* is counteracted by the mortar's *bond* with the existing substrate (which is assumed to be stable at any given temperature). A tensile stress is thus established in the mortar which will persist as long as the latter continues to adhere to the substrate. At the same time, the mortar's stress capacity will gradually increase as it sets and cures. The situation is thus governed by two phenomena that operate simultaneously: the increase in tensile stress resulting from shrinkage, and the increase in the mortar's mechanical strength. These phenomena can lead to cracking if the mortar's stress capacity is exceeded or to the mortar detachment if the bond between the substrate and the mortar at the interface between the two materials is not sufficient to counteract the tensile stress in the

mortar. *Creep* phenomena (fluage) help promote the system's stability because they reduce the tensile stresses in the applied repair mortar, keeping them below the breaking stresses. The thickness of the applied mortar layer is also a factor, as the tensile stresses set up in the mortar as its shrinkage is counteracted must be balanced by the tangential stresses at the mortar/substrate interface. If the bond strength is exceeded, mortar detachment may occur.

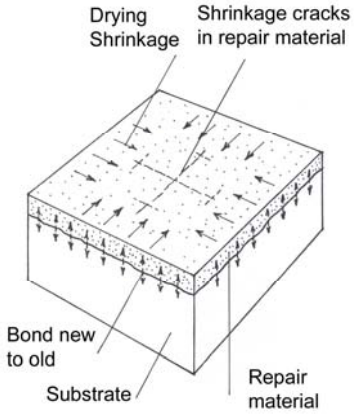

Figure 1. Schematization of the phenomena tied to the drying shrinkage of repair mortar applied to a support.

A further aspect that affects durability concerns the fact that the repair material's *modulus of elasticity* (E) must not be higher than that of the concrete substrate. If the system is subject to external stresses (e.g., compression at a pier or along a beam), the stiffer repair mortar would be required to absorb higher stresses, and could thus break off or detach from the substrate. In general, the *coefficient of thermal expansion* of repair mortars is similar to that of concrete. However, abrupt changes in temperature at the applied mortar layer can cause excessive stress to build up as a result of shrinkage, leading to cracking or detachment from the substrate. The repair mortar's *water transmission* must also be borne in mind, as it must be sufficiently high to reduce the likelihood that interstitial condensation will be formed in cold weather, when outdoor temperatures and water vapor levels are significantly lower than in the building's interior, thus causing water vapor to be transmitted from the interior to the exterior through the building envelope. Other properties that promote repair durability include a high *carbon dioxide diffusion resistance* and low *surface water absorption*. Repair mortars are thus formulated to provide an excellent bond with the substrate, a modulus of elasticity that does not exceed certain specified levels (depending on the properties of the substrate), modest drying shrinkage, a coefficient of thermal expansion similar to that of concrete, low water vapor transmission, high carbon dioxide diffusion resistance, and low surface water absorption.

3 RESULTS OF EXPERIMENTAL INVESTIGATIONS OF ACCELERATED AGING TESTS. STANDARD EUROPEAN TEST METHODS

A series of experimental investigations have been carried out at the Politecnico di Torino Second School of Engineering in Vercelli by R. Nelva and R. Vancetti. This work was performed together with the DACD – Department of Environment Construction and Design – Experimental Technical Laboratory (Prof. Tiziano Teruzzi, supervisor) at SUPSI – University of Applied Sciences of Southern Switzerland – Canobbio (CH), and with the cooperation of a number of manufacturers in the sector. The purpose of these investigations was to assess accelerated aging test methods for repair mortars, analyze the behavior of applied products, verify test significance and carry out comparative tests on the basis of recent European standards.
European standards covering repair products specify a number of tests for assessing the durability of repairs by evaluating the thermal compatibility of the materials involved, i.e., the mortar and the concrete substrate. These standards include EN 1504-3 (2006), which contemplates two test methods for exposed facade elements: carbonation resistance as per draft standard UNI EN 13295, and thermal

compatibility as determined by means of the thunder shower cycling test (EN 13687-2) and the dry thermal cycling test (EN 13687-4). In the latter two tests, concrete specimens measuring 30x30x10 cm to which repair mortars have been applied are subjected to thermal shock cycles, and the effects of aging are assessed by visually inspecting specimen surfaces and by means of pull-off bond strength tests. Bond strength tests are also carried out on control specimens which were not subjected to accelerated aging. Dry thermal cycling tests (temperature cycles in air at –25 °C/+55 °C) were carried out using an Angelantoni CH 250 environmental chamber. For the thunder shower cycling tests (cycles of water spray on a specimen heated to 60 °C), a special test rig was designed and constructed for the purpose.

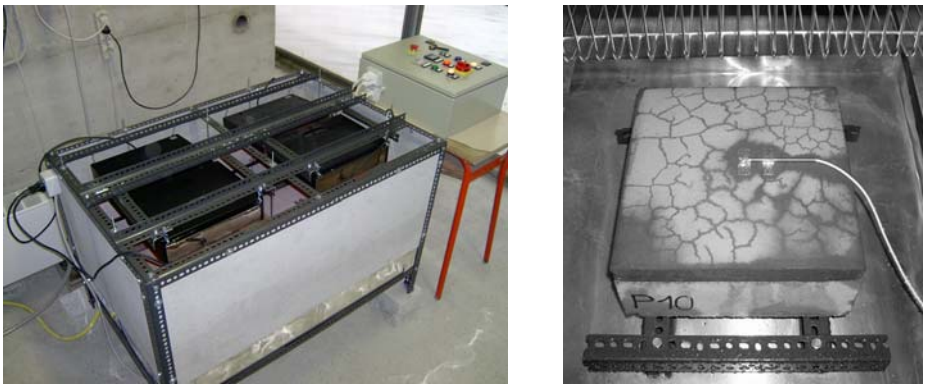

Figure 2-3. Apparatus for tests of quick aging "Thunder Shower cycling".

Findings of laboratory tests were as follows:

- Elastoplastic protective paint on the exterior surface significantly improves the system's performance as regards microcracking as well as water permeability, which was almost nil even after the artificial aging cycles. Performance as regards carbon dioxide permeability was also improved, with specimens coated with protective paint showing lower carbonation depth.
- In the pull-off bond strength tests, it was found that when failure does not take place in the finish layer, the values determined after aging are good, averaging between 1 and 2 N/mm^2 (with peaks up to 3 N/mm^2), as against bond strengths of 2 to 3 N/mm^2 (with peaks up to 4 N/mm^2) for unaged specimens. If failure occurs at the interface between the surface finish and the mortar (or within the finish layer), bond strengths are markedly lower, often falling below 1 N/mm^2 both before and after aging. This fact must be borne in mind when comparing results with specified performance requirements.
- In comparing the results of the thunder shower cycling and dry thermal cycling tests, it was found that the former would appear to be more stringent and leads to greater degradation, reducing pull-off bond strength, increasing water permeability, and causing cracks.
- In general, the tests demonstrated the mortars' high modulus of elasticity and good bond with the substrate, as well as their low vapor permeability. These properties must be borne in mind when designing repairs in order to ensure that they are compatible from the physical and static standpoints.
- Careful product application procedures were found to be crucial to the end result.

4 OPERATING SEQUENCES AND SPECIAL PRECAUTIONS

The intervention systems for the repair and the maintenance of the reinforced concrete elements can be summarized in two main typologies: conservative intervention (punctual and less impacting) and intervention of reparation. The first system has the purpose to protect the structures, when the deterioration is not still advanced, or to correct defects of concrete castings of new realization. A conservative typical intervention is the action of attenuation of the aesthetical defects which are present on a concrete façade and the consequent protection of the structure. A typical intervention is

the sealing of the "nests of gravel", that consists in the stretching of a thin layer of mortar and in the removing the part in excess, in order to close the superficial porosities. The intervention of reparation, instead, consists in the identification and elimination of the deteriorations through the substitution of the decayed material and in the protection against a further stadium of deterioration. In this case it is important to know the physical-mechanical characteristics of the original concrete and to identify its state of deterioration and its causes. Then it is necessary to conduct a series of cognitive investigations in order to determine, by tests in situ, the following characteristics (with these data it is possible to elaborate correctly the executive project of the intervention):

- depth of the carbonation (by a phenolphthalein indicator);
- state of corrosion of steel bars (by visual check and by measuring electric potential);
- modulus of elasticity (for the correct choice of the reparation mortars);
- compressive strenght (indicative of the mechanical properties);
- bond strenght by pull-off test (that furnishes a datum of reference for the subsequent phases of control and test);
- surface water absorption (indicative of the quality and of the state of deterioration of the concrete).

The main phases of these works of reparation are: the surface preparation of the concrete, the cleaning of the steel bars, the protection treatement of steel bars, the application of repair mortars, the application of finishing levelling mortar and of the elastoplastic superficial protective film. The work has to follow the instructions of the UNI EN 1504-1÷10, "Products and systems for the protection and repair of concrete structures".

Figure 3-4-5-6. Removal of decayed material and roughering of concrete substrate by mechanical demolition and by high-pressure water jets.

The choice of the products to apply is related to the causes of deterioration, to the properties of the existing concrete, to the local stresses and to the requested durability. On the basis of the modulus of the elasticity of the existing concrete it is necessary to require a mortar with a smaller modulus of elasticity than the one of the existing concrete. The phase of preparation of the concrete surface substrate is fundamental to get a suitable bond of the repair systems; this requires the removal of decayed material and the roughening of the concrete substrate. The removal of the decayed materials and the products of corrosion is obtained by the high-pressure water jets or by the mechanical demolition. The first technique employes an high pressure water jet and it is proper to the removal of superficial layers and to the demolition. The efficiency of the technique depends on the pressure of water jet and on the water-flow. For the choice of the technique of concrete preparation it is necessary to consider the impact of workmanship on the building site and on the environment (noise, dusts, etc.). The risks in the use of the high-pressure water jets are tied up to possible physical damages of workers and to the damages of structures and plants. The following phase consists in cleaning of the steel bars by abrasive blasting (the operation is not necessary if high-pressure water jets have been used).

Figure 7-8-9. Comparison of steel bars cleaning: by mechanical demolition, by high-pressure water jets, by abrasive blasting.

The degree of cleaning of the steel bars is indicated by the EN ISO 8501-1:2001 and by the UNI EN 1504-10:2005. The standard provides two different methods of cleaning: the abrasive blasting (the degree of cleaning is pointed out by the Sa code following by a numerical index among 0 and 3), or the brushing (the degree of cleaning is pointed out by the St code following by a numerical index among 0 and 3). Subsequently it is necessary to apply the protect treatment of the steel bars against the corrosion. The application of a cement alkaline mortar, with or without a polymeric modifier, allows to get an inhibition effect. The possible additional or substitutive steel bars may be fixed by mechanical connectors, welding, lapping on the existing steel bars or anchorage in the existing concrete (UNI EN 1504-10:2005).

Figure 10. Application of the protect treatment of the steel bars against the corrosion.

The application of the mortar may be mechanically by shotcrete machines in the case of large areas and substantial thicknesses. The equipment may be a dry-mix shotcrete (repair material is placed dry into shotcrete machine and mixed with compessed air; the mixture is transported to the exit nozzle where water is introduced) or a wet-mix shotcrete (pre-batched and thoroughly mixed repair material is transported via pumpline to an exit nozzle). The spray application of the mortar has to be made with an angling as near as possible to 90° related to the existing concrete surface. The applied mortars have to be protected with wet sheets to avoid a rapid drying in the first days after the application.

The finishing consists in the application of the levelling mortar in thin thickness (by hand with plastering trowel) and in the subsequent application of a superficial elastoplastic protection. The elastoplastic protective coating on the exterior surface improves significantly the system's

performance in regard to microcracking as well as water permeability; performances in regard to carbon dioxide permeability are also improved (film thickness about 400-500 μm).

Figure 11-12. Application of the mortar mechanically sprayed (by wet-mix shotcrete) and finishing by hand with plastering trowel.

Figure 13-14. Protection of repair mortar by wet sheets and finishing by elastoplastic superficial protection.

5 MONITORING REPAIR WORK – FINAL INSPECTION

A series of initial tests has to be done to have some data with which compares the tests during the execution and the final inspection. The trial sample has to be choised in a significant zone of the building that represents the main situations of the whole intervention in order to check the application of the complete cycle of restoration. The tests consist in the determination of bond strenght (Pull-off, UNI EN 1542:2000 after 7 days from the application of the layer of mortar of reparation and after 28 days). On the basis of the results at 7 days of the pull-off tests, the site engineer may require ameliorative measures concerning the materials or the cycles of preparation and application. In order to evaluate the test results at 7 days it's necessary to know the diagram of the resistance increase in time correlation of the repair mortars. These data should be furnished by the producers. At the beginning it is possible to refer approximatly to the Swiss Standard Sia 162/5-1997, "Conservation des structures en béton" witch shows that the resistance values of pull-off test at 7 days can reach 70% of those at 28 days. Recent experimentations showed that this value can be also lower. The test results at 28 days are useful to the setting of the tests for the final ispection. The tests that are performed for the final ispection are:
- bond strenght by pull-off test (UNI EN 1542:2000);
- surface water absorption (Karsten method, UNI EN 1504-10:2005);
- thickness of the superficial elastoplastic protection film.

The evaluation of the results of the pull-off tests needs particular attention: it is necessary to take into consideration the position of the plans of separation (it's necessary to examine the extracted cores).

The values to be fixed as minimum limit for the acceptance of results of the pull-off test are connected to the characteristics of the substrate concrete and of the repair mortars. The standard Sia 162/5 shows indicative values for the preliminary tests of the mortars (28 days resistance: structural mortars M3 r = 2,5 N/mm^2; for the building-site qualification tests r = 1,5 N/mm^2 for all types of repair mortars). The standard UNI 1504-3:2006 EN fixes resistance values in laboratory tests r = 2 MPa (R4 class) and r = 1, 5 MPa (R3 class); for the non structural materials r = 0,8 MPa. These values have even to be reached after accelerated aging tests for repair mortars ("dry thermal cycling" and "thunder-shower cycling"). Concerning the surface water absorption tests, the Sia standard 162/5 requires k≤ 0,5 kg m^{-2} h$^{-0,5}$.

Figure 15-16. Determination of bond strenght by pull-off test.

Figure 17-18: Two extracted cores of the pull-off test wich show different positions of the plans of separation.

ABSTRACT

Coated wooden claddings are widely used in Norway and some other countries, and this is expected to endure due to environmental issues. However, discolouring fungi on outdoor coated wood are an increasing concern, both because of increased focus on aesthetic service life and due to ongoing climate changes. This paper presents an ongoing research project that is being carried out in cooperation between Norwegian universities, research institutes and industry. The main objective is to develop new methods for early prediction of durability and longer aesthetic service life of outdoor coated wooden claddings. Various test specimens from Norway spruce (*Picea abies)* are exposed to natural and artificial weathering. Two methods, qPCR and FTIR spectroscopy, are studied as tools for quantitative and qualitative identification and evaluation of early colonization by discolouring fungi on painted surfaces. These methods will be compared with other existing methods for evaluation of discolouring fungi. The wood materials used in the project are carefully selected and characterized, in order to find effects of wood quality on the performance of coatings. Wood materials, wood surface structure and treatment will be studied to find the optimal combinations that serve long maintenance intervals of painted claddings. Finally, studies will be performed of how the test results can be implemented into service life prediction procedures according to ISO standard 15686.

1 INTRODUCTION

1.1 Project Description

The project presented in this paper started in 2007 and will run until the end of 2010. The main objective is defined as

"Develop new methods for early prediction of durability and longer aesthetic service life of coated outdoor wooden claddings related to consumer needs and new building and environmental regulations."

The project work is organised in 7 Work Packages (WP), and the titles should explain the content of the WPs and the overall work to be done in the project. The Work Packages are:

WP1: Method development for evaluation of fungi - qPCR
WP 2: Method development for evaluation of fungi - FTIR
WP 3: Comparison of evaluation methods
WP 4: Natural and artificial weathering of wooden claddings
WP 5: Characterization of wood materials - implications for fungal growth
WP 6: Characterization of coatings and wood performance
WP 7: Service life prediction of wooden claddings

1.2 Cooperation Partners

The project is carried out in a joint cooperation between the following research institutions:

- Norwegian University of Science and Technology (NTNU), project management
- Norwegian Forest and Landscape Institute
- Norwegian Institute of Wood Technology (NTI)
- Norwegian University of Life Sciences (UMB)
- SINTEF Building and Infrastructure

Two industry partners are involved in the project. Jotun AS and Kebony ASA are supplying surface treatment and modified wood materials (furfuryl alcohol treated), respectively.

1.3 Project Funding

The project work is mainly funded by the Research Council of Norway. In addition, funding is received from The Norwegian Sawmilling Industry, Viken Skog BA, and the Wood Research Fund at the Norwegian Institute of Wood Technology. The research institutions involved in the project are also contributing to the project work by various ways of funding and support.

2 PRODUCTS TO BE TESTED

2.1 Wood Materials

The performance of wood in outdoor applications depends on wood quality as well as surface treatment. Numerous studies have been performed on wooden cladding, and some have taken wood quality into consideration. Studies have been performed on the influence of surface roughness and porosity on coating adhesion [Williams & Feist 1994; Nussbaum et al. 1998], the influence of annual ring width on water sorption properties of wood [Flæte & Alfredsen 2004], and the influence of heartwood content on water sorption properties and fungal growth [Bergstrom & Blom 2005]. The influence of wood-coating interactions on the growth of discolouring fungi is still not well enough

known. In many studies of coated wood, the description of the wood is sparse and the variation between the wood specimens is seemingly of little interest.

Since wood is a heterogenous and non-isotropic material, some variation will always be present. This might influence the effects of the treatments if it is not taken into consideration. According to Kollmann & Côtè [1968], the properties that influence most on sorption behaviour are fibre angle, density and content of extractives, i.e. heartwood content. Williams et al. [2000] mentioned knots as an important factor for coating performance. In spruce, heartwood content has been found to influence growth of surface fungi and water affinity rather than water absorption [Bergstrom & Blom 2005].

In order to have different levels of annual ring width, materials of Norway spruce (*Picea abies*) were sampled from two fertile sites and two poor sites in South-eastern Norway. Sites were classified as poor if the site index, defined as dominant height at 40 years age, was 14 m or lower and as fertile if the site index was 20 m or higher. While the trees at the fertile sites were about 50 years old, had large annual ring width and small taper, the trees from the poor sites were about 150 years old, had small annual ring width and larger taper. Five trees with breast height diameter between 27 and 30 cm and five trees with breast height diameter between 32 and 35 cm were sampled from each site. This sampling also represents some difference in wood density since it is negatively correlated to annual ring width within a site index and a geographical area [Klem 1934].

Butt logs and second logs were processed to claddings with dimensions 19 x 98 mm^2. While butt logs contain wood with small and dry knots, second logs usually contain wood with larger and often sound knots. Since fibre deviations are related to knot size, these two positions also represent some of the variation in fibre angle. The claddings to be analyzed were chosen from both inner centreboards and outer centreboards. The sawing pattern is presented in Fig. 1. Inner centreboards are mainly heartwood and contain some proportion of juvenile wood. Juvenile wood is defined as a number of growth rings from the pith and is characterized by shorter fibres and larger variation in wood density than mature wood [Kucera 1994]. Outer centreboards contain mature wood with longer fibres and smaller variation in wood density, and they may have some proportion of sapwood.

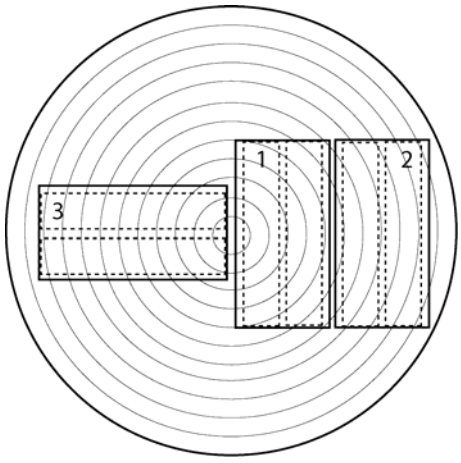

Figure 1. Claddings were produced from (1) inner centreboards, (2) outer centreboards, and from (3) radially sawn boards.

Moisture-induced deformations of wood might lead to cracks in coatings that are exposed to variations in temperature and relative humidity. Since shrinking in tangential direction is about twice as large as that in radial direction [Kollmann & Côtè 1968], one may expect more cracks and then a shorter lifetime for tangentially sawn claddings than radially sawn claddings. To test this difference some of the material was produced as radially sawn claddings as seen in Fig. 1, and those are compared to a corresponding part of tangentially sawn claddings. Moisture-induced deformations of tangentially sawn claddings may also lead to cupping. Cladding with the internal face exposed is recommended

since it is more stable on the wall. Since most sawmills also produce claddings where the external face is exposed, a sub-sample was painted on the external face to test if this has any effect on the coating.

The sample of claddings represents a wide range of wood properties. Since the number of specimens was limited, many properties were measured but not stratified in the sample. These variables, i.e. heartwood proportion, annual ring width, density, fibre angle and knot size will be treated as covariates. Heartwood content was measured from CT-images of the timber scanned before drying. Knots, reaction wood, and other defects were measured on the specimens before painting. Annual ring width and density were measured from small pieces of clear wood. Fibre angle will be measured later when the claddings have been exposed.

2.2 Wood Treatment

The claddings produced from the various trees as described in clause 2.1, were treated with an oil based primer and two exterior acrylic top coats by an industrial process at Moelven Langmoen AS, Brumunddal, Norway. This was done to avoid handmade differences and uncertainties of the various claddings. Red or white colour of the surface treatment was applied, respectively. The red colour was applied to achieve maximum temperature variations within the exposed specimens during testing, and the white colour was applied in order to see the discolouring fungi on the surface as early as possible. The surface treatment was carried out before cutting the specimens to be exposed to natural weathering or tested by artificial weathering in the laboratory.

The test programme also includes Norway spruce (*Picea abies*) treated with furfuryl alcohol. These materials were not prepared from the trees described in clause 2.1. The furfuryl alcohol is applied as an impregnation to the wood material, and is polymerized as a result of heat treatment. It is shown to improve the durability and service life of wood. This type of treatment is found to be more environmental friendly than metal based inorganic salts.

3 NATURAL AND ARTIFICIAL WEATHERING

3.1 Natural Weathering

Specimens to be tested are exposed at two outdoor test sites in Norway. One is situated in Sørkedalen outside Oslo, and the other is situated at Voll, Trondheim. Climate data for the two sites are given in table 1.

Table 1. Position and climate data for outdoor test sites at Sørkedalen, Oslo *) and Voll, Trondheim.

Test site	*Position*	*Monthly minimum temperature [^oC]*	*Monthly maximum temperature [^oC]*	*Annual average temperature [^oC]*	*Monthly minimum precipitation [mm]*	*Monthly maximum precipitation [mm]*	*Annual average precipitation [mm]*
Oslo	60^{o}10´ N 10^{o}20´ E	-5.6 (Jan)	13.6 (Jul)	3.5	60 (Feb)	138 (Oct)	1200
Trondheim	63^{o}25’ N 10^{o}27’ E	-3.0 (Jan)	13.0 (Jul)	4.8	45 (Apr)	110 (Sep)	855

*) The actual data are for Tryvasshøgda, close to Sørkedalen.

The specimens are mounted in racks positioned at an angle of 45^o, facing south. An example of mounting at Sørkedalen is shown in Fig. 2. The specimens will be checked regarding various degradation parameters on a regular basis during the project period.

Figure 2. Wood cladding specimens mounted at the outdoor test site at Sørkedalen, Oslo.

3.2 Artificial Weathering

Natural climate exposure and ageing of exterior materials require long time periods to achieve reliable results. Therefore, numerous laboratory test methods for artificial (accelerated) weathering of materials have been developed, and a number of them are standardized. In a standard for service life prediction of building materials and components [ISO 15686-2], the procedures are based on a combination of test results from both natural and artificial weathering. Most methods for artificial weathering have been developed for testing of various types of materials, and some of the methods include only one exposure parameter (temperature, moisture, UV radiation). In this project, the following standardized test methods will be applied: NT Build 495 [NT Build 495] including UV/light radiation, heat radiation, water spray and freeze exposure, and QUV cabinets for UV radiation and water spray. The QUV cabinets conform to numerous international standards, e.g. EN 927-6 [EN 927-6]. In addition, specimens will be exposed to UV/light radiation, heat and moisture in a commercial climate chamber.

4 METHODS FOR CHARACTERISATION OF DISCOLOURING FUNGI

4.1 Quantitative Polymerace Chain Reaction (qPCR)

Polymerase chain reaction (PCR) based techniques can be used for sensitive and specific monitoring of phytopathogenic microbes in their natural substrates. Real-time PCR is currently a promising PCR method for quantifying DNA. The measurements are performed during the exponential phase of the reaction, when PCR efficiency is not influenced by limiting reagents, small differences in reaction components, or cycling conditions. The incorporation of probes increases the specificity relative to traditional PCR and allows the monitoring of several DNA targets in the same reaction tube (multiplex real-time PCR). As a result, real-time PCR has been increasingly used for the quantification of infectious agents.

The development of DNA-based real-time PCR (polymerase chain reaction) and taxon-specific primers has provided new possibilities for specific detection and quantification of fungi in their natural substrates [Hietala et al. 2003]. In qPCR (quantitative real-time PCR), the accumulation of the PCR product is detected for each amplification cycle. These highly sensitive techniques have already been applied to quantify plant pathogens in a number of cases [Mumford et al. 2000; Weller et al. 2000; Hietala et al. 2003] and in wood materials [Eikenes et al. 2005].

4.2 Fourier Transform Infrared Spectroscopy (FTIR)

Performing a fourier transform infrared radiation (FTIR) analysis yields a fingerprint of the material specimen, and changes due to ageing processes, e.g. artificial climate ageing, may be studied. That is, decomposition and formation of chemical bonds and products can be investigated in a FTIR analysis. Both qualitative and quantitative FTIR measurements may be performed. Studies of different changes occuring within the material, ranging from chemical reactions to concentration changes, are possible. Both solids, liquids and gases, including fast reactions, may be studied. In addition, as in this project, biological growth, e.g. mould and fungi, may also be examined by FTIR analysis, as well as the impact on the attacked material. Several aspects may complicate an FTIR analysis, e.g. the FTIR signals from the degradation products in the surface might be hidden behind the signals from the substrate material. Further, several chemical reactions may be occurring simultaneously or at different times, making it difficult to differentiate between them. Inhomogenities in the fungus specimens, depending on the physical dimensions, will also complicate the FTIR measurements.

FTIR characterization is carried out by using an FTIR spectrometer with a horizontal attenuated total reflectance (HATR) accessory (single reflection) with a diamond crystal. The wavelength range is from 4000 cm^{-1} (2.5 μm) to 400 cm^{-1} (25 μm) in an atmosphere with minimalized CO_2 and H_2O content. Each FTIR spectrum presented is based on a recording of 32 scans at a resolution of 4 cm^{-1}. In order to ensure satisfactory contact between the HATR diamond crystal and the specimen, three or more FTIR spectra are recorded at various locations on the specimen.

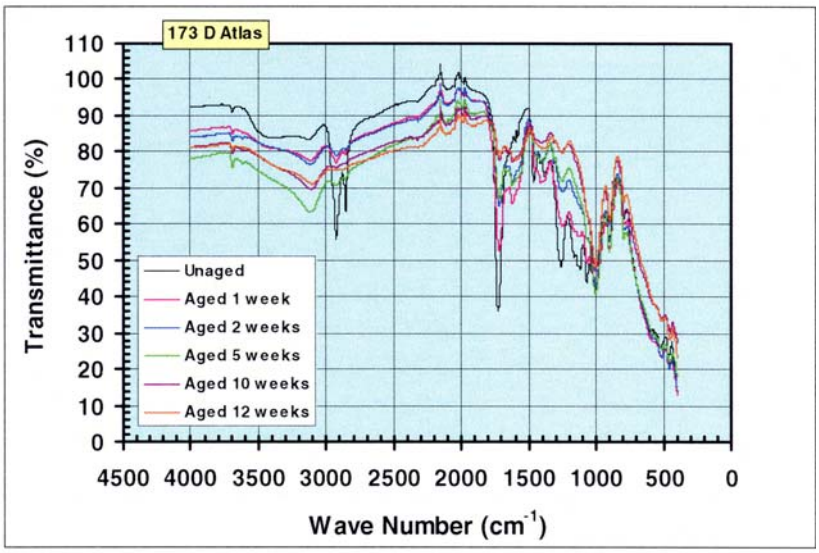

Figure 3. Example of an FTIR spectrum of paint on wood substrate [Olsen 2007].

5 TEST AND EVALUATION METHODS

In general, all the test results will be applied to study the durability of the surface treated and furfuryl treated wood materials, and the extent of discolouring fungi on these materials. Special attention will be paid to the effect of the wood characteristics on the various properties.

For the specimens exposed to natural weathering, visual inspections will be carried out once a year. In addition, specimens will be cut out for further analyses in the laboratory. For the specimens tested by artificial weathering in the laboratory, a number of standardized test and evaluation methods will be applied, e.g. methods to study water vapour permeability, liquid water permeability, cracking, blistering, flaking, chalking, adhesion and colour change. The test results from the artificial weathering exposures will be carefully studied and compared to the test results from natural

weathering. It will be important to establish a variety of degradation and durability data for the test materials, in order to see how these data can be applied as input to the service life prediction procedures as described in ISO 15686 [ISO 15686-2]. There is also a need for further studies of the relations between natural and artificial weathering of materials, and how specific climate parameters can be varied and combined in order to simulate various natural climate exposures artificially in a reliable manner.

6 SERVICE LIFE PREDICTION

Finally, in the last phase of the project, the test data from both the natural and the artificial weathering of the various materials will be applied as input to the service life prediction procedures as described in the international standard ISO 15686. This standard in fact comprises a series of specific standards, altogether describing different aspects of service life prediction. Two alternative procedures are described for a careful prediction or a more simple estimation of the service life, respectively. It will be important to study how the test data obtained during this project can be applied as input to the two procedures mentioned, and to what extent this type of data can be applied to predict or estimate the service life of various wooden claddings.

ACKNOWLEDGMENTS

The authors want to thank the Research Council of Norway and the following institutions for funding the project: The Norwegian Sawmilling Industry, Viken Skog BA and the Wood Research Fund at the Norwegian Institute of Wood Technology. Further, we thank Jotun AS and Kebony ASA for providing paint and treated wood materials to the project, respectively, and Moelven Langmoen AS for preparing the painted specimens by an industrial handling process. Finally, we want to express our thanks to our colleagues at the cooperating institutions.

Study on the Relation Between Mockup Test and Lifecycle of Curtain Wall Construction - Case Study in Taiwan

Chih-Min Chi [1]
Chun-Ta Tzeng [2]

T 24

ABSTRACT

The performance of curtain wall could be simply divided into two parts: one is performance of material and another is performance of system. When we think about the durability of curtain wall, we shall consider the life of curtain wall. Lifecycle theory is one of the important method for studying constructions and materials of sustainable building. Lifecycle of curtain wall construction has been divided into several parts, including plan, design, test, manufacture, installation, usage, maintaining, renew, and recycle.

Mockup performance test is common method to make sure of objective by phases of lifecycle. Development of Pre-fabricated curtain wall in Taiwan is over 30 years. In the meantime, the economy of Taiwan is on the decline. And the bidding of Construction changed from Best Value Contracting (BVC) to Lowest Price Contracting (LPC). Recently, the price of material has raised a lot. With factors mentioned above, some management problems were discovered, such as some contractors would never fabricate according to drawings, and they change the design by themselves.

Mockup test is one of the full-size performance tests of exterior wall and it is one of the macro methods to control quality of the construction. In this study, the results and applications of 30 test cases were investigated. Results of this study included wrong test attitude of constructor, workers of installation in test and in site were not the same, and the results of tests did not feeding back to designer and manufacturer, etc.

1 INTRODUCTION

Curtain wall is one kind of Building exterior wall. Development of Pre-fabricated curtain wall in Taiwan is over 30 years. In the meantime, the economy of Taiwan changed from the highest to the lowest. And the bidding of construction changed from Best Value Contracting (BVC) to Lowest Price Contracting (LPC). Recently, the price of material has raised a lot. With above factors, some problems of management were discovered, such as some contractor never made according to drawing and changing the design by themselves. With all this problems, it direct affected the system performance of curtain wall. The relation between results of mockup test with initial performance of curtain wall will be discussed in this study.

2 METHOD

This study use two methods, literature review and case study. Method of literature review is used to search and collect data of curtain wall, including definition, category, performance, installation, test and lifecycle of curtain wall. Method of case study is use to collect cases of mockup test and their tracing data when the building finish constructing.

The cases shall conform to following:
a. Building located in Taiwan.
b. Completed Project.
c. Test items follow total laboratory procedure of CNS 14280 or AAMA 501.

3 LITERATURE REVIEW

3.1 Definition of Curtain Wall

According to Republic of China Building Construction Regulations [Government of TAIWAN, Republic of China 2007], the definition of curtain wall is “exterior wall of frame-construction building, which only bearing self weight, wind load and earthquake load, and un-bearing or no-passing other loads.” In another word, exterior wall which is not load-bearing wall is curtain wall.

A standard curtain wall contains 4 kinds of components: surface material, supporting frame, connector for stress passing, and filler. [Fig. 1]

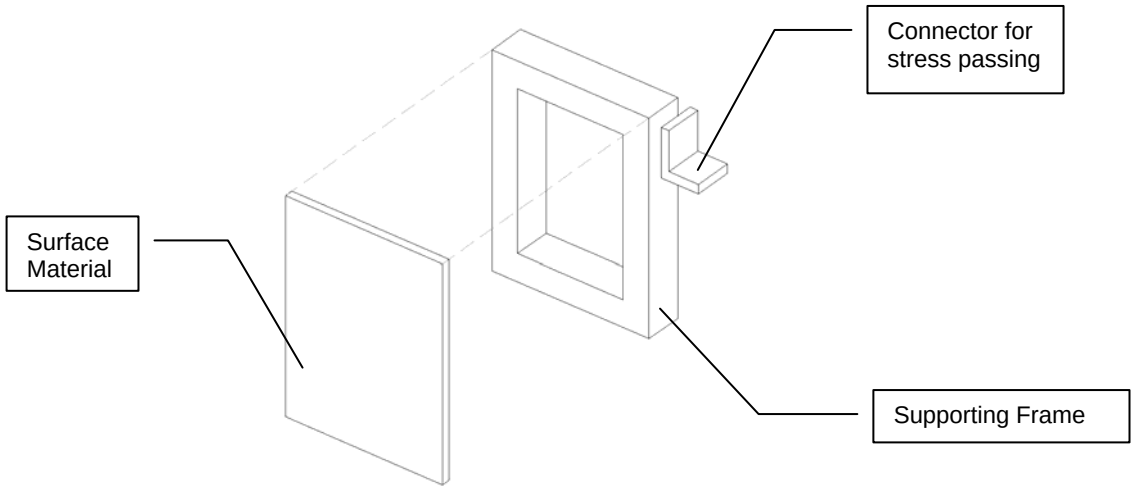

Figure 1. Components of a standard curtain wall [Chi & Chen 2003].

3.2 Lifecycle of Curtain Wall

Lifecycle of curtain wall has been divided into several parts, including plan, design, test, manufacture, installation, usage, maintaining, renew, and recycle. [Fig. 2]

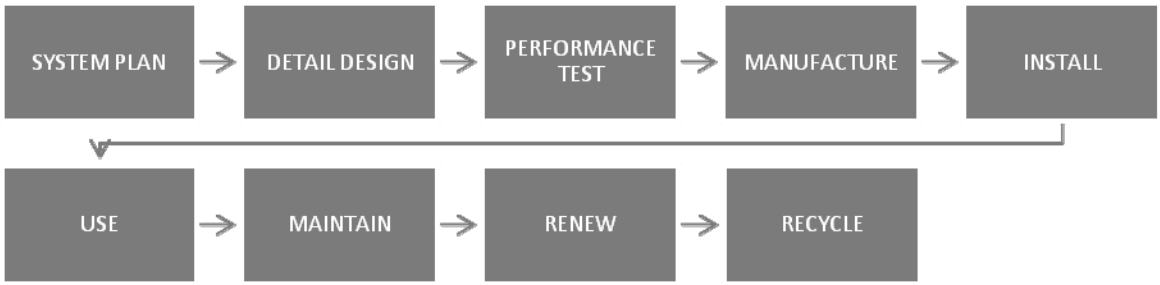

Figure 2. Lifecycle of Curtain wall.

In the area of sustainable curtain wall, 2 important control points shall be focused:

a. System plan:
In this phase, the total cost, construction and main materials, and lifecycle of curtain wall will be setting. Decisions in system plan phase have great effect upon the lifecycle of curtain wall.

b. Performance test:
Mockup test is one of the full-size performance tests of exterior wall and it is one of the macro methods to confirm the system function of the curtain wall. The result will determine the possible lifecycle setting.

3.3 Performance of Curtain Wall

Performance of curtain wall could be divided into two parts [Chi and Chen 2003], performance of materials and performance of physics (knows as system).

a. Performance of materials:
Including metals (e.g. aluminum, steel, stainless, etc.), precast concrete (e.g. concrete, rebar, aggregate, etc.), glass (e.g. plate glass, glass brick, etc.), sealant (e.g. fixed form sealing, non-fixed form sealing, etc.), and others (e.g. skirt, fire stopping, etc.).

b. Physical performance (system performance):
This performance include wind pressure resistance, watertight, storey deformation absorption, and airtight.

3.4 Classification of Curtain Wall

There are many types of curtain wall, and many kinds of sorting ways, in general it is classified according to Surface materials, Frame materials, Functional, Structural, System, Building appearance and etc. At present in Taiwan, Architects and owner prefer to classify by Cladding materials, but most of the curtain wall contractors classifies by system and frame materials. However, for students and researchers, system classification is the most common used. Chi and Chen [2003] offered a sounder definition of System classification: stick, unitized, semi-unitized (unit-and-mullion and column-cover-and-spandrel), panel, and structure glass. [Figs. 3 –8]

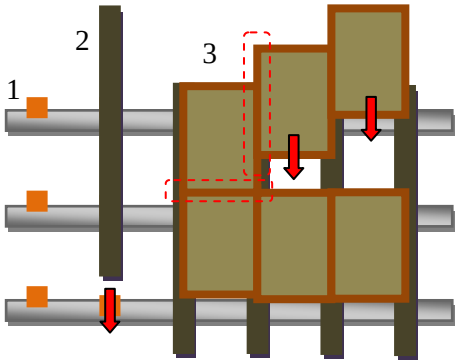

Figure 5. Unit-and-mullion Curtain wall.

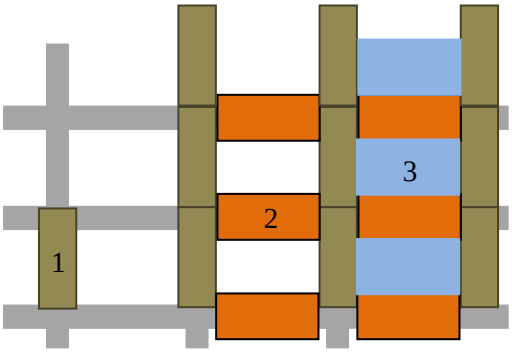

Figure 6. Column-cover-and-spandrel Curtain wall.

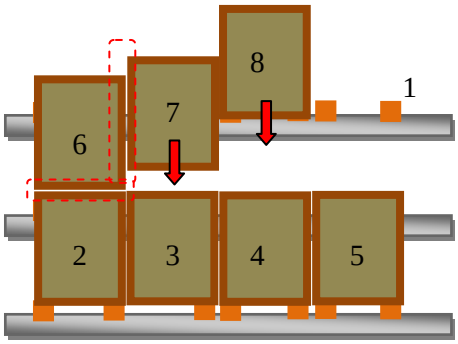

Figure 7. Panel Curtain wall.

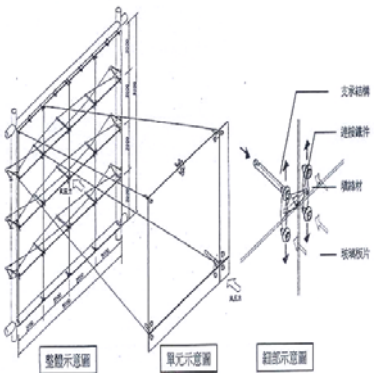

Figure 8. Structure glass Curtain wall [Hsueh & Huang 2002].

3.5 Mockup Test

The purpose of mockup test is to confirm whether the required performance of curtain walls is satisfied and thereby back up the safety and working function of the products. According to CNS14280 [Government of TAIWAN, Republic of China 2007] or AAMA 501[American Architectural Manufacturers Association 2007] requirement, the major test items include: test for air infiltration (CNS 13971, ASTM E 283), test for water penetration with static pressure (CNS 13974, ASTM E 331), test for water penetration with dynamic pressure (CNS 13973, AAMA 501.1), test for structure under static pressure (CNS 13972, ASTM E 330), and test for storey deformation (CNS 14281, AAMA 501.4). [Figs. 9 –13]

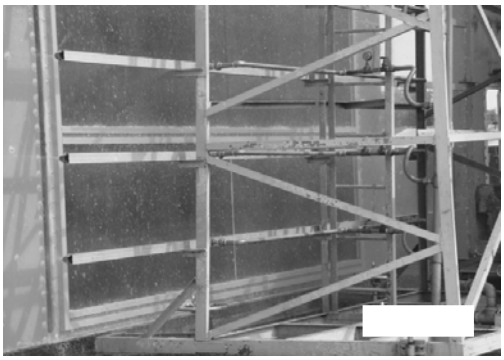

Figure 10. Test for water penetration with static pressure.

Figure 11. Test for water penetration with dynamic pressure.

Figure 12. Test for storey deformation.

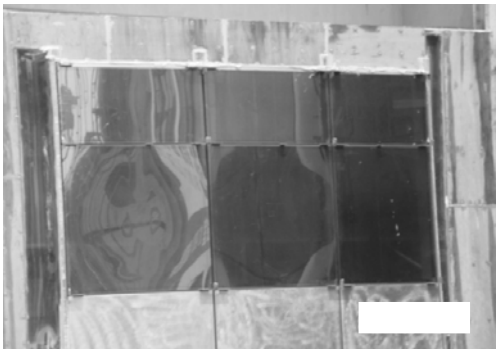

Figure 13. Test for structure under static pressure.

4. CASE SYUDY

4.1 Sample of Case

According to the limitation in this case study, we have selected 30 samples, from 2001 to 2006 [Fig. 14]. From the selected samples, the ratio of government buildings to private buildings is almost one to one [Fig.15].

Figure 16 showed the ratio of various curtain wall systems. Stick curtain wall is the most popular system in the market, because it is the ancient system that use in most building and lower price due to its simple component, which make it more competitive compare to the other system. Figure 17 showed

there are 8 cases of different workers use in laboratory and in the site. The reason of the first 2 samples is because the company laboratory is far apart from the construction site (i.e. different country). The reason for the remaining 6 samples is due to the misleading project time, where they have to test on time, but they had not found a sub-contractor at the same time.

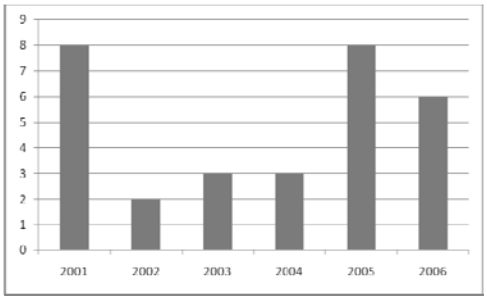

Figure 14. Year range of 30 samples.

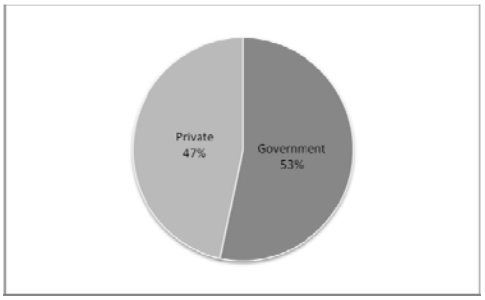

Figure 15. Ratio of government/private building.

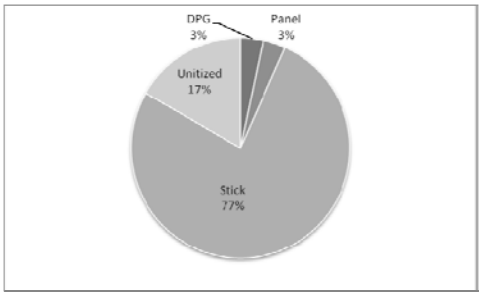

Figure 16. Ratio of curtain wall system from 30 samples.

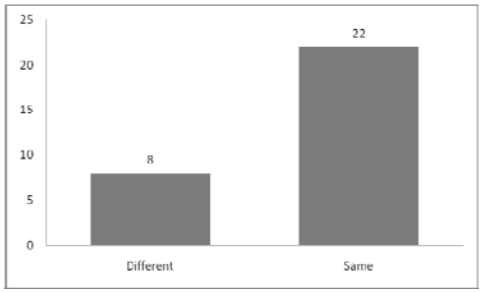

Figure 17. Workers in laboratory and in filed.

4.2 Data Analysis

Figure 18 showed only 30% of samples passed the prepare test for water penetration with static pressure when they finished mature time. In other words, these curtain walls might be unsuccessful in sites, if they did not conduct the test. This also shows that mockup test is important. 67% of samples passed all test items during one time [Fig. 19]. It means that there still 1/3 of the samples have problems during the mockup test. 90% of these problems are water penetration [Fig. 20]. It means that the biggest problem for curtain wall system design came from water penetration. 78% of water penetration samples failed in first time of test for water penetration with static pressure [Fig. 21]. 45% of prepare test failing samples failed in first time of test for water penetration with static pressure (Figure 22). Although CNS, AAMA, ASTM test standards allow curtain wall manufacturers to repair test specimens in site, the rate of success for repair is still too low.

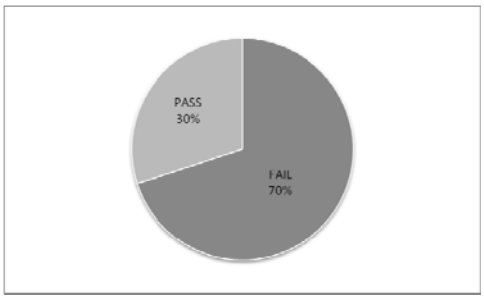

Figure 18. Ratio of passing the prepare test of 30 samples.

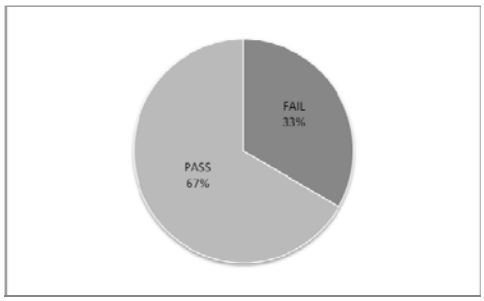

Figure 19. Ratio of passing all test items during one test of 30 samples.

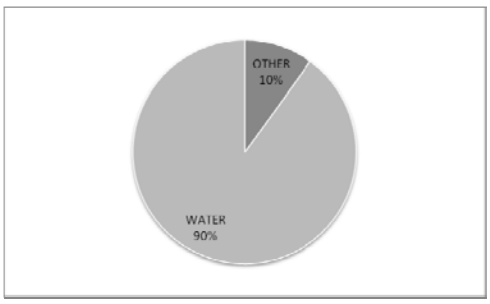

Figure 20. Ratio of problems during the test of test failing samples.

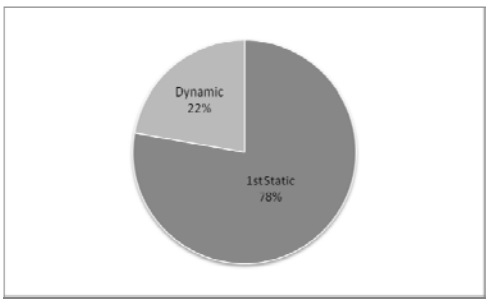

Figure 21. Ratio of water penetration problems.

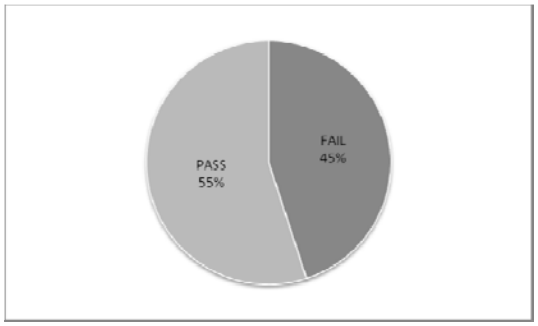

Figure 22. Ratio of 1st water penetration of prepare test failing samples.

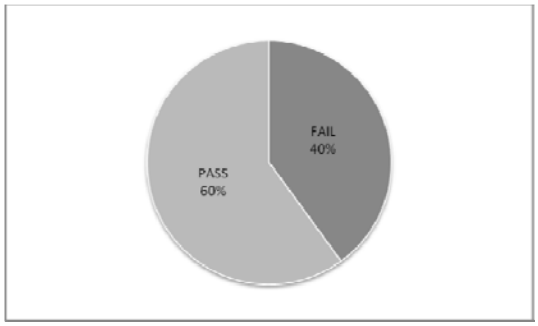

Figure 23. Ratio of watertight test in site of 30 samples.

4.3 Result of Samples Tracing

40% of 30 samples repeated water penetration at test area in the site [Fig. 23]. 80% of passing test samples (i.e. all test items) had not found water penetration in the site [Fig. 24]. This indicates that mockup test is helpful. Figure 25 showed 94% of 80% samples workers work in both laboratory and in the site. We have found 3 points:

a. The mockup test is helpful to check the performance of curtain wall.
b. It can help manufacturers to train their workers during the test before quantity installation in the site.
c. Same workers in the laboratory and in the site are easier to share experience. Different workers might let test become only paper work, the results of test are helpless to building.

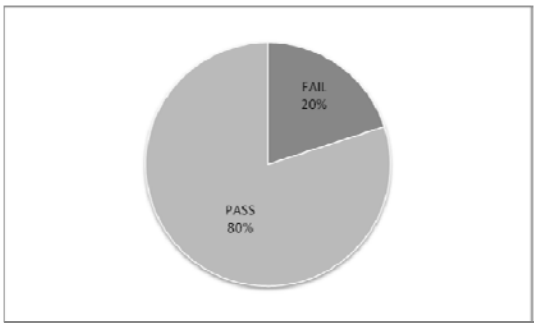

Figure 24. Ratio of water penetration in the site of passing test samples.

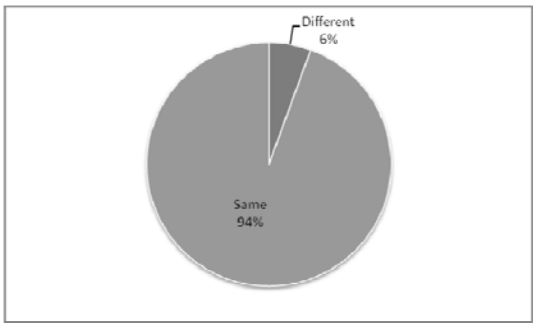

Figure 25. Ratio of workers work both in laboratory and in the site of no water penetration in site samples.

5. CONCLUSION

Setting of lifecycle is necessary for constructions and materials of sustainable building. The main points of control the lifecycle of curtain wall are the system plan phase and the performance test phase. We set the period of lifecycle of curtain wall in system plan phase, and we make sure the setting is correct in performance test phase.

Recently in Taiwan, almost all bidding of construction is Lowest Price Contracting (LPC). This make the lifecycle of curtain wall short, hence it is important to make sure the lifecycle of curtain wall will not be shorter for performance level down.

Mockup test is one of macro methods to control early day performance and quality of exterior wall. These performances directly influence life of every material, and these might shorten the whole life of curtain wall.

From the results of samples and their tracing data, we can conclude follow points:

a. Curtain wall manufacturer in Taiwan should pay more attention on preventing water penetration.
b. The attitude of curtain wall manufacturer can be seem from the way they selected the worker, and it effect the result of performance of curtain wall in both laboratory and the site.
c. The successful rate of passing prepare test for water penetration when finishing mature is too low. This shows that pre-education and training is very important before the installation work start.
d. During water penetrating, the success rate of repair/ reinforce is too low. It is better to check all over the system again rather than only repair the positions of penetrating.
e. If the mockup test is passed, 80% guaranty that the job is successful in the site. Thus, mockup tests certainly a good tool to check lifecycle of curtain wall.

Decay Diagnosis of Goan Laterite Stone Monuments

Sutapa Das [1]

T 25

ABSTRACT

Heritage monuments in laterite stones have suffered from harmful intervention during restoration due to inadequate research done on laterite as masonry material based on its great regional variation and mixed property of stone, brick and soil. To preserve these structures, it is crucial to conduct monument investigation for defect analysis along with characterization of local laterite. This research was undertaken for decay diagnosis of Goan laterite monuments with the Basilica of Bom Jesus, India as a case study along with a combination of field and laboratory tests on freshly quarried stones.

During the monument investigation, a majority of the 20 visible defects indicated that efflorescence and biological growth due to water ingress were responsible for deterioration. An in-situ profile study of the quarry showed that though the stone was a matured variety of laterite, however presence of salt, clay-mineral, quartz, and iron patches were responsible for efflorescence, high water absorption, hard patch, and staining respectively. Hence a megascopic study was required for obtaining good quality masonry material. From laboratory tests on freshly quarried samples for geochemical-mineralogical, physical and engineering properties, again it was proved that durability of laterite masonry was attributed to water tightness rather than strength. Physical protection from water by design detailing or application of preservative treatment for water proofing can significantly enhance the lifespan of monuments.

1 INTRODUCTION

Laterite is a weathered rock found in tropics and sub-tropics and is named after the Latin word 'Later' or brick [Buchanan, 1807]. Numerous monuments including prehistoric megaliths of Kerala and world heritage sites of churches of Goa, India, third generation Angkor temples or walls in Group G monuments of My Son, Vietnam are made of laterite. Laterite is neither soil nor does it belong to the triplet group of including igneous, metamorphic and sedimentary rocks [Aleva, 1994]. On the contrary, due to its mixed property of stone, brick and soil, laterite has remained as a subject of controversy among geologists and engineers over a century [Banerjee, 1998]. Perhaps this is the only stone that is soft during quarrying, hardens after atmospheric exposure [Gidigasu, 1976; Nichol, 2006], and yet requires a waterproofing plaster and a dense damp proof course [Das, 2007].

Great regional variations has hindered in depth research to characterize laterite as masonry material. It has lead to harmful interventions during restoration of monuments [Bhandari, 1995; Engelhardt, 2005]. To preserve these heritage structures, it is of paramount importance to conduct a comprehensive decay diagnosis comprising of: (1) monument investigation for identification of defects and their analysis; and (2) characterization the local laterite as masonry material. To address this knowledge gap, the current study was undertaken to investigate Goan laterite block masonry with the Basilica of Bom Jesus as a case study. Old Goa on the west coast of India is known as 'The Vatican of East' for its group of beautiful Baroque churches. This 16th century basilica built by the Portuguese rulers is a world heritage monument and is one of the best examples of fine ashlars masonry in Goan laterite [Rajagopalan, 1987].

2 RESEARCH METHODOLOGY

For any natural stone, its composition and microstructure determine its engineering properties and durability [Fitzner, 2000]. The properties of laterite vary widely with location and depth of the quarry [Kasthurba, Santhanam & Mathews, 2007]. Moreover its hardness depends on: (1) degree of weathering of parent rock [Gidigasu, 1976]; (2) quantity, nature and distribution of iron [Alexander & Cady, 1962] and (3) homogeneity, structure and age [Maignien, 1966]. Hence for a thorough understanding of the decay mechanism of laterite, a three pronged approach had been adopted in this study:

- Monument investigation to identify the signs and causes of decay.
- Profile study at a local quarry to study depth-wise variation of laterite of that region.
- Laboratory experiments on freshly quarried stones to determine its engineering properties.

2.1 Monument Investigation

A detailed field study at the basilica was conducted just after the rainy season for easy identification of defects. Only non-destructive tests were allowed at this protected site, hence the investigation was limited to expert walkthrough, photo documentation of the defects, discussion with the personnels of Archaeological Survey of India (ASI) and review of past restoration records.

2.2 Field Survey

The in-situ testing was carried out at Patradevi quarry at north Goa for a profile study and qualitative strength tests. Patradevi was selected for this research due to the fact that stones from this active quarry have similar characteristics as that of the original stones used in the monument and is highly recommended by ASI, for restoration of Goan monuments [Architectural Conservation Cell, 1999]. A detailed profile study of the exposed vertical face of matured laterite layer was conducted. A depth-wise variation of surface hardness as a qualitative indicator of strength was measured for a particular

profile using Type P pendulum hammer [Proceq, 2003]. About three tons of samples were collected from various depths, marked, sealed in wooden crates and transported to the laboratory.

2.3 Laboratory Experiments

As mentioned earlier the engineering property and durability of laterite is a function of its chemical composition and microstructure, hence the following test programme was developed to study the engineering properties of laterite:

- Chemical or wet analysis: gravimetric method for impure silica and volumetric method for Fe2O3, Al2O3 [IS 2720: Part 25]
- Atomic absorption spectrometry for trace alkali metals [Varma, 1985]
- Petrography thin section study for maffic [dark] and felsic [light] mineral [DIN EN 12407]
- X-Ray diffraction [XRD] analysis for altered clay minerals [Moore & Reynolds, 1997]
- Test for water absorption, specific gravity and porosity [DIN 52103]
- Test for water absorption coefficient through capillary action [DIN EN 1925]
- Test for compressive strength [DIN 52105] and flexural strength [DIN 52112]
- Salt crystallization test [DIN 52111]

3 RESULTS AND SISCUSSION

3.1 Findings from Monument Investigation

From the internal reports of ASI [1964-1999], it was noted that majority of the problems started in 1930s after de-plastering of 2m thick walls to solve the problem of water seepage through them. As it was difficult to introduce a damp proof course, external lime plaster was peeled off to apply paper poultice for removal of efflorescence. Since that date various restoration activities have taken place. Most of these interventions were irreversible in nature and had shown detrimental effect in the long run. For example, walls lost breathability due to the application of acrylic paint on inner surface, stronger cement mortar used for re-pointing was incompatible with soft stone, pruning effect of pulling and plucking to prevent vegetation growth in reality resulted in abundance of vegetation etc.

Most of the decay features were found to be associated with the external walls only, except very few surface cracks in floor and ceiling. Twenty visible defects were identified and grouped into 5 major categories [Weathering Research Gr., 2003], namely: (1) mechanical weathering; (2) efflorescence; (3) material and methods of construction; (4) human intervention and (5) biological decay (Table 1).

3.2 Findings from Field Study

Patradevi is an active quarry. Hence, the strata such as duricrust, lithomerge and parent rock were not observed. The visible laterite zone was about 9m deep appeared as a uniform brick wall without any significant variation. However, a close inspection revealed patches of salt, clay, quartz and iron which may lead to efflorescence, water absorption, hardness and staining respectively (Figure 1).

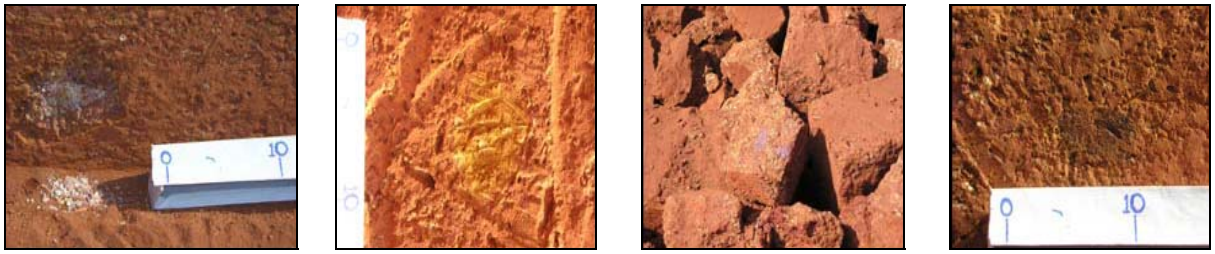

Figure 1. Defects found by visual inspections (L to R: patches of salt, clay, quartz and iron)

Table 1. Summary of decay features.

Category	*Description of defects*	*Probable cause*
Mechanical weathering	Granular disintegration	Cement holding the grains together is weakened by water and washed away.
	Flaking (depth <5mm)	Salt weathering and wetting-drying cycle
	Scaling (depth >5mm)	Accumulation of salt at a frequent wetting depth within the stone and the eventual lifting away of the outer layer
	Honeycombing	Merging of adjacent depressions due to multiple flaking, granular disintegration and salt accumulation
	Caverns	Severe honeycombing
Efflorescence	Salt patch / stain	Lashing rain and rising moisture
Materials and methods of construction	Inadequate plinth protection	The conventional practice of a nonporous granite damp proof course is absent
	Loss of mortar	Poor workmanship at pointing leaves the mortar joints weak and susceptible to rainwater ingress.
	Cracks by corrosion	Volume increase of iron fixing due to corrosion
	Heterogeneity	Inferior quality blocks placed along with good ones become weak point for a wall
	Widening of joints	Due to absence of drip course, the water follows the mouldings and gets absorbed through mortar joints.
Human intervention	Incompatible mortar	Stronger cement mortar used for re-pointing of soft stone
	Peg mark	Use of pegs to maintain uniform plaster thickness
	De-plastering	Repair work
Biological decay	Biological colonization & fern growth	High silica content and presence of moisture
	Bio-chemical weathering	Formation of dark crust due to leaching of iron at the places of root penetration
	Cracks	Root penetration through soft and porous stone
	Deformation	Thick roots causing dislodgement of stone blocks

3.3 Findings from Laboratory Experiments

3.3.1 Geochemical and Mineralogical Analysis

Laterite samples from upper, middle and bottom level of quarry was tested for major oxides and trace elements (Table 2). As the depth-wise variation in both field investigation and chemical composition was found insignificant, in later studies depth of quarrying was no more considered as a criteria. High silica content implied a high amount of clay responsible for water absorption.

Table 2. Quantity of major oxides and trace elements

Sample No	*Major oxides [%]*				*Trace elements [ppm.]*			*Total*
	SiO_2	Fe_2O_3	Al_2O_3	*LOI*	Na^+	Ca^{++}	Pb^{++}	[%]
GA1 (upper)	52.34	21.79	9.22	14.23	150.09	8.34	332.60	97.58
GA2 (middle)	57.73	16.34	8.93	16.23	162.83	15.23	310.50	99.23
GA3 (bottom)	54.54	18.86	10.45	15.05	170.47	22.69	277.50	98.90
Average	54.87	19.00	9.53	15.17	161.13	15.42	306.87	98.57

XRD analysis detected abundance of clay minerals namely, kaolinite, biotite and chlorite (Figure 2). According to Schelmann's [1981] definition the high content of secondary silica indicated matured variety of laterite. Petrographic analysis of thin sections (Figure 3) revealed presence of both: (1) maffic mineral (haematite and red iron oxide) and (2) felsic minerals (feldspar and quartz).

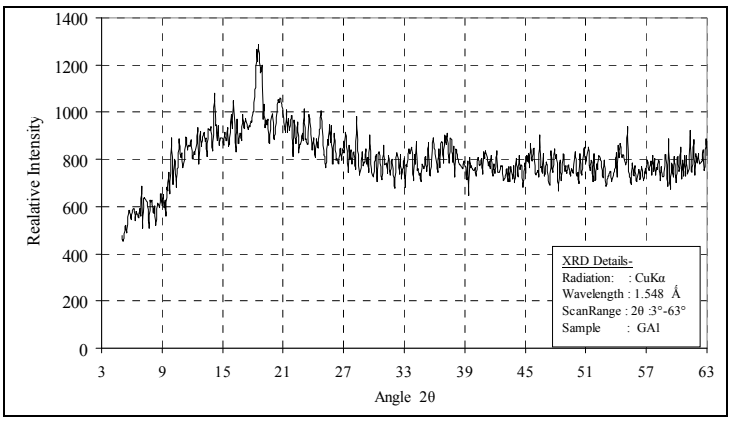

Figure 2. Result of X-Ray difractogram

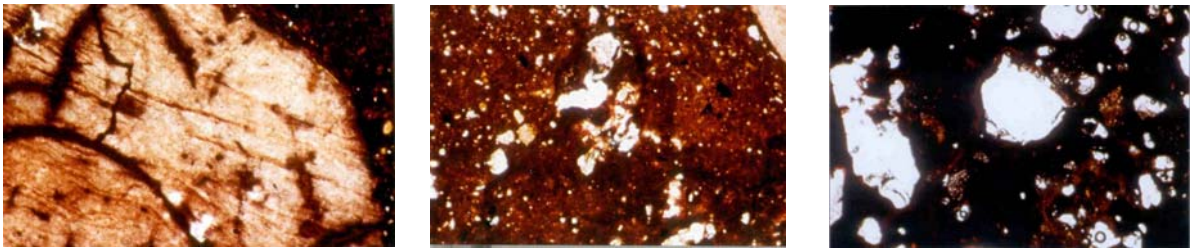

Figure 3. Result of thin section study

3.3.2 Physico-mechanical Analysis

Results of the physico-mechanical analysis is presented in Table 3.In spite of the difference between apparent and true specific gravities, the apparent and true porosities had similar values. Although the high porosity of laterite was reaffirmed in this result, it is difficult to explain the difference in the specific gravities or in other words, it is not easy to suggest that all pores in the system were interconnected. This anomaly might be a result of the fact that while measuring the actual saturated surface dry (SSD) mass of the specimen, it is almost impossible to keep the near-surface pores fully saturated. Average value of water absorption was found as 11.45%. Both porosity and water absorption were fairly low while compared to range of standard values [IS 2720: Part 25] indicating a matured variety of laterite. The value of 1641 g/m² / $min^{0.5}$ for coefficient of absorption through capillarity was found to be lesser than that of sandstones [Jäger & Burkert, 2002]. Hence it can be concluded that though laterite is porous, numbers of micro-pores are less and not susceptible to capillary action.

Table 3. Results of physico-mechanical tests

Properties	*Sub-properties*	*Values*	*Unit*
Capillarity	---	1641	g/m² / $min^{0.5}$
Water absorption	---	11.45	%
Specific gravity	Bulk	1.79	---
	SSD	1.99	---
	Apparent	2.25	---
	True	3.06	---
Porosity	Apparent	25.75	%
	True	26.48	%
Compressive Strength	---	5.05	MPa
Flexural strength	---	1.23	MPa

The average values of compressive and flexural strength of the sample were found to be 5.06 MPa, and 1.28 MPa respectively (Table 3). This indicates that laterite is a weak stone, even weaker than good quality brick [IS 1077]. This value is much lower than the calculated average strength of 10.3MPa found from rebound hammer test. Such a large difference in values occurred because in quarry a continuous surface was tested while the manufacturer's conversion graph was meant for 20 cm cubes.

3.3.3 Salt Crystallization Test

In the salt crystallization test of 15 weathering cycles, there was sharp weight gain of 5.07% on the first day but the rate of weight gain became steady up to 8-th cycle with a marginal difference within 3%. The large surface-pores accumulated salt crystals to a great extent on the very first day. As more salt solution seeped in, there was a slow but steady weight gain. Between 6th and 8th weathering cycles, specimens showed rapid weight loss of 4.7%. But during next three cycles, though there was again weight gain, but in later cycles the specimens started losing integrity and finally almost crumbled down (Figure 4). Probably during 6th to 8th cycles, resistance of samples was lost by a considerable extent such that pressure exerted by volume increase of salt crystals dislodged a few grains. Assuming most of these grains were internal, it can be concluded that some previously inaccessible pores might have got exposed to salt solution allowing more salt to enter, crystallize and cause weight gain. But in later stages, the excessive amount of salt had a splitting effect on week laterite and hence caused total disintegration of the specimens.

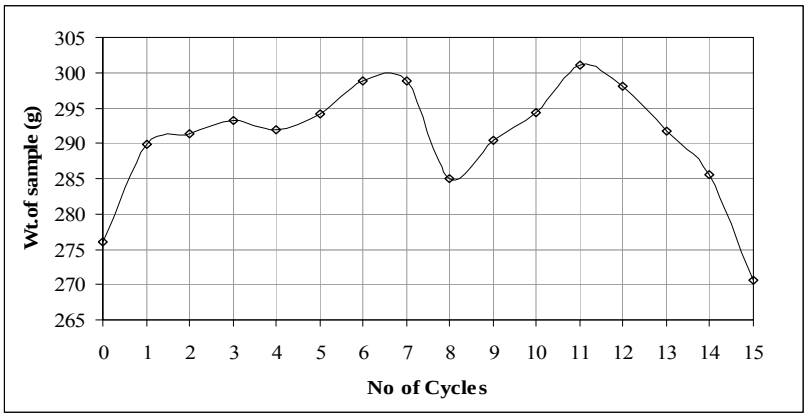

Figure 4. Result of salt crystallisation test

3.4 Discussion

From the monument investigation, the root cause of most of the defects was identified as water ingress either from lashing rain or from rising moisture leading to salt efflorescence and vegetation growth. Until1930, application of lime plaster before each monsoon prevented the harmful weathering actions to a great extent. Structural failure was not visible, hence a preliminary conclusion can be drawn that durability of laterite is more dependent on water tightness rather than strength. At local quarry, no significant depth-wise variation was found, but presence of clay minerals affirmed that though Goan laterite is a matured and stronger variety of laterite, it is susceptible to water ingress. Laboratory testing affirmed these facts. It was also found that though the stone has high porosity, the pores might not be interconnected and large enough to resist capillary action.

4. CONCLUSION

Goan laterite was tested at a world heritage monument, at local quarry and in laboratory using chemical analysis, petrographic microscopy, and physical tests to determine the decay mechanism. Most of the defects were as a result of water ingress. At quarry a matured type of laterite with less variance with depth was observed. Hence through megascopic analysis, good quality masonry material

can be selected to achieve the first line of defence against weathering. In spite of high content of strength-giving iron oxide, Goan laterite is weak in compression and flexure even compared to standard brick. Hence the durability of masonry was attributed to water tightness rather than strength. It can also be concluded that water repellence in the form of design detailing or water proofing agent can significantly improve the life span of monuments built in Goan laterite. The facts obtained from this study can contribute to an integrated database of laterite research and can be applied in the development of stone preservatives enhancing the pore structure and water tightness.

ACKNOWLEDGMENTS

This research was conducted under the supervision of Prof. Manu Santhanam of Indian Inst. of Technology, Madras. Additional research support from Prof Wolfram Jäger and Dr. Toralf Burkert of Chair of Load Bearing Structures, Technical University of Dresden, Germany and financial support from the Ministry of Human Resource Development of India are gratefully acknowledged.

Faults and Repairs in House of Bagheri: A Cultural Heritage Construction in Gorgan (North of Iran) – A Case Study

Mehrab Madhoshi [1]
Javid Eimanian [2]

T 25

ABSTRACT

This papers aims to show some features of one of the most important old constructions of Gorgan (North of Iran), called House of Bagheri, which, was built approximately 150 years ago with a built up area of 3000 m^2. Solid wood was utilized in large amounts as a construction material in structural elements like beams, columns, rafters, roofing and flooring system. Bricks and cob (a mixture of clay and straw) were used for walls. Doors and windows are completely wooden and look intact. The building is now considered as a Cultural Heritage Construction and its maintenance is important for Iranian Cultural Heritage Organization because of its history and tourism potential. In this paper, some important architectural and structural characteristics are considered with particular emphasis on wood as a construction material; study was conducted on existing faults and their reasons, including biological and environmental factors. The adopted repair methods are explained, and further comments on those methods are considered. The wooden species are identified in laboratory at macroscopic and microscopic levels and their existing mechanical strength were investigated, mainly compression parallel to grain and flexural strength. The results indicated that the domestic hardwood such as oak, elm, maple and imported softwood such as pine were used in construction of House of Bagheri. Some structural elements possessed acceptable strength in spite of their decayed appearance.

1 INTRODUCTION

Gorgan is located in North of Iran between Caspian sea and Alborz mountains where the climate is mostly mediterranean (with average rain fall of 432.1 mm and RH = 62.5% to 74%). It is considered a heritage city because of its history and historical buildings. Solid wood has been utilized as structural elements in some of them .

This papers aims to show some features of one of the most important old constructions of Gorgan (North of Iran), called House of Bagheri. This was built approximately 150 years ago with a built up area approximately 3000 m^2 (Eimanian, 2001). This building is now under repair. Solid wood was utilized in large amounts as a construction material in structural elements like beams, columns, rafters, roofing and flooring system. However, brick and cob (a mixture of clay and straw) were used for walls. Doors and windows are also completely of wood finish and are in a good condition. Nowadays, it is known as a Cultural Heritage Construction and its maintenance is important for Iranian Cultural Heritage Organization because of its history and tourism attractions.

Today, repair and restoration of historic buildings is a major challenge in societies (Lourenco *et al.* 2007). Previous studies conducted on wooden historical buildings showed that moisture and fungal decay could be considered as the main source of damge (Ronca & Gubana 1998, Pasanen *et al.* 2000). In this study of fungal decay, insects and and weathering are investigated as the source of damage (Wilkinson, 1979).

2 MATERIALS AND METHODS

A visual study was conducted of existing faults and their reasons, including biological and environmental factors. The adopted repair methods are explained and some comments on those methods are considered. Furthermore, the wooden species are identified in the laboratory at macroscopic and microscopic levels (Parsapajouh, 1988) and their existing mechanical strength investigated, mainly compression parallel to grain and flexural strength (Bodig & Jane, 1984).

3 RESULTS

3.1 Architectural and Structural Characteristics

The House of Bagheri is a collection of several main buildigs ad compounds and yards. A small pool is located in a central area of each yard and the buildings have been built around them. Although there is a one-storey building in this complex, it is mainly known as two-stories with a few steps between floors (Figure 1). The buildings have nearly identical architectural characteristics and the plan of one building is shown in Figure 2. The influance of Islamic art can be seen as the dome shaped window designs (Fig 3d).

Figure 1. Some views from House of Bagheri**.**

Thanks to its special design, air circulates easily providing good ventalation, which in turns provides a lower damp enviroment inside the building. The structure is rectangular and constructed essentially with brick and cob in shear walls and solid wood for load bearing elements. Figure 3 shows some areas where solid wood has been used as a construction material.

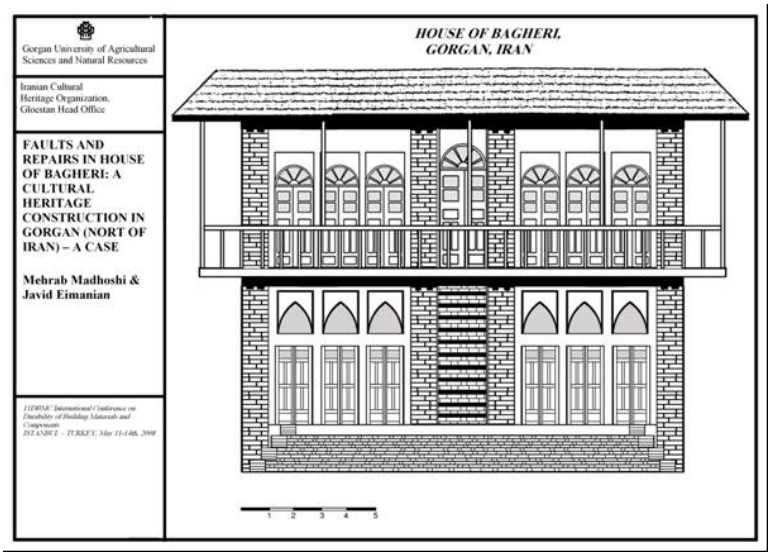

Figure 2. An Elevation of A Building in House of Bagheri**.**

Figure 3. The main construction materials used in House of Bagheri, (a) brick and cob, (b) solid wood beneath the door, (c) solid wood up the door and (d) solid wood as main beam and rafters.

3.2 Faults and Repairs

Although studies have been carried on the whole structure and other material, in this paper only the main faults/ and their reasons related to timber members are reported. The main faults can be considered in three groups as follows: 1. corrosion / by weathering, 2. decay/ by fungi attack and 3. internal holes/ by insects. These faults (or defects) are more or less common in North of Iran because of the climate. However, their distribution depends on area and species. Hence, the investigation on the type of faults existing in each building is necessary. It should be noted that faults due to dimensional variation related to swelling and shrinkage of wood were also found, but their effects were ignored in this study.

Corrosion caused by weathering (due to sunshine and rainwater splashing) was found in opening frames and balconies. In some parts, it was very intensive and combination with fungal decay, the wooden elements ad significant detemoration and could not be used again (Fig 4a). These elements have now been substituted by new members. In other elements the weathering was just a surface phenomena with the elements having nearly their primary strength (Fig. 4b). These elements could have been used again by surface intervention. Unfortunately, this method was ignored and the new members were utilized.

Figure 4. (a) Intensive weathering and (b) surface weathering, existing in House of Bagheri.

With regarding to the fungi and insect attack, the defects were disperesed over the buildings. The fungal growth and decayed parts were found mainly on rafters and internal beams exposed to moisture flows. Decay, like the weathering, depends on its severity and two conditions were noted. One recelting in colour change the other very intensive resulting in strength loss.The lullar was seen in an area with inadequate sun exposure and ventilation such as internal beams.
These elements (about 85%) have been substituted by new ones (Fig. 5b). However, they were ignored in a few areas where the elements were inside of walls. It should be noted that the moisture-related problem still remains in the replaced parts (Fig 6) leading to new stains and fungal decays.

Internal holes due to insects were also found in some parts especially where the hardwood was used (Fig. 7). It is obvious that the insects are not living anymore in wooden members, however, their effects on mechanical properties is very considerable. Although the members affected by this fault were renewed they were not considered in some areas and were ignored diving restoration.

3.3 Wood Specie

The wood members used in buildings can be considered in two main groups: domestic wood and imported woods. Domestic wood contains hardwood provided from the northern forests of Iran. Imported woods are softwood which have been probably imported from Russia. Although their identification was possible in field at a macroscopic level, a more detailed macroscopic (especially soft wood) was also considered in the lab. The species were identified: *Pinus sylvestris* (scots pine),

Figure 5. (a) Intensive decay and (b) new substituted rafters.

Figure 6. Existing moisture-related problem in new member

Figure 7. Holes due to insects attack

3.4 Mechanical Properties

Table 1 shows the measeared mechanical properties of some old members. It can be seen that the old members (except the last one which was decayed overall) possessed acceptable mechanical strength. It shows that the members should be conservatively changed because despite their appearance they were still structurally sound.

Table 1. The mechanical properties of old wood members measured in laboratory

The area of sample	MOR (MPa)	MOE (MPa)	E in C_{ll} * (MPa)
Rafter (nearly sound)	79.12	10465.95	3116.48
Rafter (sound)	88.73	8901.518	3429.06
Coulmn (sound)	-	-	2436.92
Up of door (nearly sound)	79.77	9099.37	1007.74
Up of door (decayed oveall)	12.67	2124.28	2148.97

- Modulus of elasticity in compression parallel to grain

CONCLUSION

1. The House of Bagheri is a heritage construction building in Gorgan in which the timber members have some damages and building required to repair and restoration.
2. The main faults considered in the builidng are corrosion, fungal decay and insect attack.
3. Some adpoted repair methods should be changed.
4. Domestic and imported wood was used in construction of building.
5. The mechanical propeties of wood showed that the old members possessed still acceptable strength.

Issues in the Identification and Monitoring of Historical Structures – Monuments

Yasemin Didem Aktaş [1]
Ahmet Türer [2]

T 25

ABSTRACT

This paper aims to introduce a general methodology for the structural identification and monitoring of historical monuments. The identification and monitoring procedure was discussed within four main frameworks: (1) visual inspection, (2) finite element modeling, analysis, updating, validation and simulation, (3) short term measurements, and (4) long term monitoring. The defined approach targets to determine the current state (material data, structural behavior, and existence/extend of damage) of structure as well as monitor changes and extrapolate them over time or event basis (e.g. environmental deterioration and earthquakes). The mentioned steps were presented in the form of a detailed and hierarchical schema regarding both methodology and instrumentation. The methods proposed for the structural identification and material characterization of monuments were mainly non-destructive. In addition, the eminent monuments of the Mount Nemrud in Adıyaman, Turkey were chosen as a case study, briefly explaining the preparation studies carried out so far.

1 INTRODUCTION

The identification, monitoring, and evaluation of historical structures / monuments have some additional difficulties in comparison with that of modern structures. These difficulties were mentioned before by many scholars [i.e. Lourenço 2002 and Binda & Anzani 1997]. The most important of them can be briefly listed as follows:

1. There are no standards applicable for monitoring and system identification (St-Id) of historical structures,
2. The physical, mechanical, chemical, and compositional characterization of materials are difficult, expensive and sometimes too destructive to be accepted in the case of historical structures,
3. Masonry walls are generally composite structures. While the material properties of each individual building material (e.g., brick, mortar, stone etc.) can be successfully obtained, it is still a problem to determine the overall effective material properties of composite masonry walls,
4. Masonry is a heterogeneous material both in terms of constitution (rubble stone masonry, multi-leaf walls, or those having inclusions and/or voids) and material properties (historical brick and mortars not produced according to some common standards and therefore having different characteristics throughout the structure). Therefore, it is difficult to obtain meaningful representative values by considering just a few reference locations; however, taking many samples from a historical structure is not preferred due to nondestructivity principle,
5. The damage to a historical structure by taking material samples may be minimized by taking micro samples; but, samples taken under these circumstances are not in standard test size and shapes,
6. Structure's inner and outer walls are normally covered with plaster and like, so it is not possible to see the masonry surface to evaluate the external texture parameters such as mortar joint thickness, distribution and size of building blocks, etc.,
7. Since the original material properties of a historical structure are not well known, it is usually not possible to evaluate the material damage caused by environmental conditions over time, except for the original material can be found from nearby quarries or other resources,
8. The experimental data to be used for calibration of analytical models are usually not available or not adequate,
9. History of structural modifications (e.g. removing load carrying walls, opening windows, adding floors etc.), functional modifications (house, library, museum), structural damages (e.g. seismic), repairs, or restoration works on the monument may not always be available.

Facing up to these matters necessitates unique approaches for each case to collect needed data, processing, evaluation, and management of them. For these purposes, the authors developed a hierarchical schema regarding both methodology and instrumentation, which is described in the following section.

2 A GENERAL METHODOLOGY FOR THE STRUCTURAL MONITORING

Structural monitoring is more than arbitrarily attaching a few sensors and collecting data for a selected period of time. The general approach to structural monitoring may be considered to be a three dimensional matrix where the width can be defined as (1) visual inspection, (2) finite element analysis, (3) short term measurements, and (4) long term monitoring. The depth can be defined as different parameters to be monitored/evaluated and methods used for this purpose. The height of the defined three dimensional methodology matrix is formed by the type, number, and location information; however, these parameters show great variation and are highly case dependent. Therefore, the methodology matrix developed in this study was limited to only two dimensions, which are the width and depth. It is important to note that this study was aimed to present a general framework for the structural monitoring and evaluation of the historical structures; however, each individual case may have specific requirements and conditions. Each individual item of the presented matrix is described under each heading below.

2.1 Visual Inspection

Visual inspection step is the most direct and economical step of the condition assessment and structural monitoring of historical structures. The qualitative evaluation of the state of conservation is mainly based on visual inspection which can detect:

- Structural anomalies (structural cracks, deformations, tilted columns and walls, sagged slabs etc.) which gives idea on load transfer mechanisms and possible foundation problems,
- Mechanisms of material deterioration, degradation, and decohesion (visible in the form of efflorescence, biodeterioration, color changes, non-structural cracks, flaking, detachments etc.), their potential causes (unhealthy drainage, large temperature changes, wetting-drying cycles, damping problems, freeze and thaw, previous restorative interventions performed with incompatible material such as concrete), level of deterioration (in a relative manner), and their distribution in the structure,
- Some basic features of structure in terms of construction materials, structural technology (different construction materials and techniques used, mural and structural typology etc.), possible plan or elevation irregularities in geometry,
- Perceptible structural changes and adaptations performed throughout the life of a structure (an added bell tower, a divided room etc.) and the traces of previous repairs and restorations.

Visual inspection method obviously cannot be performed to detect invisible features or to obtain quantitative data and yet it is a very basic part of structural investigation of a historical structure / monument. As a matter of fact, visual inspection methods are frequently referred during short and long term measurements for structural monitoring, as a strong complementary support.

Visual inspection can be additionally used for on-site environmental survey, to evaluate close range water sources, topographical features such as slopes, soil conditions (clay, sand, rock), potential construction material resources, similar structures in the vicinity (from structural, material, and exposed conditions' points of view). Thereby, a regional catalogue of mural morphology can also be developed using open cross sections.

2.2 Finite Element Analysis

Finite element analysis is defined to have five stages: modeling, analysis, updating, validation, and simulation. Modeling stage would include preliminary, original, and calibrated analytical models. The preliminary model approximately reflects the geometrical and material characteristics of the structure, and used to give an idea about the structural system and behavior. The original model uses basic dimensions taken during on-site measurements or from available plans. The calibrated model would form the last modeling step and mostly uses short-term test results; the static loading and dynamic measurement results (mode shapes, modal frequencies) are tried to be replicated by the analytical model and the structural parameters (such as effective elastic modulus, poisons ratio, density, support-boundary conditions) are iteratively modified until the simulated and measured responses are closely matching. The calibrated analytical model would closely reflect the actual structural behavior/response and be used for structural identification (St-Id). The calibrated models are especially important in the case of historical structures, since there are many uncertainties associated with the material, boundary, and geometrical features.

The field tests conducted for calibration of analytical models and related structural identification studies need to be in the linear range to prevent any damage to the structure. The constructed model is analyzed under certain loading cases defining the normal service conditions as well as those thought to be critical. Response of historical structures should often times be evaluated for extreme loading cases such as earthquakes, where demand on the structure is in the non-linear range and material and geometric nonlinearities should be considered. Therefore, the choice of the analysis type to perform is a function of the level of loading and forms another crucial point [Lourenço 2002].

The available modeling types, such as smeared (macro) modeling or micro modeling, would also play an important role for the simulation studies. The overall modeling of a structure would usually be not feasible using micro modeling, since large number of members and related degrees of freedom would require extensive amount of computer time. The global behavior of a structure in the linear range may be well simulated using elements that would reflect the average properties of composite structural members; on the other hand, non-linear range modeling and simulation using smeared (macro) modeling may only give a rough idea. Although exact nonlinear behavior of a historical structure can never be fully modeled, modeling carefully each detail of composite geometry and material characteristics of the whole structure (micro modeling on a global scale) would give the closest results to actual response.

2.3 Short Term Measurements

Short term measurements may include parameters related to structural morphology such as
- geometrical features (member size and dimensions, type and distribution of load carrying members, crack width, differential settlement, tilt, section loss, georadar, etc. measurements)
- technological characteristics of structural members defining the material type and distribution (material variation across the thickness of a masonry multi-leaf wall, physical, chemical, mechanical, and compositional characterization of building materials, connection of members, ultrasonic pulse velocity, elasticity etc. measurements)

Furthermore, dynamic and static test results constitute the products of form and structure of a system and would also be collected during short term measurements. The static tests generally include loading the structure with a known magnitude of force which would remain in the linear range of the system. Dynamic tests are conducted using either ambient vibration or forced vibration excitation. The structural parameters are obtained in the form of structural stiffness-flexibility and mode shapes, frequencies, damping ratios. All these parameters should be evaluated and used to update the original finite element model.

2.4 Long Term Monitoring

At the long term monitoring step, the parameters exhibiting change over time are investigated; these parameters would include environmental factors like temperature, humidity, wind and rain, and other factors related to structural changes over time such as crack width variation, dynamic characteristic changes etc. Long term measurements might as well include short term static and/or dynamic measurements which are repetitively conducted over time (mostly with equal time intervals such as once every three months). Long term static measurements mostly consider measurements of temperature, humidity, change in crack width, strain, tilt etc. and these are repeated with frequent intervals in a quasi-continuous manner (such as one measurement at every 30 minutes). On the other hand, the continuous measurement of dynamic characteristics of a structure generates large size data packets which are not possible to store as raw data. Therefore, all dynamic data are not recorded; instead, the data are processed online and only relevant dynamic characteristics (such as periods) are stored. In the case of repetitive loading – such as vehicles passing over a historical bridge – statistical methods are utilized to generate histograms.

As seen, the four steps mentioned above are interrelated. The correct management of the collected data requires a multi-level comprehension. In the given schema, the potential methods and instruments that

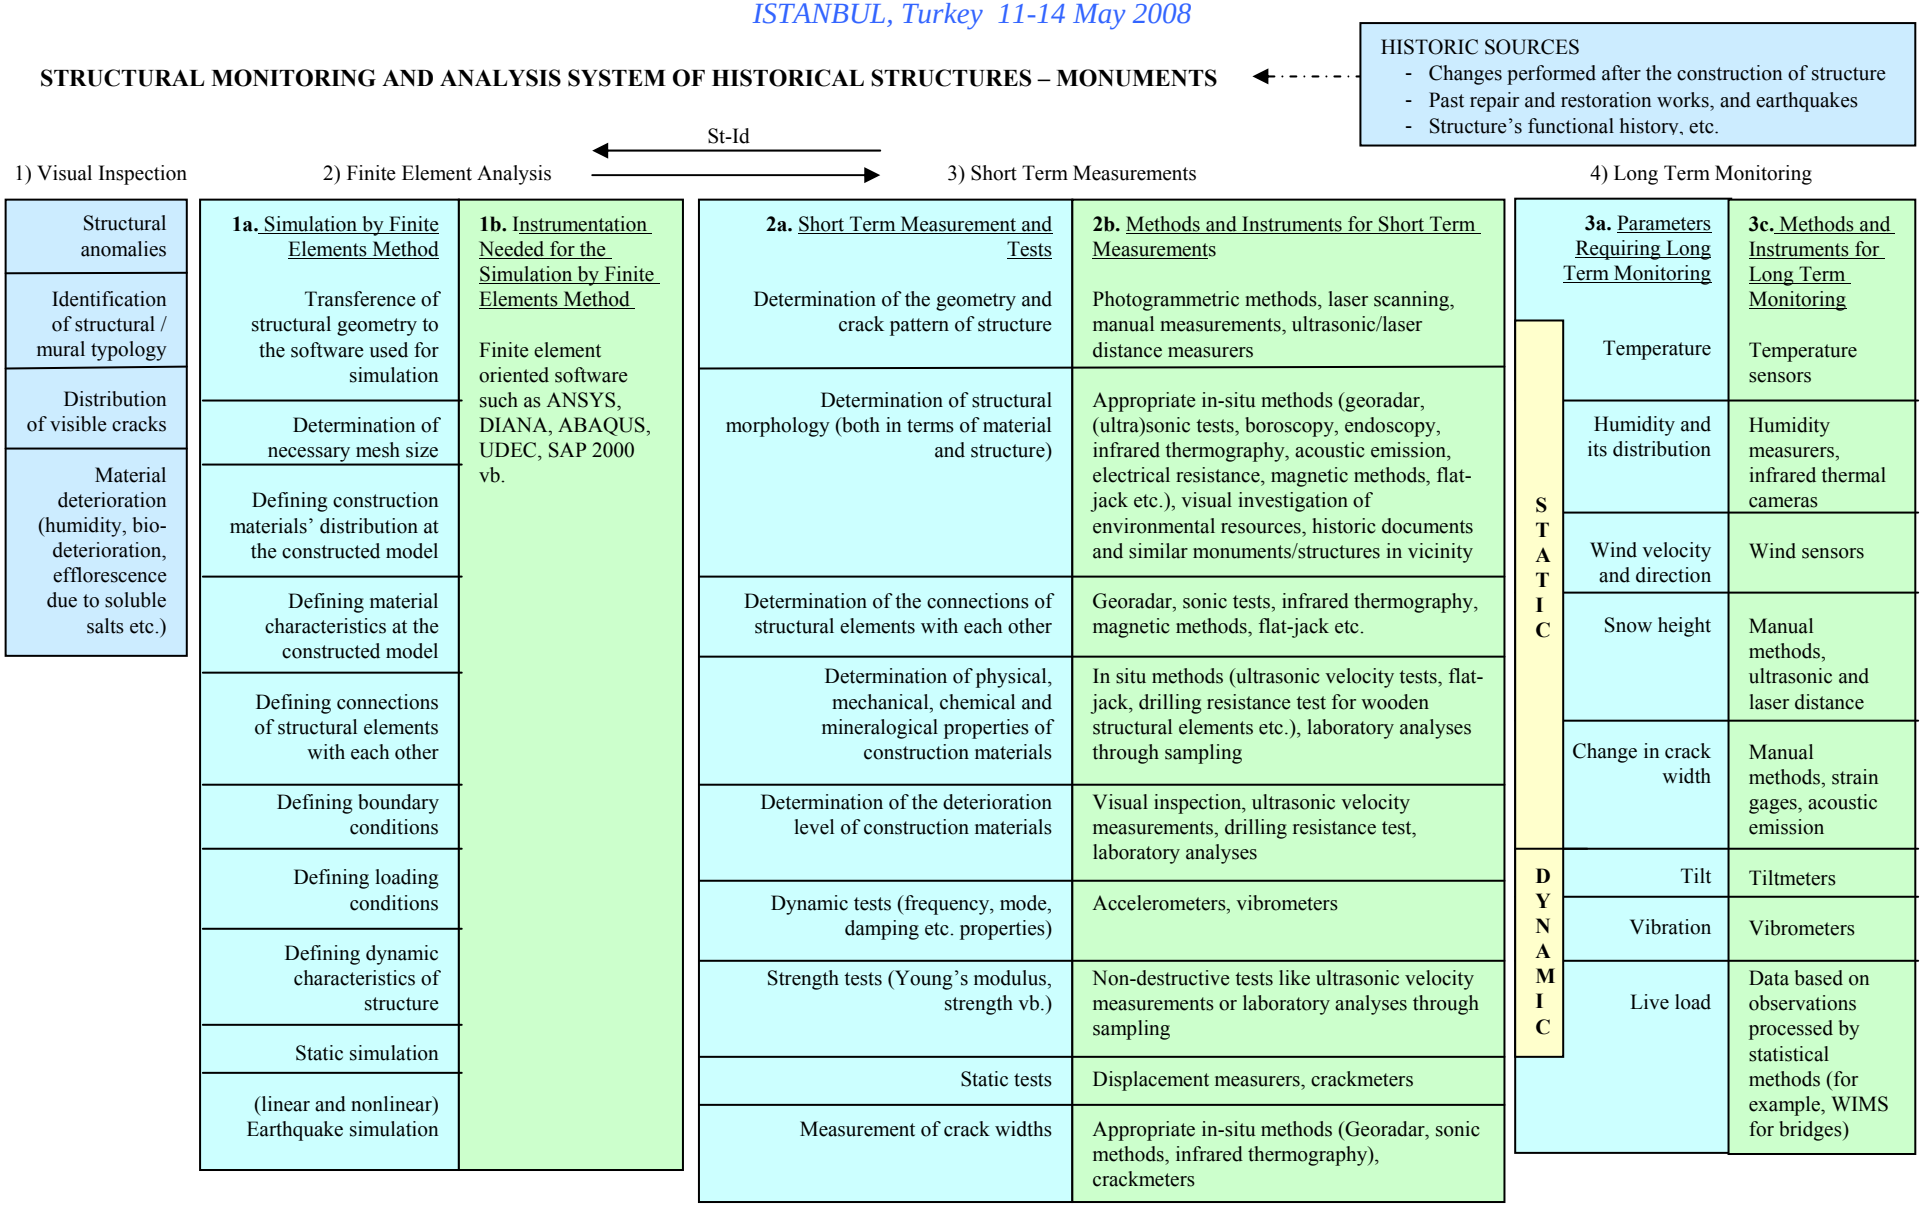

Figure 1: Schema for the structural monitoring of historical monuments

are related to measurements are also listed in the second column of Fig 1. The examples presented in Fig 1 are general; therefore, each unique application case should be evaluated individually for the method and instrument selection. The needed level of accuracy and information, available human resources, and budget also play an important role in the choice of instrument, which points out the significance of planning in such studies. In the case of historical structures, the selected methods are expected to be as non-destructive as possible. Since non-destructive methods give generally indirect results, one method should always be supported with one of its complementary methods (in the relevant literature, there are many studies on NDE and complementary techniques [i.e. Binda *et al.* 2004 and Binda *et al.* 2003]). It should also be noted that some indirect non-destructive investigation techniques on historical structures may be lacking calibration (e.g., ultrasonic pulse velocity, georadar) for different types of heterogeneous and aged materials used in historical structures. Similarly, standards may not be applicable for some specific NDT techniques (such as forced infrared thermography) applied on historical structures. The ongoing studies are promising for their reliability when each technique is used within its specific applicability limitations. Another problem of common NDE methods is that the raw data obtained are mostly difficult to evaluate, requires post-processing, and therefore depends on expertise causing possible increase of the evaluation costs.

In addition to all of these, historical sources may also be put to use if present. These historic sources can be inscriptions, visual and/or written archive documents, travel books, etc. The use of available documents can constitute a tool for anamnesis, informing us on the changes, adaptations, additions / cancellations performed on the structure, repair and restoration works carried out, the seismic and functional history of the structure.

3 NEMRUD MONUMENTS

Nemrud is an archaeological site in Adiyaman, in the eastern part of Turkey. The site, which was discovered in 1835, is famous with the big monumental statues (8 to 10 meters in height) more than two thousand years old, lined up in the form of two rows on two sides (east and west terraces) of a centered tumulus. The site belongs to an ancient kingdom called ‘Commagene’ and is located at the top of Mount Nemrut (2150 m). Each statue, except that of the king building the site, represents a Greek god / goddess corresponding at the same time to a Persian sacred figure, which is sitting on a throne. At the backsides of the thrones there are some inscriptions which render the site also valuable in terms of the presence of written documents [Cimok 1995].

The bodies of the statues are composed of big stone blocks. They are probably simply put on top of each other without any physical binder or mechanical connection like mortar or metal clamps. The heads are made of a single piece of stone. The statues are made of limestone which is a readily available material of the region. Moreover, the statues on the east and west terraces are almost identical. In spite of these similarities, those in the east terrace are in relatively good structural condition in comparison with those located on the west terrace. The west terrace statues were torn down towards west, while the statues on the east side have a better physical integrity and yet, all of the statue heads were detached from their bodies and fallen down. The site is located at a highly seismic zone; therefore, the detachments are thought to have happened during a previous strong earthquake or series of earthquakes. Furthermore, the difference between the two terraces in terms of physical integrity is thought to be caused by non homogeneous distribution and accumulation of snow load due to high winds. The accumulated snow might be pushing down the slope, slowly moving segments of stones over hundreds of years causing a progressive failure.

There are different material deterioration phenomena observed in Nemrud Monuments. Material is further abraded due to physical and mechanical inducements of environment such as wind, serious seasonal and daily temperature variations, precipitations, sun exposure etc. For all these reasons, an international Nemrud project was funded by the Turkish Ministry of Culture, World Monument Fund, and TUBITAK (104I011). The aim of the project is to execute a more structured and proper damage assessment and diagnosis of the monuments in a multi-disciplinary, integrated manner from structural

and materialistic assessment, conservation, site presentation, restoration points of view. The preliminary site and material investigations have begun in 2006 within the framework of current project and some in-situ studies, such as ultrasonic velocity measurements and stone deterioration maps were obtained. Two temperature and humidity sensors as well as a sensor to meaure the direction and velocity of wind were installed on site which would continuously collect data and can be remotely connected via GSM modem (Fig 2). Meanwhile, the preliminary FEM of a typical Nemrud monument was constructed and a modal analysis was carried out to have an idea about the range of natural frequencies and mode shapes. The initially obtained mode shapes indicate that the heads may have fallen because of an earthquake (Fig 3-4). Moreover, dynamic tests were conducted to obtain the natural vibration frequencies of the standing statues.

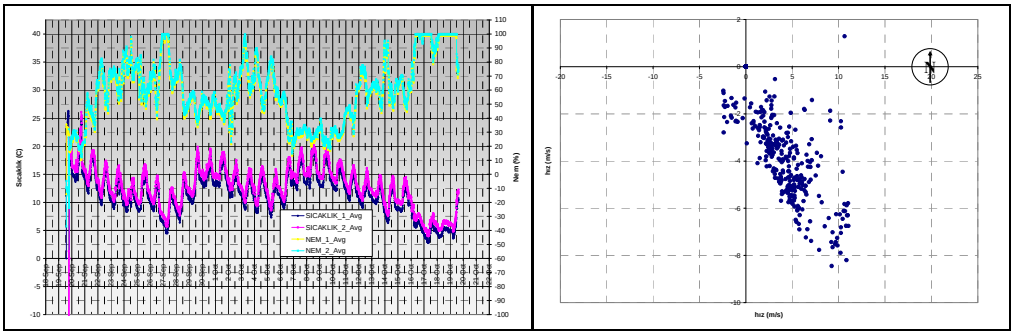

Figure 2. An example data reading obtained for temperature and humidity, and for wind velocity and direction, respectively.

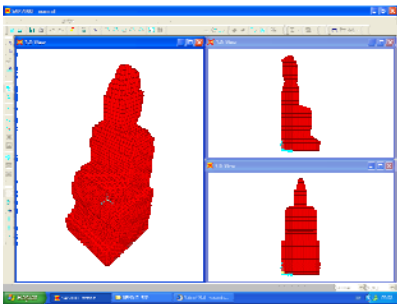

Figure 3. 3D FEM of a typical Nemrut monument

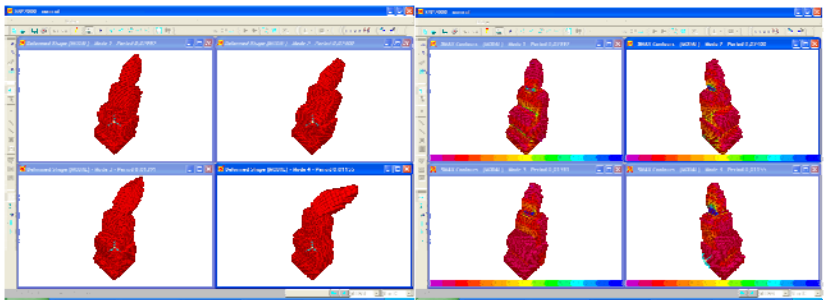

Figure 4. The obtained modal shapes and the corresponding maximum stress distributions

In 2007, the sensors to monitor the snow height will be installed. Moreover, the stone location map of collapsed statues will be obtained by photogrammetric methods. The structural investigations are planned to be continued with more detailed calibrated linear and non-linear FE models, synthetic and recorded earthquake simulations, and the formation of retrospective damage scenarios. The 3D-FE model will be updated using field measured dynamic data to conduct St-Id. The short term dynamic measurements and long term monitoring results will be combined to understand the behavior and

deterioration mechanisms. The calibrated analytical model will be used to simulate possible earthquake loading and pertinent damage scenarios. These investigations will be fed by the data regarding the materials, obtained by more in-situ measurements and laboratory analyses. Finding sensors functioning at extremely harsh environmental conditions is another challenging task in the Nemrud project. In addition, the site is at the top of a mountain, far from settling areas, which brings in additional difficulties e.g. easy access, accommodation, lack of electricity, and security concerns.

3 CONCLUSIONS

- This paper aims to introduce a four-step framework for structural monitoring of historical / archaeological structures regarding both methodology and instrumentation. According to this framework, a structural monitoring study can be handled as (1) visual inspection, (2) finite element modelling, analysis, updating, validation and simulation, (3) short term measurements, and (4) long term monitoring. These four steps form the general approach of identification and monitoring of historical structures – monuments,

- The structural monitoring of historical / archaeological structures entails some extra difficulties in comparison with that of modern structures. These difficulties should be tackled within the constraints recognized for cultural heritage investigations (e.g., non-destructivity),

- As the Nemrud example indicates, each case of historical / archaeological structure / monument / site exhibits particular problems that should be specially considered. The information and accuracy needed, available human resources and budget etc. are other factors playing role in the constitution of monitoring approach. Therefore, each case is unique within itself.

Umberto Rodonò [3]
Salvatore Secondo [4]

T 25

ABSTRACT

The operation on the existing estate demands the employement of compatible solutions (from the material and technological, as well as environmental and typological point of view), which are suitable to satisfy new requirements (by reason of the evolution of the required performig levels, but also with regard to the possible changes of in-use destination and/or variation of intensity of the straining context) and mostly durable or rather capable to maintain over time the required performing levels.
The proposed research activity enters in this field and aims at identifying innovative materials and components to employ in the operations on existing building, evaluating their performances over time.
In the specific case, the carried out study aims at putting into practice an experimental evaluation of the durability of materials to employ in the operations on building curtains and, in particular, in the coverings (both traditional and innovative) to apply to the stone facade equipment (limestone) typical of "iblea" area.
The results of this kind of investigation may contribute to represent the basis for setting up an abacus containing all the operitive possibilities of operation on each noticed finishing category, as well as the procedures in order to proceed to a correct employement of the external finishing materials, plaster, stone parameters, and finally the superficial treatments to employ.

1 THE OPERATION ON EXISTING BUILDING

The operation on existing estate requires, as everybody knows, a marked sensitivity, a deep technical competence and a cosiderable respect for the history of the building. The line of material, technological and environmental compatibility is already consolidate, but often it must be faced the problem to intervene on the manufactures that, on account of the renewed in-use destination and mostly of the changed environmental conditions, are at present submitted to new straining conditions. It follows that it is necessary to know which choice allows, in the respect of the building and tradition, to obtain durable solutions over time. Moreover, it is necessary to explain the opportunity to re-propose traditional materials or rather to decide for innovative solutions (in part or on the whole), that are suitable to answer to the current performing requirements. What is just explained is referred to every kind of operation on the historical building estate and in a particular to the operations concerning the external covering of building; in fact, as the covering is in direct contact with the external environment particularly agressive, it requires continuous maintenances.
The work which is presented below is a part of a study that the research unit is carrying out in order to define preliminary methodologies and tools to the redaction of the Colour Plan of the town of Ragusa. Colour plan intended as a real operative plan of operation, which is not limited to face the problem of the hypothetical "colour" of the facades but rarher is aimed at going into the theme both in terms of modality of approach and of real operations.

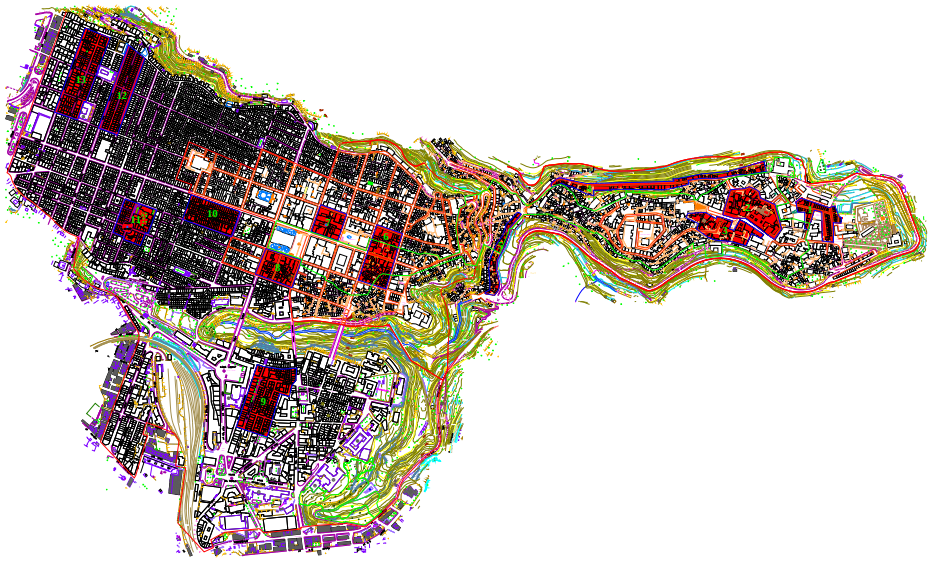

Figure 1. City plan of the historical centres of Ragusa

The town of Ragusa is developed in two historical units, the former more ancient, "Ragusa Ibla", closed between two deep valleys, and the latter more recent, "Ragusa Superiore". The first unit represents a medival area on which eighteenth-century reconstruction has been superimposed (post-earthquake of 1693). The result is both a curious and charming effect of internal contrast characterized by narrow and winding alleys, picturesque stairs and sumptuous facades of baroque churches and buildings. The second unit, "Ragusa Superiore", planned after the earthquake of 1693, follows a chequered scheme with long parallel roads characterized by majestic late baroque fronts of buildings and culminating in theatrical perspectives. Since 2002 Ragusa is part of Unesco humanity estate.

2 THE CARRIED OUT INVESTIGATION

In order to produce a preliminary study to the redaction of the colour plan, the research group has pursued the following stages:

1. bibliographical and archival investigation to identify typical building material and finishes of "iblea" area; the aim of this section is to gather all the information to know the modalities and techniques of execution of building finishes, with great attention to the gathering of news obtained directly by technicians and local workers.
2. cognitive investigation of the buildings that belong to a pilot area made up of 13 sections (figure1). Such a section has been carried out through filling in synoptic cards of survey (filled in situ) containing information about characteristics and conditions of: plasters, stone facade equipement, covering and metallic elements;
3. geometrical, material (instrumental) and chromatic[1] survey of the building curtains that belong to the pilot area;
4. experimental investigation for evaluating the duration of traditional and innovative treatments in order to protect stone surfaces. This last phase is coming up in this paper.

3 THE TYPICAL MATERALS OF IBLEA CURTAINS

Bibliographical and archival investigation, together with technicians information and local workers, as well as inspections carried out on pilot areas have made it possible to identify the materials that characterize the historical town centre of Ragusa. The main characteristics of plasters, stone facade elements and employed finish products are explained briefly as follows.

3.1 The Plasters

The carried out studies made it clear that the plasters of the town of Ragusa were usually manufactured by lime mortar and lime sand (sometimes pounded terra-cotta). Generally, they were spread on two layers: the first, nearly 3 cm, of rough inert materials, and the second of di 5-10 mm, of thinner granulometry. The proportions between inert material and limestone were of 1:2. To protect the plaster was generally added a further finish (cf. 3.3).

3.2 The Stone Facade Equipment

The employed stones to decorate building facades of Ragusa were essentially white limestone (hard, for the elements of skirting board, basement, external paving, corners, steps; or soft, for stone frames, capitals and every kind of decoration, cf. figure 2A) and the asphaltic grey-black rock, that is a swinestone, the material of which iblea plateau is rich.[2] The swinestone presents two varieties distinguished in the level of bitumen impregnation, so in consistency, so in workability, so in employement:

- **pietra pece (pitchstone)**, at high bitumen impregnation, darker, softer, (employed for decorative elements, figure 2B.) but also more wear-proof (this characteristic has made it suitable for the flagstones of balconies and for pavement;
- **pietra zoccolo**, harder, because of at low bitumen impregnation. It was employed for the basement, steps and brackets of balconies (figure 2C).
-

Figure 2. A: white limestone; B: pietra pece; C: pietra zoccolo.

As the asphaltic stone tend to whiten over time, because of the atmospheric agents, it was (if left at the sight) covered by linseed oil and carbon black.

3.3 The Finishes

Plasters as well as stone decorations were generally protected by:

- light coverings with linseed oil and coloured earths (sometimes when added albumin), figure 3A;
- whitewashings with fast coloured lime water (when added oxides) or light coloured (when added natural earths), figure 3B;
- "lime paint", always made up of lime dissolved in water and combined with colouring earths, but of a consistency more mellow than the whitewashing, figure 3C.[3]

Figure 3. A: Samples of light coverings with linseed oil and natural earths.; B: Plastering with lime water and natural earths.; C: "Lime paint" on plaster (lime milk and oxides).

4. THE EXPERIMENTATION

The aims that are being persued in laboratory exposing the samples to artificial ageing cycles are those to identify and study phisical and performing decays primed by strainings artificially produced by the cycle and to compare these decays with those examined on samples exposed to a natural ageing. Regulation (ISO 15686, UNI11156, etc.) has developed some protocols for the evaluation of the durability of the building components, but some points of the procedure are still to define in a sole way. More precisely, the formulation of the standard of the accelerated ageing cycle is not well defined yet. This has great importance in the experimentation. It must be suitable to reproduce strainings artificially that are referable, in type, intensity and duration to the strainings to which the technical solution, which is the object of the investigation, is exposed during the course of its life.
In relation to what is explained above and to the experiences that have been carried out on further building components by the research unit until now, (Caponetto R., 2006) it has been considered right

to set up the experimental investigation in such a way as to perfect the sizing of the accelerated ageing cycle compared to what have been done by our team until today.

4.1 Object of The Experimentation

The experiment which is presented below has carried out the evaluation of the durability of covering systems of the stone facades equipment of Ragusa. More precisely, tests of durability on two kinds of more recurrent stone material (limestone and swinestone) have been carried out in laboratory and outdoors examing different kinds of coverings (traditionals and not). The set up of the accelerated ageing cycle is shown in paragraph 4.1.2. The results of this test will be, as it is provided for by regulation, compared with those resulting from the natural ageing, so as to evaluate the trend of the performances in time and thus to determine the service life of the investigated component under certain straining conditions.

4.1.1 Definition of The Solution and Samples

The choice has been that of testing, for the two stone materials, the following solutions of superficial covering:

Table 1. Testing solutions

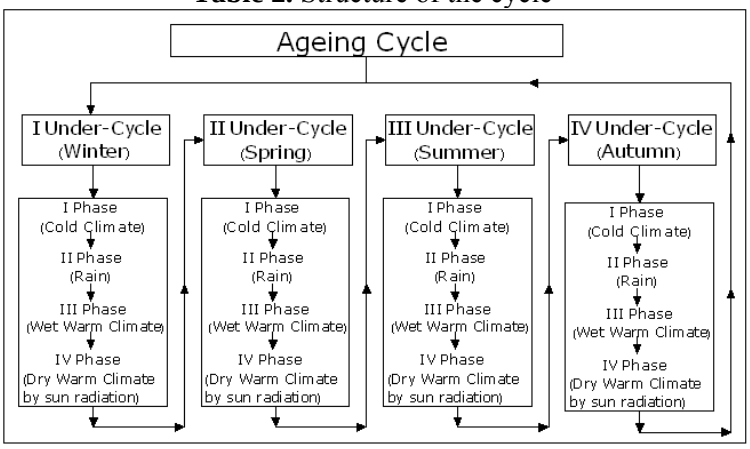
PITCHSTONE		*WHITESTONE*	
A1	Covering with linseed oil	**B1**	Covering with linseed oil
A2	Covering with linseed oil and carbon black	**B2**	Covering with lime milk with natural pigments
A3	Covering with linseed oil plus carbon black with compound a basis of siloxanes	**B3**	Covering with lime milk and acrylic resin (Acrylic 33) with natural pigments
A4	Covering with compound a basis of siloxanes in organic solvent	**B4**	Covering with compound a basis of siloxanes in organic solvent

For each solution 6 cylinder-shaped samples three of which of diameter and height 5 cm and three of diameter 8 cm and height 3 cm have been realized.

4.1.2 Definition of Accelerated Ageing Cycle

The accelerated ageing procedure to set in climatic room checks a cycle characterized by a structure that re-proposes the natural sequence of the four climatic seasons: Winter, Spring, Summer and Autumn. The cycle is made up of four under-cycles which are divided into four phases, each of them representing a climatic condition simulating by the engine: Cold climate (Phase I), Rain (Phase II), Wet warm climate (Phase III), Dry warm climate by sun radiation (Phase IV).

Table 2. Structure of the cycle



In order to determine the values of the climatic parameters of the single phases of each under-cycle, data characterizing the climate of the town of Ragusa[4] have been employed, making reference to a

period of time which goes from 1968 to 1994. Thanks to simple mathematical formulas[5], the values of the climatic parameters for each season have been characterized (Table 3).

Table 3. Values of climatic parameters characterizing each season

Season	*Temperature min (°C)*		*Temperature max (°C)*		*Relative humidity*	*Mean Precipitation*	*Dealy mean sun radiation*
	Mean	*Peack*	*Mean*	*Peak*	*(%)*	*mm*	*hours*
Winter	+01.47	-03.16	+09.25	+11.31	78.3	77.97	10.46
Spring	+07.28	+02.66	+29.43	+36.41	45.8	27.48	13.54
Summer	+13.07	+08.31	+34.25	+39.51	58.2	18.13	13.55
Autumn	+06.32	+01.79	+13.77	+18.60	88.1	79.22	10.39

The characteristic values of each individual phase, for each under-cycle, to assign to the climatic cell have been determined according to the standards described by the following Table 4:

Table 4. Standards of Choice of the Intensity of the Degrading Agents

PHASE	*PARAMETER*	*SEASON (UNDERCYCLE)*			
		WINTER (I°)	*SPRING (II°)*	*SUMMER (III°)*	*AUTUMN (IV°)*
I	T	Minimum of peak	Mean	Mean	Minimum of peak
COLD	R.U.	no	no	no	no
CLIMATE	SUN RAD.	no	no	no	no
	RAIN	no	no	no	no
II	T	no	no	no	no
RAIN	R.U.	no	no	no	no
	SUN RAD.	no	no	no	no
	RAIN	Firing[6]	Firing	Firing	Firing
III	T	Mean	Maximum of peak	Maximum of peak	Mean
WET	R.U.	Mean	Mean	Maximum of peak	Mean
WARM	SUN RAD.	no	no	no	no
CLIMATE	RAIN	no	no	no	no
IV	T	Mean	Maximum of peak	Maximum of peak	Mean
DRY	U.R.	no	no	no	no
WARM	SUN RAD.	Firing	Firing	Firing	Firing
CLIMATE	RAIN	no	no	no	no

For what concerns the definition of the time of actions of such agents, the first step has been to impose that the cycle lasts 40 hours[7]. Time T of each idividual under-cycle is determined by simple proportion starting from no. of days characterizing each individual climatic season (respectively 90, 92, 94, 89, Table 5).

Table 5. Time T of Each Under-Cycle

Under-cycle - Season	*Proportion*	*Time T*
I Winter	40:365 = T:90	T = 9h and 50min
II Spring	40:365 = T:92	T = 10h and 04min
III Summer	40:365 = T:94	T = 10h and 18min
IV Autumn	40:365 = T:89	T = 9h and 48min
Total		T = 40 hours

Obtained time T of each individual under-cycle, times of each single phase, of each under-cycle, are determined assigning some weights P (Table 6):

Table 6. Weights of Each Phase for Each Under-Cycle

Under-cycle - Season	*Time T*	*PHASE I*	*PHASE II*	*PHASE III*	*PHASE IV*
I Winter	9h and 50min	P_{11} x T	P_{12} x T	P_{13} x T	P_{14} x T
II Spring	10h and 04min	P_{21} x T	P_{22} x T	P_{23} x T	P_{24} x T
III Summer	10h and 18min	P_{31} x T	P_{32} x T	P_{33} x T	P_{34} x T
IV Autumn	9h and 48min	P_{41} x T	P_{42} x T	P_{43} x T	P_{44} x T

The weights P of phases I, III e IV depend on daily hours of seasonal exposure to the sun while the weights of phases II on the mm seasonal rain (Table 3) and they are obtained by the following formulas:

- Data P_{x1}, P_{x3}, P_{x4} (where x represents the season or the under-cycle), the sum of the three weights must be equal to 1(phase 2 of rain do not have sun radiation), that is: $P_{x1} + P_{x3} + P_{x4} = 1$
  The propotion that must be considered to obtain the weight of the phases of wet warm climate and dry warm climate is the following:

  $(P_{x3} + P_{x4})$: (hours of mean exposure to the sun of x) = 1 : 24 h

  $P_{x3} = P_{x4}$

  For the cold phase:

  $P_{x1} = 1 - (P_{x3} + P_{x4})$

  Datum P_{x2}, the sum of the weights of phases II must be equal to a 1, that is:

  $P_{12} + P_{22} + P_{32} + P_{42} = 1$

- The propotion that must be considered for each weight is the following:

  $P_{x2} : 1 =$ (mm of rain of x) : (annual mm of rain)

In the light of what is said above the result is the following:

Table 7. Weights

Undercycle - Season	*Time T*	*PHASE I*	*PHASE II*	*PHASE III*	*PHASE IV*
I Winter	9h and 50min	0,58 x T	0,38 x T	0,21 x T	0,21 x T
II Spring	10h and 04min	0,42 x T	0,13 x T	0,29 x T	0,29 x T
III Summer	10h and 18min	0,42 x T	0,09 x T	0,29 x T	0,29 x T
IV Autumn	9h and 48min	0,58 x T	0,40 x T	0,21 x T	0,21 x T

In conclusion, times of each under-cycle and those of each individual phase are expressed in the following table[8]:

Table 8. Times

Under-cycle - Season	*PHASE I*	*PHASE II*	*PHASE III*	*PHASE IV*	*TOTAL time*[9]
I Winter	5h and 42min	1h and 52 min	2h and 03 min	2h and 03 min	11h and 40 min
II Spring	4h and 13min	0h and 39 min	2h and 55 min	2h and 55 min	10h and 42 min
III Summer	4h and 20min	0h and 28 min	3h and 00 min	3h and 00 min	10h and 48 min
IV Autumn	5h and 41min	1h and 58 min	2h and 03 min	2h and 03 min	11h and 45 min

The trend of the cycle is represented by Figure 4.

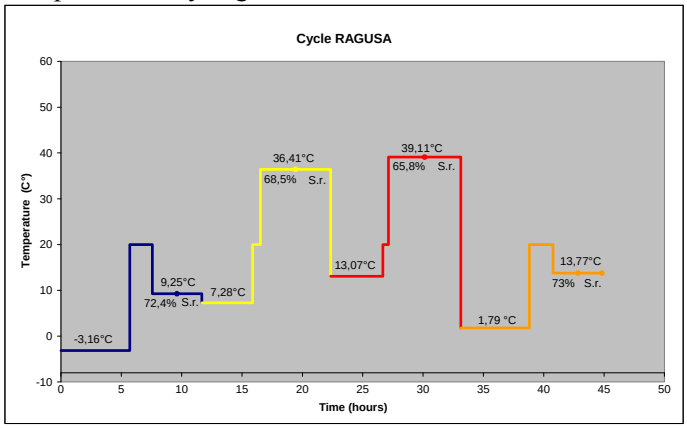


Figure 4. Characterization of Ageing Cycle

4.1.3 Definition of The Characterizing Test Program

Tests of characterization to evaluate the decay of the performing characteristics of material over time are carried out on the bases of the definition of ageing cycle as well as of the recurrence, formality and execution time provided for by regulation. Such tests are performed at zero time and at the end of each accelerated ageing cycle.
The performing characteristics noticed during the tests are:
- Weight P (kg);
- Capillary absorption coefficient A (kg/(m$^2 \cdot$ h0,5));
- Water vapor permeability ω (kg/(m$^2 \cdot$ Pa));

By means of photographic relief also the chromatic alterations of the surface of the samples are noticed.

What is explained above represents the structure of the investigation that has been carried out. It has been useful to present it because it is a step forward in the improvement of the accelerated ageing. The results of the tests that requires two more months will be exposed during the congress.

[1] The material and chromatic survey of the facades has been carried out by the group Boero Bortolomeo S.p.a. of Genova.
[2] Sedimentary cenozoic limestone rock, constituted of alternate calcarenites and calcirudites, impregnated of bitumen. Bitumen impregnation goes from 4% to 10%. Is not submitted to the crumbling phenomenon. Scanty external chromatic gelation. Excellent internal chromatis gelation. Good external physical durability. Excellent internal physical durability. The presence of bitumen make it suitable in wet climate.
[3] The difference between "whitewashing" and "lime paint" is suggested by the will of reproposing the local lexicon. Actually, the kinds of finish could be gather together in two cathegories: light coverings and whitewashing (the latter more or less thick).
[4] Data extracted from SIAS regional centre.
[5] The values of the climatic parameters of each season have been obtained considering the values characterizing each individual month belonging to that season, as regards to the number of the total days of the same season.. Es. In order to obtain the value of the minimun peack of temperature of the winter season (I Under-cycle) it has been solved in the following ratio:

$$\frac{\left[(10(\text{g. December})\times(-2.5)+31(\text{g.January})\times(-3.5)+28(\text{g.February})\times(-3.4)+21(\text{g.March})\times(-2.5))\right]}{90(\text{g.winter season})}=-3.16°\text{C}$$

[6] As for the parametrs Rain and Sun Radiation is concerned, which characterizes Phases II and IV of each under-cycle, it is not possibile to determine the intensity as it happen for the temperature and humidity parameters as the climatic cell does not have the possibility to modify in an automatic way the Capacity of rain and the Thermic Power.
[7] In 40 hours times of transition are excepted (that is technical times of the engine to pass from defined climatic conditions to other) and times of phase II (Rain).
[8] It could be noticed that times of actions of rain obtained through the proportion in relation to the mm of seasonal rain have been all halved because they have been considered excessive for the samples.
[9] Transition times excepted.

Durability Properties of Innovative Plasters for Renovation of Historical Buildings

Radka Pernicová [1]
Milena Pavlíková [2]
Robert Černý [3]

T 25

ABSTRACT

The current practice of the solution of the problem of historical buildings surface layers damage is based more or less on the method of analogy. At a reconstruction, usually such material and method of its application is used which is according to the meaning of supervisory authorities compatible with the original treatments and which already was found to be suitable at an application on some other building before. The durability of new surface layers is mostly estimated on the basis of experience because too few parameters are known for a reliable durability estimate. The choice of a material for reconstruction is then often less suitable regarding to the moisture and salt content in the masonry which leads to low durability and short service life of surface layers. In this paper, main durability properties of innovative lime plasters with metakaolin admixture, namely water sorptivity, moisture diffusivity, water vapor diffusion coefficient, thermal conductivity and specific heat capacity are determined, together with the main mechanical parameters such as compressive and bending strengths. Comparative measurements with common lime plaster are done as well. On the basis of the experiments performed, it can be concluded that the analyzed lime-metakaolin plasters are suitable for an application in reconstruction of historical buildings. While their mechanical properties are significantly better compared to the reference lime plaster, their thermal and hygric properties are mostly similar or slightly improved.

1 INTRODUCTION

In many historical buildings parts of the original mortars, which have been deteriotated by natural weathering, need replacement. From the point of view of a historian, it is not acceptable to use lime-cement plasters in Romanesque, Gothic, Renaissance and Baroque buildings. The demands of conservators who take care of historical monuments are, that the materials for repair or innovation of plasters must have the most similar composition as the historical materials and they have to be applicable by the original methods [Hošek & Losos 2007]. This concerns especially the number and the structure of coated layers, the way of plaster surface treatment by striking, indentation or making it smooth. In most cases, inventions had employed cement and polymer based materials, which resulted in advancing the destruction, since harmful by-products have induced severe damage to the background stone blocks or bricks [Maravelaki-Kalaitzaki *et al.* 2005]. In addition, the polymer-based materials are incompatible to the existing materials of the original masonries, thus exhibiting different behaviour in the environmental conditions.

Plaster can play its function, ie architecturally and as a protection against negative environmental conditions, only if it creates a compact cover with surface treatment. Contemporary plasters meet these requirements due to their proper raw materials, technological processing, suitable storing and final application. Historical facade restoration brings not just new plaster creation but also protection of existing one. It is difficult and mainly unsuitable to produce plasters with the same composition and behaviour as historical plasters. The current solution of the problem of surface layers damage of historical building is based more or less on the improvement of technology and properties of each input raw material with preservation of visual and physico-chemical compatibility to original plaster.

As the chemical analyses of many plasters from historical buildings show, the past centuries external plasters that are preserved until today contain products formed by lime reaction with pozzolanic or hydraulic admixtures. Pozzolanic admixtures appeared to have positive effect on properties of lime binder in the past [Rojas and Cabrera, 2002]. According to the composition of the applied pozzolana, compounds similar to Portland cement products were formed but even compounds of zeolite character were found, such as phillipsite $3CaO.3Al_2O_3.10SiO_2.12H_2O$ and analcime $Na_2O.Al_2O_3.4SiO_2.2H_2O$, in connection with microcrystalline calcite. These compounds are the cause of the plaster resistance against environmental conditions and in this way of the durability of these plasters [Cabrera & Rojas 2001].

The lime plasters are known to have high values of liquid water transport parameters. This is not a very convenient feature from the point of view of their exposure to the external environment as any intensive rain can lead to water penetration deep into the material. Therefore, an application of hydrophobization admixtures seems to be a logical solution for achievement of the increase of service life of lime-based plasters. In this paper, we used zinc stearate as the hydrophobization admixture for lime-pozzolana plaster and investigated its effect on mechanical and hygric properties.

The main reason was construction materials deterioration are salt crystalization, water and salt solutions movement through the walls by capillarity and harsh environmental conditions. Therefore, in this paper, we are focused on the basic material characteristics and water vapour and liquid water transport parameters of basic lime plaster in the comparison with innovative plasters.

2 EXPERIMENTAL

Several different types of innovative lime plasters for renovation of historical buildings were tested to compare their durability properties to pure lime plaster (denoted as VO) with the same composition. Metakaolin as a pozzolanic admixture was used in the case of mixture denoted as VOM as binder increment, in the case of other two mixtures, denoted as VOM II and VOM H as replacement of lime. To improve high values of liquid water transport parameters we used zinc stearate as the

hydrophobization admixture for the lime-pozzolana plaster VOM H. The water/binder ratio was modified according to mixture workability. The composition of mixtures for sample preparation is presented in Table 1.

Table 1. Composition of tested plaster mixtures.

Type of mixture	*Amount* [kg]				
	Lime	*Sand 0/2mm*	*Metakaolin*	*Hydrophobization admixture*	*Water*
VO	4.80	14.40	-	-	4.80
VOM	4.80	14.40	0.80	-	5.50
VOM II	4.00	14.40	0.80	-	4.80
VOM H	4.00	14.40	0.80	0.02	4.20

2.1 Materials

Plaster mixtures were prepared using laboratory mixing machine with forced rotation for 3 minutes and then compacted using vibrating machine. Each mixture was cast into a standard prism form, after two days all prisms were taken out of forms and then cured for 28 days in high relative humidity environment.

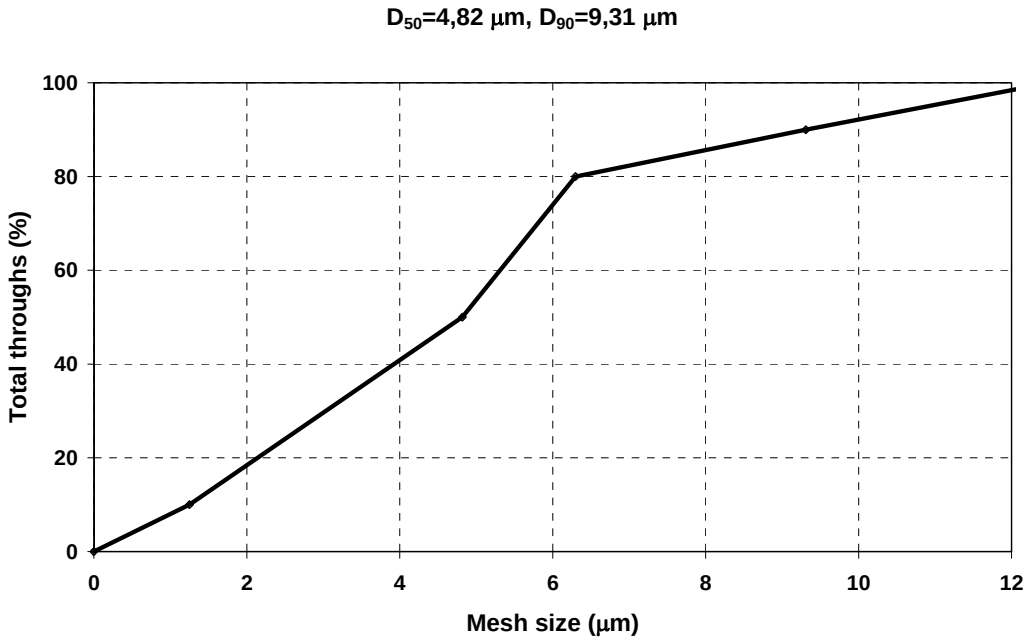

Figure 1. Granularity of used metakaolin.

The lime CL 90 was produced by limekiln Morká, Czech Republic. Metakaolin MEFISTO K05 was a product of České lupkové závody Inc., Nové Strašecí. It is a highly active pozzolanic material on metakaolinite basis. MEFISTO is supposed to be used first of all as an alternative silicate binder. It can replace 5-15% of cement by weight at concrete production where it can be used instead of microsilica. It can also be utilized in the production of geopolymers. The reason for using MEFISTO in the mentioned applications is the supposed increase of compressive and flexural strength and frost resistance, decrease of water absorption and reduction of the occurrence of efflorescence. Dominant compounds of metakaolin MEFISTO represent SiO_2 (55%) and Al_2O_3 (41%). Fe_2O_3, TiO_2, CaO,

MgO, and Na_2O are present in minor amounts. Average particle size of metakaolin is in the interval of 3 to 5 μm, see Fig. 1.

Hydrophobization admixtures have to reduce pore walls wettability and replace capillary suction by capillary depression. Addition of hydrophobization admixture to lime plaster leads to lower sorptivity and better resistance to water and aggressive solution penetration. Fatty acid salts are often used as a hydrophobizator, namely calcium or zinc stearate. One end of the carbon chain is hydrophilous and it is connected to mineral structure while the other end which is formed of hydrophobic group is oriented outside the structure and can repulse water.

Sand 0/2 mm fraction was delivered by Heidelberg Cement Group, Brněnské písky Inc., affiliate Bratčice, normalized according to EN 196-1. The grain-size distribution curve of applied sand is shown in Fig. 2.

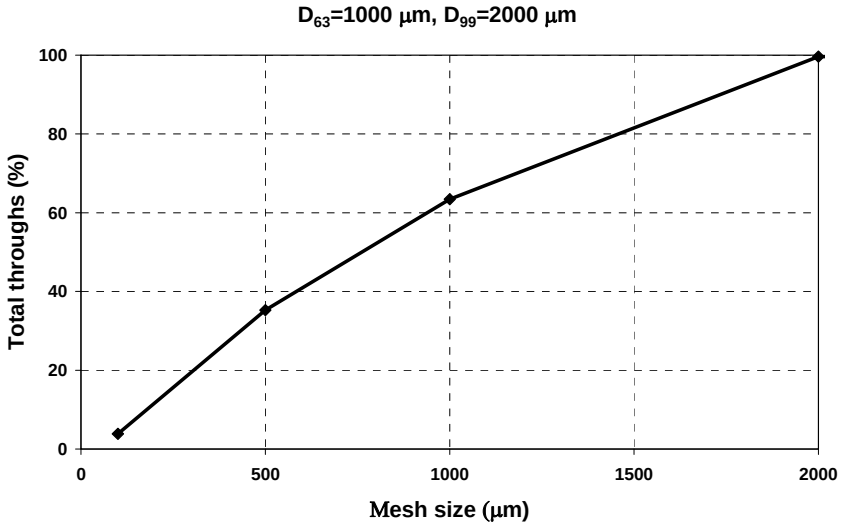

Figure 2. Granularity of used sand.

2.2 Experimental Methods

At first, basic material properties of all tested lime plasters were determined. As fundamental physical material characteristics, bulk density ρ_b [kg m^{-3}], matrix density ρ_m [kg m^{-3}], and open porosity ψ [%] were determined. Bulk density was measured using gravimetric methods. Matrix density was obtained using Pycnomatic ATC, automatic helium pycnometer with fully integrated temperature control with precision of ± 0.01 °C and real multi volume density analyzer. The samples for the basic material parameters determination were cut from cubic prisms with the size of 40 x 40 x 40 mm and their dimensions were 40 x 40 x 20 mm.

Investigation of mechanical parameters was carried out according to the norm [ČSN EN 196-1, 2005]. The compressive and flexural strengths were determined as the most important mechanical parameters for lime-based plasters. For each measurement standard prisms 40 x 40 x 160 mm were tested with DSM 2500 hydraulic testing device, Inova Praha. The flexural strength was measured using standard three-point bending test. The compressive strength was determined using the same test device on the remainder of the specimens after bending test. The measurements were done after 7, 14, 28, 90 and 180 days of hardening period.

The thermal conductivity as the main parameter of heat transport and the specific heat capacity as the main parameter of heat storage were determined using the commercial device ISOMET 104 (Applied Precision, Ltd.). ISOMET 104 is a multifunctional instrument for measuring thermal conductivity, thermal diffusivity, and volumetric heat capacity. It is equipped with various types of optional probes, needle probes are for porous, fibrous or soft materials, and surface probes are suitable for hard

materials. The measurement is based on the analysis of the temperature response of the analyzed material to heat flow impulses. The heat flow is induced by electrical heating using a resistor heater having a direct thermal contact with the surface of the sample.

The cup method was used for determination of water vapour transmission properties. The measurement performed in this work was based on the standard [ČSN 72 7031]. The measurement is carried out in steady state under isothermal conditions. It is based on one-dimensional water vapour diffusion and measuring the water vapour flux through the specimen and partial water vapour pressure in the air under and above specific specimen surface. Water vapour transmission properties of a material are obtained by placing a specimen of the material on the top of a cup and sealing it. Two versions of the common cup method were employed in the measurements of the water vapour diffusion coefficient. In the first one, the sealed cup containing burnt $CaCl_2$ (0% relative humidity) was placed in a controlled climatic chamber at 25±0.5°C and 45% relative humidity and it was weighed periodically. In the second one, the cup containing saturated K_2SO_4 solution (97% relative humidity) was placed at 25±0.5°C and 45% relative humidity environment. Firstly, samples sizes of 95 mm in diameter x 20 mm were cut from the standard prism 100 x 100 x 100 mm and water vapour-proof insulated with epoxy resin. Then, the sealed cups with samples were weighed periodically. The steady state values of mass gain or mass loss were utilized for the determination of the water vapour transfer properties. In the practical calculations of water vapour transport parameters in porous buildings materials, the diffusion coefficient of water vapour D [m^2s^{-1}] and water vapour diffusion resistance factor μ [-] were determined.

The simplest way, how to describe liquid water transport through a porous material is realization of a one-dimensional free imbibition experiment [Roels *et al.* 2004]. Specimens sizes of 40 x 40 x 20 mm were cut from the original prisms and then water and vapour-proof insulated with epoxy resin on four lateral sides, and after that dried in an oven. The face side of each sample was immersed 1-2 mm into water on top of a saturated sponge. The sample mass was measured continuously. The water absorption coefficient, A [$kgm^{-2}s^{-1/2}$], was calculated from the linear part of the dependence of the increase of tested sample's mass on the square root of time. Then, the apparent moisture diffusivity κ [m^2s^{-1}] was calculated using the vacuum saturation moisture content w_{sat} [kg m^{-3}] and water absorption coefficient [Kumaran 1994].

3 RESULTS AND DISCUSSION

Basic properties of all materials are summarized in Table 2. Each result represents the average of five measured values. The open porosity was found not to be distinctly affected by the metakaolin and zinc stearate addition. The observed differences were between 3-5 % in the case of lime-metakaolin plasters, and 8% in the case of hydrophobized plaster which is clearly due to the lower water/binder ratio. So, the addition of fine grained metakaolin MEFISTO did not change the basic material properties as bulk density, matrix density and total open porosity in a significant way. The observed differences were within the range of the accuracy of applied measuring methods. All studied materials have proven high porosity, which is a very positive factor from the point of view for application on historical buildings. The high porosity of plaster guarantees fast water vapour transport, and so its fast removal from the load bearing structures of reconstructed historical buildings.

Table 2. Basic properties of studied mixtures.

Type of mixture	ρ_b [kg m^{-3}]	ρ_{mat}	Ψ [%]
VO	1 650	2 575	36.0
VOM	1 670	2 570	35.0
VOM II	1 695	2 580	34.0
VOM H	1 745	2 625	33.0

The survey of mechanical properties of studied plasters is presented in Figs. 3 and 4. Each result represents the average value of six or three values in the case of compressive and flexural strength measurement, respectively.

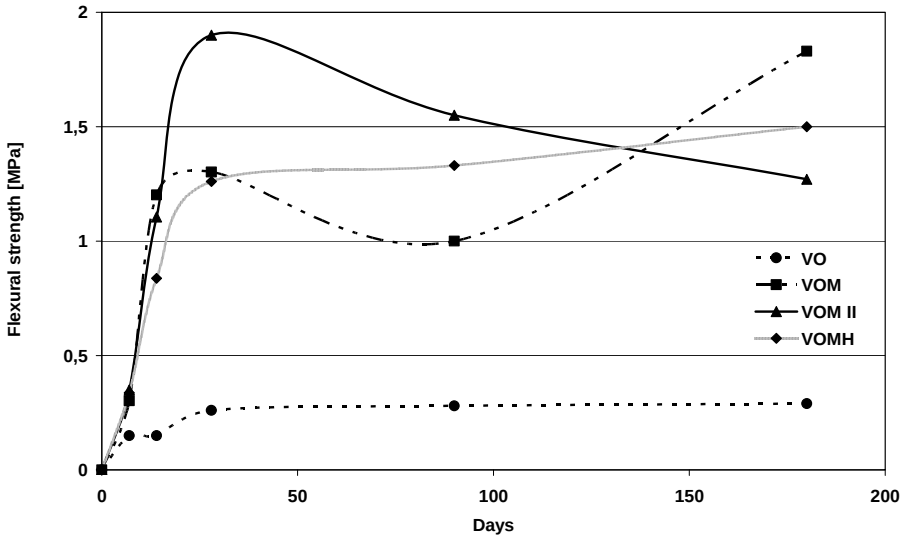

Figure 3. Flexural Strength of Tested Plasters.

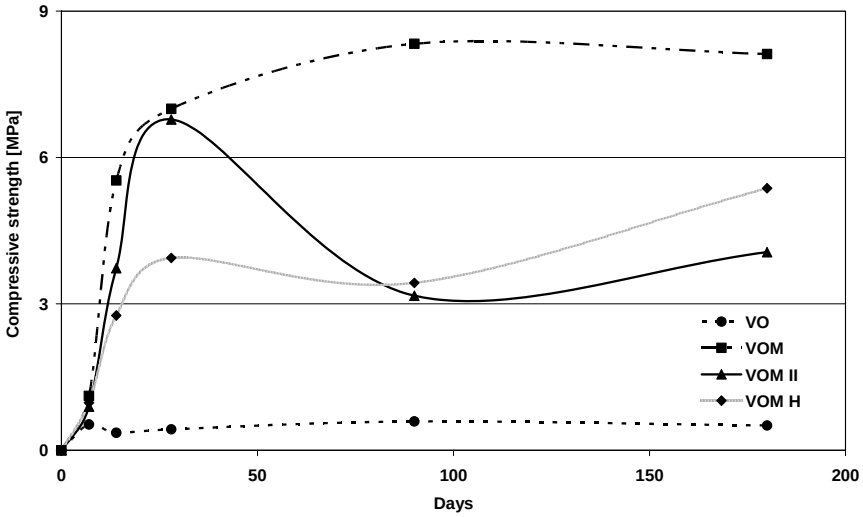

Figure 4. Compressive strength of tested plasters.

The flexural strength of pure lime plaster reached its maximum after 28 days and then it had almost the same value even after 180 days hardening period. Its compressive strength, on the other hand, had somewhat fluctuating character. Lime plasters with metakaolin addition have proved two times higher both flexural and compression strength than pure lime plaster already after 7 days of hardening. In the case of incremetal metakaolin addition (VOM mixture) the flexural strength exhibited certain decrease after 28 days of hardening but after 180 days it was the highest among all tested plasters, six times higher than for the pure lime plaster. The compressive strength of the same mixture increased more continuously. Its maximum was achieved after 90 days of hardening, where it was eight times higher than after 7 days and even fourteen times higher than the compressive strength of pure lime plaster at the same time. In the case of metakaolin replacement mixture (VOM II) the flexural strength increased until 28 days of hardening then it slowly decreased. The maximum was nearly five times higher in the comparison with flexural strength of pure lime plaster. The VOM II mixture reached fourteen times higher value of compressive strength than pure lime plaster after 28 days but then a substantial decrease was observed. The hydrophobization admixture addition caused reduction of both flexural

and compressive strengths at the same time in comparison with other lime plasters with metakaolin addition, but both compressive and flexural strength development had ascending trend.

Thermal properties of the studied plasters are presented in Table 3. The lime-pozzolana plasters exhibited slightly higher thermal conductivity than the reference lime plaster. This is in accordance with their higher bulk density and lower porosity (Table 2). The values of specific heat capacity were very similar for all the studied mixtures, the differences being within the error range of the applied method.

Table 3. Thermal properties of studied mixtures.

Type of mixture	λ [W/mK]	c [J/kgK]
VO	0.67	580
VOM	0.71	590
VOM II	0.88	620
VOM H	0.85	610

The results of water vapour and liquid water transport parameters determination are presented in Table 4, each result represents the average value from five measurements.

Table 4. Water vapour and liquid water transport parameters.

Type of mixture	D [m^2s^{-1}]		μ [-]		A	w_{sat}	κ
	97-45% RH	0-45% RH	97-45% RH	0-45% RH	[kg $m^{-2}s^{-1/2}$]	[kgm^{-3}]	[m^2s^{-1}]
VO	2.90E-6	4.50E-6	9.0	5.0	2.20E-1	359.0	4.40E-7
VOM	2.50E-6	5.10E-6	10.0	4.5	2.70E-1	350.0	5.70E-7
VOM II	1.80E-6	5.70E-6	13.0	4.0	2.20E-1	343.0	4.30E-7
VOM H	1.60E-6	4.40E-6	15.0	5.0	6.50E-2	332.0	3.90E-8

The water vapour transport parameters were not very different for all studied plasters. Lime-metakaolin plasters had higher water vapor diffusion resistance factor than the reference lime plaster but the differences were not very significant. From the quantitative point of view, the obtained values of water vapour diffusion parameters of innovative plasters are very promising for application in restoration of historical buildings and renewal of the old materials. The values of liquid water transport parameters were in case of lime-metakaolin plasters without hydrophobization similar or slightly higher than for pure lime plaster. This may be considered as a negative finding in general because the rain water could be transported either the same fast or even faster into the load bearing structure. However, from the quantitative point of view the differences were not very high so that this is only a minor flaw on otherwise significantly improved material. In the case of zinc stearate addition the liquid water transport parameters decresed in a significant way, the moisture diffusivity by about one order of magnitude, which is a very positive feature.

4 CONCLUSIONS

Main durability properties of innovative lime plasters with metakaolin admixture were determined in the paper and compared with the reference lime plaster. The modified plasters showed significant improvement of mechanical properties. Another good point with the studied lime-metakaolin plasters was that the hygric and thermal properties were basically unaffected by the metakaolin addition. The

material retained the good water vapour transmission properties which are characteristic for the lime plasters and exhibited also acceptable thermal properties. The application of hydrophobization admixtures in lime-pozzolana plasters was proved successful. It resulted in an order of magnitude decrease of moisture diffusivity which means a significant reduction of liquid water transport in the plaster.

ABSTRACT

In this work, a fuzzy classification system is presented for the assessment of cleaning interventions on sulphated marble surfaces. The acquired data by Scanning Electron Microscopy with energy dispersion by X-ray analysis (SEM-EDS), Digital Processing of SEM Images, Laser Profilometry (LP) and Colorimetry, determine the (a) chemical and mineralogical composition of marble surfaces, (b) texture roughness and fracturing of the surface and (c) color parameters. These results comprise the input variables which under the process of decomposing produce the necessary fuzzy sets. In parallel, the fuzzification process includes the formation of fuzzy sets for the output variable, which in this case is cleaning performance index (CPI) for sulphated marble surfaces. The knowledge base of the fuzzy system is completed when a set of fuzzy if-then-else rules is used to process the inputs and produce a fuzzy output. Finally, an effective knowledge based expert system is produced in order to make decisions concerning cleaning interventions performance on sulphated marble surfaces. The designed fuzzy logic system is demonstrated in practice on marble surfaces of a historic building in Athens, Greece.

1 INTRODUCTION

Sulphated marble surfaces are commonly found on historic buildings located in polluted urban atmospheres. Sulphur dioxide (SO_2) attacks calcite ($CaCO_3$) of marble and after reaction produces gypsum ($CaSO_4 \cdot 2H_2O$). Gypsum along with black particles, soot, iron oxides and alumino-silicates forms black-grey crusts at rain sheltered areas, [Moropoulou *et al.* 1998]. Black crusts greatly affect not only, the physico-chemical condition of the historical monuments, but also their aesthetic view. Discontinuities detected in the crusts functions as areas, where the deteriorative factors are concentrated. The presence of deteriorated areas on marble surfaces not only alters the visual appearance of the stonework due to the discoloration development, but also leads to further decay. Gypsum layers and black-grey crusts absorb a great amount of humidity resulting in the development of a lamellar texture and subsequently to the abruption of the crust and loss of the stone material, [Maravelaki – Kalaitzaki *et al.* 1999]. Furthermore, apart from discoloration, the accumulation of black depositions in black-grey crusts acts as catalyst for the sulphation processes, accelerating further decay. Therefore, the employment of cleaning becomes essential not only for the conservation of the deteriorated areas, but also for preventing further erosion phenomena. Moreover, apart from physicochemical reasons, esthetical ones are important as well for the employment of cleaning, in order to reveal and preserve monuments' artistic value. The most objective parameters for the assessment of cleaning interventions are those concerning physicochemical characteristics of materials, surface morphology, as well as aesthetic characteristics like color, [Biscontin *et al.* 1995]. Threshold values of these parameters have not been established yet and therefore their combinations for decision making on the evaluation of a cleaning method is a complex procedure. Thus, the need of using a modeling tool that can resemble the way experts make decisions based on their knowledge and experience is great.
In this work, a knowledge based expert system that can assess cleaning interventions, applied on sulphated marble surfaces (black-grey crusts) is developed. This system uses as a modeling tool Fuzzy Logic which can resemble the way humans think; make inferences and decisions, [Vakalis *et al.* 2004]. Fuzzy logic theory has emerged over the last years as a useful tool for modeling processes which are too complex for conventional quantitative techniques, or when the available information from the process is qualitative, inexact or uncertain. Fuzzy inference systems have been successfully applied in fields such as automatic control, data classification, decision analysis, expert systems, and computer vision. The most popular fuzzy model suggested in the literature, is the Mamdani's method, proposed in 1975 by Ebrahim Mamdani [Mamdani & Assilian [1975] as an attempt to control a steam engine and boiler combination by synthesizing a set of linguistic control rules obtained from experienced human operators. In this work, the Mamdani type of fuzzy model, was developed under Visual Studio using the C++ programming, in order to design a decision – making system on marble cleaning.

2 RESULTS & DISCUSSION

2.1 Experimental Procedures and Techniques Used for Cleaning Assessment

The evaluation of cleaning interventions is fundamental during pilot cleaning applications or final cleaning treatment works, for the determination of the cleaning efficacy of each applied method (for particular material and particular decay pattern). Cleaning interventions assessment is focused on the modifications that cleaned surfaces are sustained concerning chemical and mineralogical composition, texture roughness, fracturing and color. In this work, Scanning Electron Microscopy with energy dispersion by X-ray analysis (SEM-EDS) is used for the chemical and mineralogical composition of the cleaned surfaces, Laser Profilometry (LP) is used for the texture roughness assessment, Digital Image Processing (DIP) of SEM images is utilized for the measurement of surface fracturing and colorimetry evaluates color modifications of the cleaned surfaces. More information on the techniques used for the presented case study and the selection of fuzzy system input parameters are given bellow:
(SEM-EDS) is applied on collected monument samples, (a) before cleaning, for the identification of mineralogical and chemical composition of the substrate, the presented patinas and decay patterns

(which in this case were gypsum layer and black depositions) their stratifcation and thickness; whereas (b) after cleaning, study of the surface morphology regarding patina, the remaining decay products, their stratifcation and thickness, the possible by-products/side effects of the cleaning method, are recorded. The core samples analyses in the presented case study, that is stone specimens cut in cross-section, were carried out using JEOL JSM-5600, OXFORD LINKTM ISISTM 300 with Energy Dispersive X-ray Microanalysis system, Accelerating Voltage 20 KV, Beam current: 0.5nA, Livetime: 50 sec, Beam diameter <2μm. All the collected images were back-scattered electron-micrograph images.

DIP of SEM images using the EDGE program which was developed by the US Geological Survey [Mossotti & Eldeeb 2000], [Mossotti *et. al.* 2002]. EDGE program was developed for the analysis of back-scattered electron-micrograph images stored in a binary file format that represents images with lateral resolution of 1.7μm/pixel. However, the images presented in this work had a lateral resolution of 2μm/pixel [Moropoulou *et al.* 2007]. EDGE measurements have to be made by computer analysis of 100x SEM images of core cross sections, consisting of 512 rows with 512 pixels per row, where each pixel is encoded with 8 bits on a 256-shade gray-scale palette. The fractal dimension of the exposed surfaces of stone specimens cut in cross-section are measured. More information on EDGE program can be found in [Mossotti & Eldeeb 2000], [Mossotti *et. al.* 2002] and [Moropoulou *et al.* 2007]. Three indexes of the marble micro-structure can be assessed, based on the fractal dimension determination and the special image calibration procedure. One of these marble micro-structural indexes is the near-surface fracture density (FD) of the stone which is a measure of the fraction of the stone volume filled by fractures, crevices, and pore space. The FD results are reported as the percentage of pixels identified as components of the fractures calculated until 100μm under the surface area. FD value was used as evaluation index of the marble fracturing after cleaning which can be ascribed as cleaning side-effect as well as susceptibility deegre of marble surface to further decay.

(LP), is one of the most recently developed non destructive testing approaches for the description of surface topography, surface roughness and surface area measurements. Surface texture includes roughness and waviness, while many surfaces may have lay, that is, directional striations across the surface. Roughness generally results from a particular production process or material condition [Avdelidis *et al.* 2004], [Stout & Blunt [1995]. The roughness parameter Rq is defined as the mean root square of the values of all points of a given surface profile and is commonly used in the fields of tribology and materials engineering, [BS EN ISO 4288:1998].

$$Rq = \sqrt{\frac{1}{l}\int_0^l z^2(x)dx}$$

In the presented case study, 3-D micro-topography plots of the monument collected core samples were attained using the Proscan 2000 with a laser triangulation sensor of 1μm resolution. The software within the instrument calculates, amongst others, the Rq parameter on a specific length scale via a two-dimensional line profile. This is important since Rq is a length scale dependant property, and therefore in order to compare Rq values they have to be evaluated over the same measurement length. According to BS EN ISO 4288:1988, the Rq values were calculated in an evaluation length of 1.25mm, with a step size of 1μm and a cut-off filter of 0.25mm. The application of cut-off filter is obligatory in order to dispatch the unnecessary frequencies (waviness information) and keep only the roughness data which include the finest (shortest wavelength) irregularities of a surface [BS EN ISO 4288:1988]. Following the above mentioned specifications, 50 line profiles across the X-axis and 50 line profiles across the Y-axis were acquired with the intention of determining the average of Rq for X-axis (Rqx) and the average of Rq for Y-axis (Rqy) for each tested stone sample. The higher mean value between Rqx and Rqy is the representative one for each sample [BS EN ISO 4288:1988]. In parallel, the ratio of actual to projected surface area was measured at each micro-topography. This ratio is a geometrical descriptor of a surface and has a very close relation with some functional properties of surfaces like wear, [Stout *et al.* 1993]. The values of these characteristics (Rq and ratio) function as assessment indexes of the surface morphology regarding to the susceptibility of the surface to further decay, that is slow reactivation of sulphation process and slow adsorption of black particles.

Colorimetry The Dr Lange color-pen LMG159/160 colorimeter, was applied in situ on the investigated marble surfaces, for measuring the L*, a*, b*, according to CIELab Uniform Colour Space. Using this non destructive testing and evaluation technique, an average of twenty five values of L*, a*, b* components was calculated per cleaning area. Hereafter, the total colour difference ΔE, the luminosity difference ΔL*, the red-green difference Δa*, and the yellow-blue difference Δb*, were calculated, taking as reference the primary values, that is before cleaning. Total colour difference ΔE, was estimated according the ASTM D2244-93, by the following formula:

$$\Delta E = \sqrt{\Delta L^2 + \Delta a^2 + \Delta b^2}$$

Therefore, colorimetry was used to assess the aesthetical modifications that the architectural surfaces undergone due to cleaning interventions, reflecting as well the degree of black depositions removal.

2.2 Short overview of Fuzzy Modeling

Fuzzy logic starts with the concept of a fuzzy set. A fuzzy set is a set without a crisp, clearly defined boundary. The fundamental difference of fuzzy logic compared to conventional modeling techniques is on the definition of sets. Traditional set theory is based on bivalent logic where an object is either a member of a set or it is not. Contrary to that, fuzzy logic allows a number or object to be a member of more that one sets and most importantly it introduces the notion of partial membership, [Klir & Yuan 1995]. Information flow through a fuzzy model requires that the input variables go through three major transformations before exiting the system as output information, which are known as fuzzification, fuzzy inference, and defuzzification. The three steps are depicted in Fig.1, which shows the structure of a fuzzy logic system and are explained in brief:
Fuzzification: It is the process of decomposing a system input variables into one or more fuzzy sets, thus producing a number of fuzzy perceptions of the input.

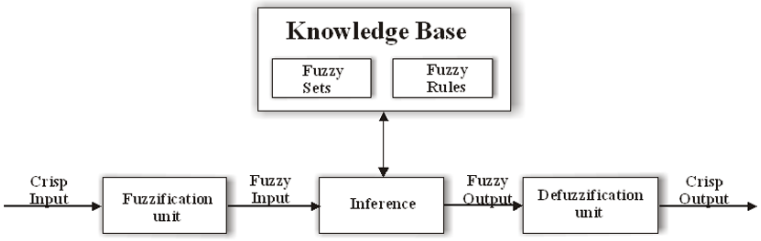

Figure 1. The structure of a typical fuzzy logic system

Fuzzy Inference: After the inputs have been decomposed into fuzzy sets, a set of fuzzy if-then-else rules is used to process the inputs and produce a fuzzy output. Each rule consists of a condition and an action where the condition is interpreted from the input fuzzy set and the output is determined from the output fuzzy set. In other words fuzzy inference is a method that interprets the values in the input vector and, based on some set of rules, assigns values to the output vector.
Defuzzification: It is the process of weighting and averaging the outputs from all the individual fuzzy rules into one single output decision or signal. The output signal eventually exiting the system is a precise, defuzzified, crisp value.
Fuzzy modeling methodologies are procedures for developing the knowledge base of the system, i.e. the set of fuzzy rules. The natural way to develop such a system is to use human experts who build the system based on their intuition, knowledge and experience. In this case the fuzzy sets and the membership functions are defined by the experts, usually based on a trial and error approach. The rule structure is then determined based on how the designers interpret the characteristics of the variables of the system.
The most popular fuzzy model suggested in the literature, also used in this work, is the one proposed by Mamdani [Mamdani 1974] that has the following formulation with respect to its fuzzy rules:

$$\forall r \in R:\ if \ \underset{1\le i\le n}{\wedge}(x_i \in A_i^r) \ \ then \ \underset{1\le j\le m}{\wedge}(y_j \in B_j^r)$$

Where; n: number of input variables,
m: number of output variables,
$x_i, 1 \le i \le n$: input variables,
$A_i^r, 1 \le i \le n$: fuzzy sets defined on the respective universes of discourse,
$y_j, 1 \le j \le m$: output variables and $B_j^r, 1 \le j \le m$ are fuzzy sets defined for the output variables.

2.3 Development of a Fuzzy Classifier for the Estimation of the Cleaning Performance Index of Cleaning Interventions on Sulphated Marble Surfaces

The fuzzy logic modeling architecture that was used to build a model for the estimation of the performance index of cleaning interventions was based on important influencing factors. In order to develop the database and the rule base of the system, human experts were employed. The experts used (a) their knowledge and experience on matters of decay of materials, as well as marble cleaning and (b) a database of measurements concerning physicochemical and aesthetical characteristics of marbles before and after cleaning. The Mamdani type of fuzzy model was selected and the development of the system was completed in three steps.

Step 1 – Selection of Input Parameters & Output Parameter: According to the cleaning assessment methods analytically described in 2.1 paragraph, the characteristics that are measured for the assessment of cleaning interventions constitute the input parameters of our fuzzy system. These characteristics concern the (a) chemical and mineralogical composition of marble surfaces, (b) texture roughness and fracturing of the surface and (c) color parameters. Therefore, the chosen input variables are:

(a) Patina preservation index (%), (SEM-EDS results)
(b) Thickness of gypsum layer (μm), (SEM-EDS results),
(c) Fracture density, (%), (DIP of SEM images results),
(d) Actual/Projected area ratio, (LP results),
(e) Roughness (μm), (measured parameter: Rq; LP results)
(f) Total color difference, ΔE, (Colorimetry results).

The output variable is the Cleaning Performance Index of cleaning interventions (CPI).

Step 2 – Development of the Fuzzy Sets: In this step, fuzzy sets were defined for all the input and output parameters. More specifically, three fuzzy sets were defined for all the input variables except for the patina preservation index for which two fuzzy sets were appointed, and the fracture density where four fuzzy sets were defined. The output variable was classified by four fuzzy sets as well. A more detailed description of the fuzzy sets appointed to each input or the output variable follows next:

Patina preservation: Two fuzzy sets, were defined on the input space, named as "Non preservation of patina" and "preservation of patina". Values belonging to the "preservation of patina" are the accepted ones, as cleaning methods which cause patina removal are totally unaccepted even by Venice Charter since 1964. Therefore, the patina preservation is a prerequisite for an effective and successful cleaning intervention.

Thickness of gypsum layer: Three fuzzy sets, namely "Low", "Medium" and "High" were proposed on the input space which measures the thickness of gypsum layer (Fig. 2). Acceptable values are those belonging to the "Medium" fuzzy set, since in this case the resulting surface holds the microcrystalline gypsum layer, which is acceptable and desirable [Moropoulou *et al.* 2007]. Microcrystalline gypsum is

the first and compact part of marble sulphation process, [Elfving *et al.* 1994] and the desirable remaining part of the black-grey crust during cleaning, since it preserves the details of carved and plane surfaces, [Skoulikidis & Charalambous 1981], [Moropoulou *et al.* 2007]. Values belonging to the "Low" set show that cleaning intervention probably has caused loss of authentic material (that is calcite and/or microcrystalline gypsum); while values of the "High" set show that cleaning intervention was ineffective, that is didn't manage to remove the crust.

Fracture Density: Four fuzzy sets, "Low", "Medium", "High" and "Extra High" were defined on the input space. In this case the acceptable values belong to the "Low" fuzzy set. Values belonging to the rest sets show that cleaning intervention has caused micro-cracking and fracturing on the marble surface, that is the resulting surface will display higher susceptibility to further decay.

Ratio of Actual to Projected Area: Three fuzzy sets were defined in this case, namely "Low", "Medium" and "High". Accepted values are considered those of the "Low" fuzzy set, that is slow reactivation of sulphation process and slow adsorption of black particles. Higher values are unaccepted, because higher ratio values indicate higher susceptibility to further decay.

Roughness: Again three fuzzy sets were defined, "Low", "Medium" and "High". Accepted values are those belonging to the "Low" fuzzy set, that is slow reactivation of sulphation process and slow adsorption of black particles. Higher values are unacceptable, because higher roughness values indicate higher susceptibility to further decay.

Total color difference (ΔE): Three fuzzy sets were defined, as "Low", "Medium" and "High". Accepted values are those belonging to the "Medium" fuzzy set. Values belonging to the "High" set show that cleaning intervention caused high difference in the aesthetics of the surface after cleaning, whereas values of the "Low" set show that cleaning intervention was ineffective, that is remaining of black depositions.

Cleaning Performance Index (CPI): The only output variable is CPI of an intervention and its range of values extends from 0 to 10. For this variable, four triangular fuzzy sets were defined as, "Not acceptable cleaning", "Medium cleaning", "Acceptable cleaning" and "Recommended cleaning-Optimum", (Fig. 3).

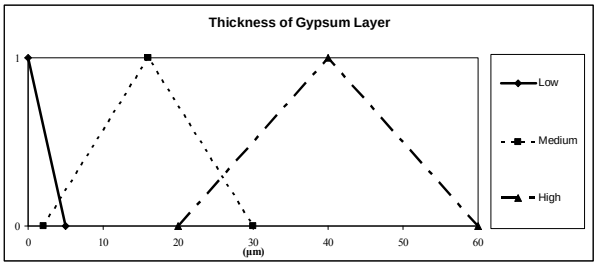

Figure 2. Fuzzy Sets of the "Thickness of Gypsum Layer" input parameter

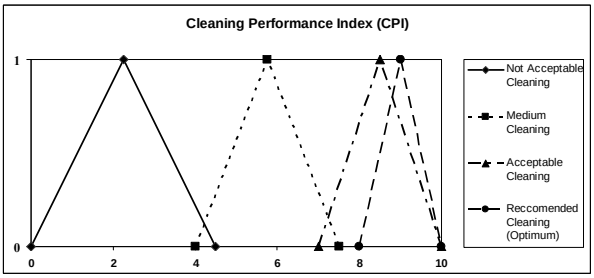

Figure 3. Fuzzy Sets of the "Cleaning Performance Index" output parameter

Step 3 – Development of the rule base: During this step, the experts were employed to develop a number of fuzzy rules, based on their intuition and experience on decay as well as on cleaning matters. The fuzzy rules were developed, so that they could relate successfully all the input conditions. At the same time these rules resulted in specific and repeatable (same inputs gives same output) results. The experts developed 648 rules, one for each combination of fuzzy rules of the input parameters. All the rules use the logical *AND* operation. An example of a fuzzy rule is shown below:

*"**IF** the patina is preserved, **AND** the thickness of gypsum layer is Medium, **AND** the fracture density is Low, **AND** the actual/projected area ratio is Low, **AND** the roughness is Low, **AND** the total color difference is Medium, **THEN** CPI is High (that is recommended cleaning-Optimum)"*

Fuzzy Model Operations: The above three-step procedure defines the knowledge base of the fuzzy system. When the fuzzy model is to be applied to a set of input parameter values, the information flows through the fuzzification – inference - defuzzification processes which are depicted in Fig. 1, in order to generate the fuzzy estimation of the degree of a cleaning intervention. For this particular fuzzy system, the three above processes are executed as follows: *Fuzzification:* During the fuzzification process, the triangular membership functions (fuzzy sets) defined on each input variables are applied to their actual values, to determine the degree of truth for the application of each rule. *Inference*: During the inference process, the real value (degree of truth) for the application and activation of each rule is computed, and applied to the conclusion part ("then" part) of the rule. This procedure results in the assignment of one output fuzzy set for each rule. The "min-max" inferencing technique has been used [Zadeh, 1973], where the output membership function of each rule is clipped off at a height corresponding to the rule activation (degree of truth). If a part of the rule is not activated (zero degree of truth) then the rule is not activated either, as the inference technique considers the minimum degrees of activation for each rule. The combined fuzzy output membership function is constructed by combining the results of all the fuzzy rules. If an output fuzzy set is activated by more than one rule, the maximum of all activations is considered in the construction of the combined output membership function. *Defuzzification*: The final output of the fuzzy system for the degree of suitability should be a crisp number, so the fuzzy output needs to be defuzzified. The centroid defuzzification method [Driakov *et al.* 1993] was used, where the crisp value of the output variable is computed by finding analytically and not numerically the (meta)center of area that is covered by the combined membership function.

2.4 The case study of National Library of Greece Historic Building – Results of test runs

The investigation area (a black-grey crust area) was an architectural surface of the historic building of the National Library of Greece (NLG), consisted of Pentelic marble (Fig. 5a-5b), [Moropoulou *et al.* 2000]. The building was constructed at the beginning of 20th century and is situated in the center of Athens. Fig. 6 presents the investigation area after cleaning, while Table 1 lists the applied cleaning methods of the pilot interventions on the investigated surface. The application of Colorimetry occurred before and after the pilot cleaning interventions in field, while core samples were collected before and after the pilot cleaning interventions for the LP and SEM-EDS examination in lab. DIP of the SEM images using EDGE programme occurred in lab, (see 2.1 paragraph for further details on all used techniques).

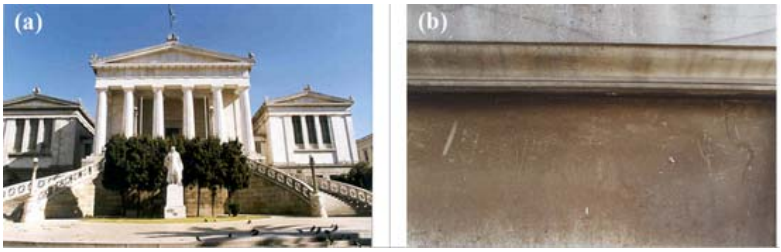

Figure 5. (a) main façade of the NLG Historic Building, (b) investigation area before pilot cleaning.

When the fuzzy model was applied with the 7 sets of input parameter values, it generated the fuzzy estimation of the Cleaning Performance Index for each cleaning intervention. Table 1 presents the results of the used experimental techniques which also represent the values of the system crisp inputs, and the fuzzy system output CPI. Figures 7 and 8 display representative SEM and LP results respectively. The input parameter of "Patina preservation index" was not included in the presented test runs, since no patina was found at the investigated surface during decay diagnosis [Moropoulou *et al.* 2000]. Therefore, the rest five input parameters were used for the test runs, while the number of the used rules were reduced to 324. It is obvious, after running the tests, that the pilot cleaning intervention which could be recommended for the removal of the black-grey crust was the application of AB57 poultice for 1h, since this technique mainly corresponds to the accepted cleaning set and marginally to the recommended cleaning-optimum (CPI value 8.05).

Table 1. Applied cleaning methods-Values of crisp inputs (results of experimental techniques)-Results of the fuzzy system (CPI)

		Values of Crisp Inputs-Results of experimental techniques					*Output*
A/A	*Applied Cleaning Methods*	*Thickness of Gypsum layer (μm)*	*Fracture Density (%)*	*Actual to Projected area ratio*	*Roughness (Rq) (μm)*	*Total Color Difference (ΔE)*	*CPI*
1	Mora Poultice* 2 hours	0	11.4	1.385	7	31.44	4.22
2	AB57 Poultice*, 2 hours	0	13.8	1.625	13	31.20	4.62
3	Poultice of $(NH_4)_2CO_3$, 10% w/v with deionized water, 2 hours	0	16.3	1.427	7	38.40	4.82
4	Poultice of Sepiolite with deionized water, 3.5 hours	50	10.0	1.350	6	5.52	5.17
5	AB57 Poultice*, 1 hour	12	10.4	1.428	7	14.70	8.05
6	Poultice of $(NH_4)_2CO_3$, 10% w/v with deionized water, 1 hour	0	10.5	1.351	6	37.70	4.58
7	Poultice of bi-sodium E.D.T.A., 3% w/v with deionized water, 1 hour	55	12.1	1.324	5	7.38	6.25

* Where, Mora Poultice is consisting of 1lt deionized water, 60gr NH_4HCO_3, 60 gr $NaHCO_3$, 25 gr of bi-sodium E.D.T.A., 10ml Desogen, 800gr sepiolite, and AB57 Poultice of 1lt deionized water, 30gr NH_4HCO_3, 50 gr $NaHCO_3$, 25 gr of bi-sodium E.D.T.A., 10ml Desogen, 800gr sepiolite.

Fuzzy system outputs (CPI) agrees with human experts considerations on the presented case study. In particular, the presented crust, as SEM results indicated (fig. 7a), consisted mostly of gypsum grains mixed with dust fall (mainly aluminosilicates and Fe), whereas the lower part of the crust was made of microcrystalline gypsum (diameter <10μm). The layer seemed cohesive, retained an intense relief and a mean width of 40μm [Moropoulou et al. 2007]. After cleaning, the surface of NLG presented the following characteristics; at the surface cleaned with poultice of $(NH4)_2CO_3$ for 2h, gypsum was entirely removed, (fig. 7c), an unaccepted fact as already described in 3.2 paragraph. Even though the marble surface presented a low to medium Rq and ratio values, many micro-cracks and fractures appeared, as a result of the effect of the cleaning, (medium to high FD value). Moreover, the high ΔE value indicated the desirable removal of black depositions, but unaccepted color modification of the surface. Therefore, the low CPI value resulted from the fuzzy system, is indeed a not acceptable cleaning. Cleaning with Mora poultice, AB57 poultice for 2h and poultice of $(NH4)_2CO_3$ for 1h

presented analogous surface characteristics to the poultice of $(NH4)_2CO_3$ for 2h. Thus, these techniques were also classified as not accepted cleaning methods, both in fuzzy system output and experts considerations. After the treatment with AB57 poultice for 1h, the width of the gypsum surface layer had been reduced (mean width of 12μm), preserving most of the desirable gypsum micro-crystals layer, (fig. 7b). The displayed low values of fracturing, Rq and ratio, as well as the medium ΔE value resulted in high CPI which is in accordance with experts opinion to classify this method as accepted cleaning and possible recommended. On the contrary, cleaning with the sepiolite poultice for 3.5h, did not reduce the gypsum layer, resulting in the retention of the black-grey crust, (fig. 7d). In parallel, the low presented values of fracturing, Rq, ratio and ΔE, classified this cleaning method as medium, both in fuzzy system results and experts estimations. A similar to the above interpretation can be given for the EDTA cleaning as well.

Figure 6. The investigation area after the application of the pilot cleaning interventions.

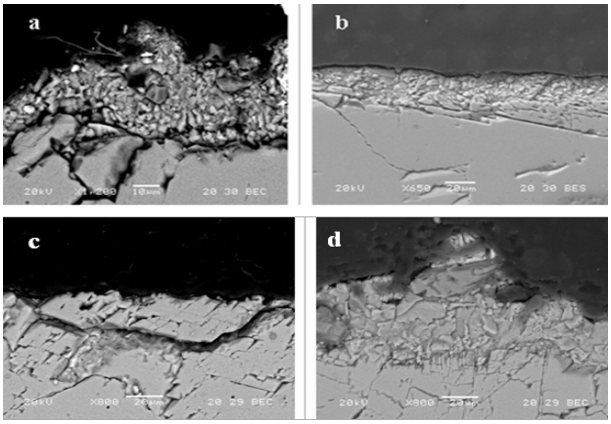

Figure 7. Representative SEM images of surface (a) before cleaning, (b) after cleaning with AB57 poultice for 1h, (c) after cleaning with $(NH_4)_2CO_3$, poultice for 2 hours and (d) after cleaning with sepiolite poultice for 3.5h.

3. CONCLUSIONS

The developed knowledge based expert system using fuzzy logic is a powerful decision making tool, as far as it concerns the assessment of cleaning interventions applied on sulphated marble surfaces. This knowledge based expert system included the following five input variables: Patina preservation index, Thickness of gypsum layer, Fracture density, Actual/Projected area ratio, Roughness, Total color difference, while the output parameter was the cleaning performance index (CPI). These input variables resulted from four different techniques: Scanning Electron Microscopy with energy dispersion by X-ray analysis (SEM-EDS), Digital Image Processing (DIP) of SEM images, Laser Profilometry (LP) and Colorimetry. The developed system was build based on the results that the above mentioned experimental techniques give when measurements in situ and/or in lab are performed according to the given specifications. The suggested decision making tool has operated with 29 different and real scenarios of cleaned sulphated marble surfaces, 7 of which are presented in this work. The results were very satisfactory and in the range of expectations, since cleaning performance classification was in aggreement with the human experts considerations. Moreover, authors have developed a similar tool for the assessment of cleaning interventions applied on washed out marble surfaces, as well as on inter-granular fractured and marble surfaces.

T 25

ABSTRACT

A well-designed roof drainage system is of vital importance for the survival of historical buildings over the centuries. In order to maintain these systems in good performance, comprehensive studies are necessary in terms of their drainage system characteristics, discharge capacities and faults. These studies should ideally be done by using non-destructive methods.

In the study, the roof drainage system of a 15th century Ottoman bath, the Sengul Hammam, located in the province of Ankara, Turkey, was examined in terms of its surface slopes, discharge capacity, faults and its potential for taking corrective action. The study consisted of the mapping of decay forms, levelling survey, infrared thermography (IRT) and roof drainage calculations together with some supportive laboratory analyses. The method used for the roof drainage calculations was based on a contemporary method modified and developed according to the characteristics of the roof at hand.

Serious dampness problems arising from certain roof drainage faults were identified in the Sengul Hammam. Its roof was configured to provide a peripheral drainage system and this system was found to have failed at present due to earlier incorrect interventions by mesh-reinforced concrete and subsequent lack of maintenance. The ideal case for the improvement of the roof drainage system was discussed together with some suggestions on the urgent remedial interventions, preventive measures and future improvements. The joint interpretation of non-destructive analyses provided a good combination for the assessment of the roof drainage system of a historical building on a quantitative basis.

1 INTRODUCTION

It is essential to better understand the original roof drainage system of historical baths (hammams) in terms of their performance, capacity and adequacy in order to keep their proper functioning for long periods of time. Extensive studies are, therefore, needed to discover those technologies and to define appropriate conservation programs for their survival.

This study was focused on the investigation of roof drainage system for a 15th century Ottoman bath, the Sengul Hammam, located in the province of Ankara, Turkey. Some non-destructive methods, such as levelling survey, mapping of decay forms, infrared thermography and roof drainage calculations, were used in the study. Its roof drainage system was examined in terms of its discharge capacity, adequacy and faults. Some urgent and long-term maintenance programs were suggested for the improvement of the roof drainage as well as for contributing to the overall rainwater drainage system.

2 MATERIALS AND METHODS

The Sengul Hammam is a typical Ottoman double bath consisting of two separate parts for men and women. It was constructed with stone masonry walls with brick transitions and a brick upper structure [Disli *et al.* June 2007], [Disli *et al.* September 2007]. The roofs above the tepidarium and caldarium sections, hot water storage and firewood storage rooms of the hammam, including the dome surfaces, were repaired with an addition of 8 cm thick mesh-reinforced concrete layer (Fig. 1). The roofs of the frigidarium sections at the north and south are timber pitched roofs covered with fired-clay roof tiles (Fig. 2). The immediate periphery of the structure was totally surfaced with asphalt pavement.

Figure 1. (a) The general view of the mesh-reinforced concrete roof above the caldarium and tepidarium sections (at left) [Disli *et al.* June 2007], [Disli *et al.* September 2007], (b) The pitched roof, A1, over the frigidarium of women's part with its discharge components: gutter and downpipes (at right)

The roof areas under study were presented in 'Fig. 3'. These areas were composed of four roof areas; A1, A2, B1 and B2, having different geometry and drainage systems (Fig. 3) [Disli *et al.* June 2007]. The roofs A1 and A2 were pitched roofs similar with each other, consisted of two parts; the four-sided pitched roof covering the square area and the lantern roof at its top. A peripheral drainage system was provided by means of zinc eaves gutters and fourteen downpipes, some of which discharge water directly onto the concrete-clad roof, B1 (Fig. 4a). The roof B1 was a low-slope roof including domes, configured to provide peripheral drainage, with flows from elevated interior edges to lower exterior ones, and then, to waterspouts located at the eaves level along the west side of the roof (Figs.4b and 4c). There were nine spouts, with similar dimensions, serving this roof area. The roof B2 was a flat roof configured to provide an internal drainage, with flows towards an internal gutter located at the middle of the roof area (Fig.4d). The water collected in the gutter was discharged through a grilled outlet located at its north end, and then, carried by a drain line (buried in the garden) to the rainwater drainage network (buried under the street).

These roof areas were examined by using some non-destructive methods. The maps of visual decay forms observed on the building facades were produced for the analysis of the problem areas in the structure, their distribution as well as the probable sources of these problems. Following this

preliminary on-site visual survey, a planimetric survey was conducted to record the topographical features of the roof. Readings were then converted into a detailed map indicating overall slopes and local falls in reference to roof drainage components (waterspouts and downspouts). This made it possible to locate problem areas with a potential risk of ponding on the map. Dimensions of all spout outlets, eaves gutter and downspouts were also taken to facilitate capacity calculations. These areas under study, together with the lower and upper parts of the exterior walls, were scanned by a thermal camera to define damp zones. Special attention was given to the lower parts of the walls at points where a roof drainage component existed overhead. Damp zones were compared with the risky areas for ponding. Drainage calculations were made to assess the discharge capacity of the roof discharge components and their adequacy whether they provide acceptable rates of water evacuation from roof surfaces. The ideal situations were also examined to achieve a proper roof slope arrangement providing evenly-distributed roof areas feeding each discharge component and to determine satisfactory flow dimensions for these components. The roof drainage calculations was based on the methods explained in the literature [Disli *et al.* June 2007], [Disli *et al.* September 2007], [Tavukçuoğlu *et al.* 2007], [Hall 1996], [Griffin and Fricklas 1995] [TSE 826, 1988], [BRE Part 1, 1976], [BRE Part 2, 1976], and adapted to the characteristics of the roof at hand.

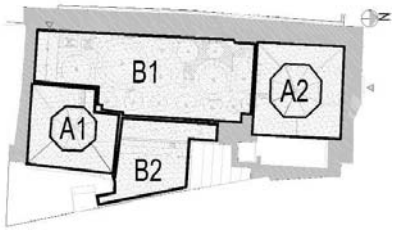

Figure 3. Plan of the building, showing the roof areas under study and immediate grounds [Disli *et al.* June 2007], [Disli *et al.* September 2007]. **A1**–timber pitched roof covered with roof tiles above the women's frigidarium section; **A2**-timber pitched roof covered with roof tiles above the men's frigidarium section; **B1**–mesh-reinforced concrete roof above the caldarium and tepidarium sections; **B2**–mesh-reinforced concrete roof above the hot water storage room and the fire wood storage room; **Grey-shaded areas**–immediate grounds of the building.

Figure 4. Views of the building, showing the roof areas under study[Disli *et al.* June 2007], [Disli *et al.* September 2007].

The results were interpreted together to examine the roof characteristics of the structure in terms of surface slopes, discharge capacity and faults and its potential for taking corrective action. The recent interventions done with incompatible materials were also discussed.

3 RESULTS AND DISCUSSIONS

The combined interpretation of the results were done in terms of the faults of the roof drainage system, adequacy of the roof drainage system and suggestions for the improvements of the roof drainage system. The results are summarized below under respective headings.

3.1 Faults of the Roof Drainage System

The present condition of the roof was determined to be unsatisfactory due to unconscious interventions and poor maintenance. In particular, the repair with mesh reinforced concrete layer added on the roof was unacceptable since it was an incompatible intervention introducing the salt problems to the structure and triggering the deterioration mechanisms in presence of dampness. This heavy concrete layer also increased the dead load of the structure and weakened it against lateral stresses. Most faults observed on the roof surfaces were inevitably the result of this concrete layer.

The map of decay forms and infrared images showed the problem areas of continuous rainwater penetration and their location in the structure. The severe material loss on masonry surfaces together with staining and salt deposits were found to correspond with the damp zones (Figs.5 and 6). Those surfaces were exposed to rainwater, overflowing from the eaves gutter, downpipes and waterspouts. Hence, the lower parts of the walls on the axis of downpipes and waterspouts were found to be damp and cold in the infrared images (Figs.7 and 8). The height of cold areas were detected to extend towards the discharge components above (Fig.8). The periodical wetting and drying at those damp zones must have caused such severe deterioration on wall surfaces. The recent repairs with cement mortar also introduced salt problems accelerating the deterioration mechanisms at the presence of dampness.

Figure 5. The maps showing the distribution of material loss (at top) and the distribution of discoloration and deposits on surfaces of the north façade (at bottom). The severe loss and detachment on surfaces was observed together with white staining and salt deposits, especially at the lower parts of the rainwater pipes at both sides of the façade and stone courses at the top, underneath the eaves gutter[Disli *et al.* June 2007].

Figure 6. The infrared image of the selected region at the north façade, showing the severe material loss as warmer areas and the detachments which were not observed visually as colder areas, both suffering from the roof drainage faults [Disli *et al.* June 2007], [Disli *et al.* September 2007].

The faults of the roof drainage system, preventing its proper functioning, were summarized as follows:

– All discharge components serving the roof areas had, in one way or another, become disfunctional (Fig. 9): All spouts were observed to suffer from the accumulation of soil deposits and plant growth, obstructing the free discharge of rainwater from the roof. In addition, all spouts, zinc gutters and downpipes were observed to be severely-deteriorated due to the wrong restoration

practices, such as repairs with cement-based mortars as shown in 'Fig.10'. Almost all metal components were observed to have corroded and lost their functions.

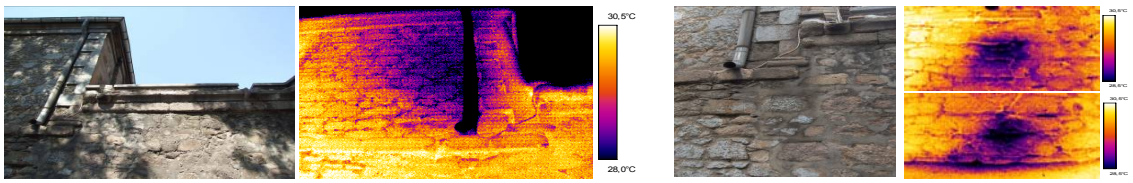

Figure 7. (a) The detached areas close to the rainwater downpipes were detected as colder areas [Disli *et al.* June 2007], [Disli *et al.* September 2007]., (b) The lower parts of the wall corresponding to the axes of the downpipe and the waterspout were found to be cold and damp [Disli *et al.* June 2007], [Disli *et al.* September 2007

- The reverse or nil falls were found to cause local ponded areas on the concrete-clad roofs, B1 and B2 (Fig. 9). Some waterspouts, particularly the spouts WS5, WS6 and WS7, were determined to be overloaded due to the improper surface slopes and direct discharge of rainwater from the timber pitched roofs to the conctere-clad roof B1 and then causing discrete roof areas feeding each spout unevenly (Fig.11). The overloaded spouts could also be detected in their IR images (Fig.12).
- A later addition of parapets on the roofs B1 and B2 were observed to cut the water flow of the rainwater towards the discharge components, causing ponding and soil/dirt accumulation in their fronts (Figs.9 and 13).
- The regions at the south of the roof B1 and at the north of the roof B2 were also the risky areas due to the lack of discharge components (Fig.9). Overflowing and/or ponding from the eaves level, therefore, were inevitable for these regions.
- The rainwater collected on the neighbouring building at the east, was observed to be discharged directly on to the roof B2, above the firewood storage of Sengul Hammam (Fig.14). This added a considerable drainage load to the interior gutter, IG and outlet, O1 [Table 1].
- As a recent unconscious addition, a green garden with 22m^2 area, was observed to exist on the roof B1 (Fig.9). This garden was attached for growing some vegetables by taking advantage of the heat and rainwater of the roof. This garden area was surrounded by a concrete parapet of 40cm height without any discharge component, acting like a pool entrapping the rainwater and, without doubt, causing serious dampness problems at both interiors and exteriors.
- Some cracks were also observed on the mesh-reinforced concrete surfaces following the slopes, inevitably causing water leakages into the sublayers and heat loss from the interiors.

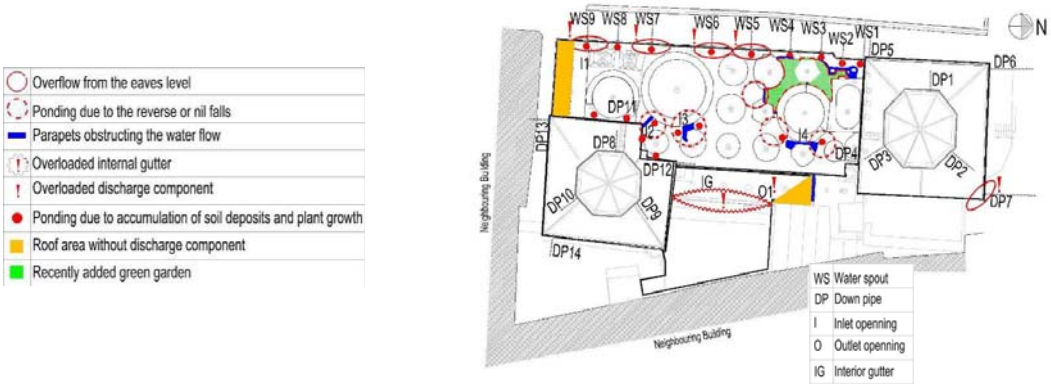

Figure 9. The map showing the faults of the roof drainage system and their location.

Figure 10. The spouts, WS1, WS4, WS5 and WS7 (from left to right, respectively) showing the severely-deteriorated sluiceways due to cement-based mortar repairs [Disli *et al.* June 2007].

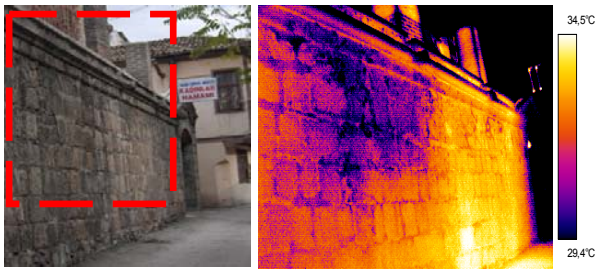

Figure 11. The roof map of the as-is case, prepared according to the results of levelling survey, showed that the discrete effective areas feeding the individual discharge components were not evenly distributed [Disli *et al.* June 2007], [Disli *et al.* September 2007].

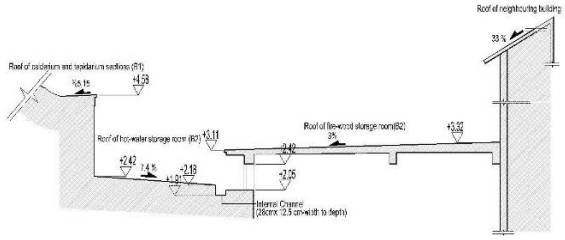

Figure 12. Darker areas in the IR image of the selected region indicated the damp zones at the upper parts of the wall due to the overflowing from the roof eaves level between the spouts WS6 and WS7. Severe material loss together with salt deposits and biological growth overlap with the colder areas [Disli *et al.* June 2007], [Disli *et al.* September 2007].

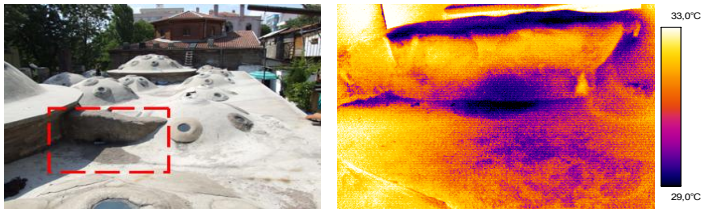

Figure 13. The IR image of the parapet cutting the water flow and causing soil/dirt accumulation in front of its outlet. The gradual decrease of surface temperatures towards the outlet exhibited the potential for absorbing and retaining rainwater [Disli *et al.* June 2007], [Disli *et al.* September 2007].

Figure 14. The cross section A-A from the roof B2 showing the roof slope arrangement towards the interior gutter and additional rainwater loading from the neighbouring building at the east [Disli *et al.* June 2007].

3.2 Adequacy of the Roof Drainage System

The roof drainage system of Sengul Hammam was evaluated in terms of its surface grading, discharge capacity and adequacy. The map showing the surface slopes, their directions and extents on roof surfaces in reference to roof drainage components were given in 'Fig. 15'.

The slopes of the pitched roofs, A1 and A2, were found to be in the range of 32% and 42%. For the roof B1, the primary slopes from east to west were in the range of 3% and 6% while the secondary slopes towards the spouts along the west side (eaves level) of the roof were, similarly, in the range of 3%-5%. The roof B2 was found to have slopes in the range of 3% and 10%, towards the interior gutter located in the middle (Fig. 15). Although it seemed to have some surface slopes providing water flow, the slope arrangement was observed to be far away from a satisfactory removal of rainwater from the concrete-clad roof surfaces. The as-is case of the roof drainage system was inadequate that not allowing a free discharge of rainwater due to the unconscious interventions of mesh-reinforced concrete layer with improper surface grading, parapets and green garden, as mentioned in the previous section.

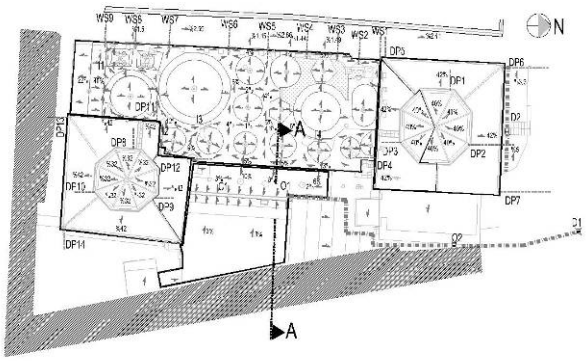

Figure 15. The map showing the direction and extent of surface slopes on the roofs of Sengul Hammam and its immediate periphery [Disli *et al.* June 2007], [Disli *et al.* September 2007].

The drainage calculations clearly exhibited the inadequacy of the roof drainage system in as-is case on quantitative basis (Table 1). For instance, the overall roof runoff rate of the concrete-clad roof B1, 18.2l/s, was almost the twice of the total discharge capacity of the waterspouts, 10.2l/s. Similarly, the total roof runoff rate of the concrete-clad roof B2, 9.7l/s, was calculated to be considerably higher than the discharge capacity of the drain O1, 5.4l/s. This drain O1 was the only discharge component of the roof B2 and in case of its partially or completely blockage, the roof B2 seemed to suffer from rainwater accumulation in considerable amounts.

The calculations also presented the uneven distribution of rainwater loading for each discharge components. For instance, the spouts WS5, WS6, WS7, WS9 and the downpipe DP7, were found to be overloaded considerably while the spouts WS1, WS2, WS3 and WS8 were found to work undercapacity [Table 1] (Fig.11). This corresponds with the results of the map showing the discrete roof areas feeding each waterspouts (Fig.11). According to the calculations, the spouts WS5, WS6 and WS7 were extremely-loaded with the roof run off rates of 5.8l/s, 4.6l/s and 3.6l/s, respectively, even reaching to the four times of their as-is discharge capacities [Table 1].

Table 1. The results of roof drainage calculations for the as-is case: The lines in red show the as-is flow capacities of the discharge components (Q_O) not enough to cope up with the individual roof runoff rate (Q_R).

Roof Spouts	A_R	A_T	Sizes width x height	Qo	Q_{TO}	Q_R	O_{RT}
	(m²)	(m²)	(cm)	(l/s)	(l/s)	(l/s)	(l/s)
WS1	24	657	8.5 x 7.5	1,18	**10,20**	0,68	**18,22**
WS2	17		9.0 x 7.0	1,13		0,42	
WS3	26		8.5 x 5.5	0,74		0,62	
WS4	35		9.5 x 6.5	1,06		0,82	
WS5	206		6.0 x 11.0	**1,48**	<	**5,79**	
WS6	162		10.0 x 7.0	**1,25**	<	**4,56**	
WS7	124		12.0 x 6.5	**1,34**	<	**3,55**	
WS8	14		9.0 x 6.5	1,01		0,38	
WS9	49		9.0 x 6.5	**1,01**	<	**1,4**	
DP7	62		Φ=10	**1,79**	<	**1,85**	1,85
IG1	325	325	28 X 12.5	**8,35**	8,35	**9,74**	9,74
O1	325	325	18 X 12.5	**5,37**	5,37	**9,74**	9,74

Q_O: the flow capacity of an outlet;
Q_{TO}: the total discharge capacity of the spouts serving each roof area;
A_I: the discrete effective areas feeding individual spouts;
A_T: the total effective area of each roof under study;
Q_R: the rate of runoff from each effective area feeding individual spouts;
Q_{TR}: the total runoff from each roof under study.

The discharge coefficient for the low-sloped surfaces of the roof B1, was also discussed according to the results of drainage calculations. The discharge coefficient of the dome surfaces was accepted as '1.0' because of their high slope [Hall, 1996; TSE, 1988]. Considering the ideal roof fall arrangement which is explained in the next section and the original spout dimensions, 10x9cm in width and depth, the surface conditions for the low-sloped surfaces at the past could be calculated. This was found to be in the range of 0.2-0.3 for the low-sloped surfaces signalling the a considerably-high water absorption capability of the surface, such as earth [Hall 1996], [TSE 1988]. Further studies are needed to discover the drainage characteristics of original roof materials.

3.3. Suggestions for the Improvement of the Roof Drainage

The study has shown up the priorities for the improvement of the roof drainage system and maintenance program particular to the building. It appeared that the roof drainage system is not possible to funcion properly anymore due to the presence of unacceptable mesh-reinforced concrete layer. This incompatible layer definitely accelerates the soluble salts and dampness problems and destroys the functioning of roof drainage system. The recent studies also showed that the concrete/reinforced-concrete repairs destroy the structural stability of the historic masonry structures [Aktas, 2006] and weaken the structures against the lateral stresses. It is essential to correct the surface grading of the roof surfaces but it is not possible to repair these surfaces with additional concrete layers. Considering all, the present roof drainage system of the mesh-reinforced concrete roofs could not be improved by usual remedial measures. The mesh-reinforced concrete layer, therefore, should definitely be removed from the structure and then the roof should be covered with the layers of compatible roof plasters in the context of a well-planned conservation program developed by the structural engineers and conservation experts. The ideal case for the improvement of the roof drainage system was suggested as follows:

(a) as much as the present surface geometry allowed, an even distribution of rainwater loading for each discharge component should be achieved as suggested in 'Fig. 16'. The arrangement of roof

slopes should be corrected accordingly for a pond-free drainage system. Special care should be given to level the reverse falls in front of spout openings properly for a fast water runoff;
(b) the extreme loading from the roof of neigbouring building at the east of the roof B2 should be prevented, without doubt, by a separate roof drainage of the neighbouring building.
(c) The discharge capacities of the waterspouts should be improved by increasing their flow dimensions. For a rainwater discharge in acceptable ranges, the ideal flow dimensions for the spouts, WS1, WS2, WS3, WS4, WS5, WS8 and WS9 were calculated to be 10cm x 9cm in width and depth, having the discharge capacity of 1.8l/s. A larger discharge capacity of 2.7l/s were needed for the spouts WS6 and WS7 with the flow dimensions of at least 11 x 11 cm in order to cope up with the roof runoff 2.5l/s and 2.8l/s [Table 2a]. The as-is dimensions of O1, 12.5 x 18.0cm in width and depth, needed to be increased to 12.5 x 28.0cm to cope up with the free discharge of the rainwater from the roof area.
(d) The internal gutter IG1 should be extended to cover the whole length of the roof B2, 17.40 m, where it suffers from the lack of drainage component (Fig.16). An alternative drain is suggested which may act as an overflow drain in case of any partial/complete blockage of O1;
(e) There is a necessity of a discharge component at the south of B1, suffering from the uncontrolled overflow and severe dampness problems on the wall surfaces. Here, the water discharge should be provided by means of an additional waterspout WS10 together with a collecting channel at the eaves level as shown in 'Figs. 16 and 17'.

Some urgent interventions related to the timber pitched roofs were also recommended to improve their existing conditions:-
(f) The timber pitched roofs should be repaired to let it properly function as a four-sided pitched roof/hipped roof as suggested in 'Fig.16'. The eaves gutter and downpipes forming the peripheral drainage system for these pitched roofs should be replaced with the properly-sized ones. The drainage systems for the pitched roofs and low-sloped roofs should be seperated. The direct discharge from the pitched roofs onto the roofs B1 and B2 should definitely be prevented by the addition of downspouts diverting rainwater to the surface-water drainage system at the immediate periphery of the structure. The placement of these downpipes were shown in 'Fig.17' and the ideal sizes for each downpipe and eaves gutter were listed in [Table 2b]. The 23 downpipes located at four sides of the roofs were recommended with diameters of 70mm for the downpipes and of 250mm for the eaves gutters while smaller diameters could be enough for the lantern part of the pitched roofs as listed in [Table 2b].

Such improvements summarized above are essential for a pond-free drainage system and the survival of the structure. In addition, some preventive measures were also suggested, such as the regular cleaning of discharge components from soil and plant deposits. For future improvements, any subsequent intervention and its effect on the discharge system should be checked by means of roof drainage calculations used in this study.

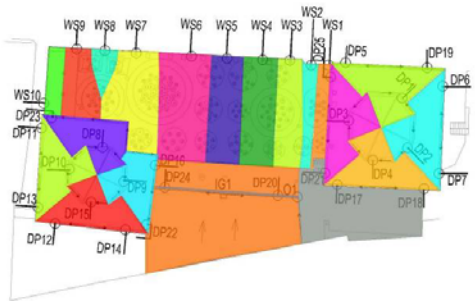

Figure 16. The ideal roof map showing the discrete effective areas feeding individual discharge component which provides an even rainwater loading for each component.

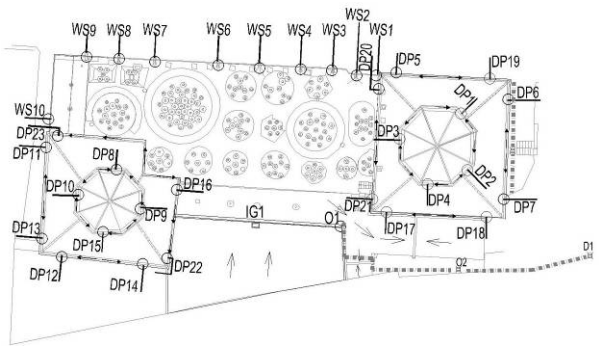

Figure 17. The roof map of the ideal case showing the location of each individual discharge component.

4 CONCLUSION

In order to have survived under the effects of the prevailing harsh climatic conditions over the centuries, Sengul Hammam must originally have had quite a well-designed roof drainage system. However, the study showed that the roof of this structure has not been able to withstand the test of time due to the inappropriate interventions and a lack of maintenance. At present, there are serious dampness problems arising from the presence of an imcompatible mesh-concrete layer above the roof structure together with certain roof drainage faults.

For a satisfactory-functioning of the roof drainage system and the survival of the stucture it is essential to remove this concrete layer from the roof structure and then cover it with the layers of compatible roof plasters. These works should be well-planned in the context of a comprehensive conservation program. The ideal case for the improvement of the roof drainage system was suggested and preventive measures have been pointed out,herewith.

The joint interpretation of non-destructive analyses, including mapping of the decay forms, IRT analyses, leveling survey and drainage capacity calculations, provided a good combination for the assessment of the roof drainage system of a historical building. The roof drainage calculations used in the case of Sengul Hammam can also be applied to the roof of historical buildings in a similar condition for the assessment of their adequacy on a quantitative basis.

The Restoration and Upgrading of The 100 Year Old Victoria Institution: the Adaptive Reuse of a School into an Auditorium

Kribanandan Gurusamy Naidu

T 25

ABSTRACT

The former Victoria Institution is located in the center of Kuala Lumpur and was year marked to be upgraded and extended in 2005 in an adaptive reuse of a cultural heritage building. The main structure was built in 1893 and was in ruins having deteriorated over time due to physical impact of human activity as well as weathering over time and the impact of a fire in 1999.

A detailed investigation, sampling and materials testing of the building and the surrounding ground conditions was undertaken to provide a basis for the redesign and upgrading works. The change of use necessitated major design changes associated with the Roof Structure to cater for long open spans required for the auditorium seating. In keeping with the Heritage guidelines a church designed by the same Architect during the same period was investigated and used as the basis to achieve historical authenticity in design.

This paper contains an overview of the award winning project including the materials intervention and the structural engineering undertaken including an innovative intervention to restore the masonry arches to achieve the adaptive reuse objectives.

Adaptive Reuse, Masonry strengthening and pinning, Building pathology, Redesign, Materials investigation.

1 PROJECT SUMMARY

1.1 Project Brief

The former Victoria Institution (V.I) now called the Kompleks Taman Budaya, Wilayah Persekutuan located in the center of Kuala Lumpur was originally built in 1893. The structure had been abandoned for several years and was in ruins having deteriorated over time due to physical, environmental and fire impacts (See Figure 1). Following the gazetment of the building under the Monument Act 1976, a contract was let to rebuild the structure in an adaptive reuse of a cultural heritage building to a modern auditorium for the Arts. Besides the upgrading and conservation works, a new Annex building with a basement was included as part of the development of the site. Prior to any intervention associated with the upgrading / rectification works, a detailed condition survey was undertaken covering the external and internal building elements as well as the infrastructure services. This was followed by an in depth sampling and testing program which formed the basis on which to develop a remedial intervention program keeping the compatibility of new and old materials in view and as far as possible minimizing the extent of physical intervention.

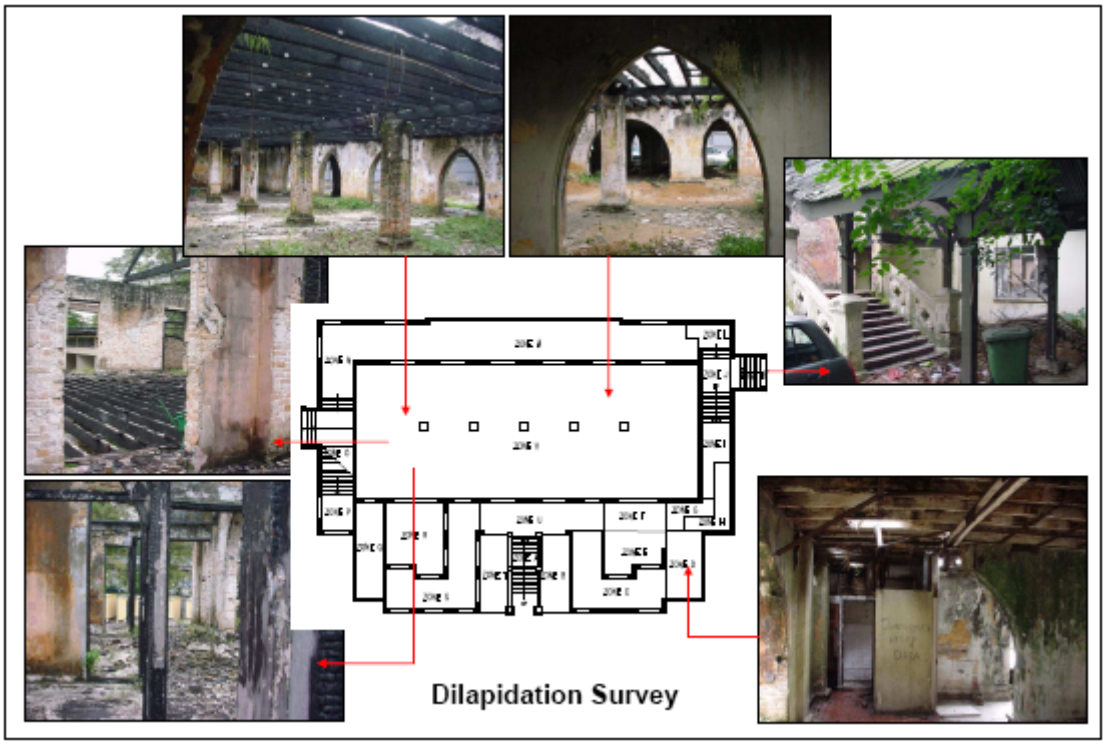

Figure 1. Photographic Record of Dilapidation Survey

1.2 Project Background

The site of the old V.I. building is in a historically significant part of Kuala Lumpur. It is located at the southern end of Jalan Tun H.S. Lee (also named Jalan Bandar) and adjacent to other buildings of historic relevance. The project consisted of:

a) Conservation and upgrading works for adaptive reuse of the former Victoria Institution.
b) An additional adjoining new annex building (3 storeys) with 1 level basement.
c) Infrastructure, facilities and services upgrading.

The overall size of the site is approximately 0.8 acres. The original size of the Conservation building was 6650m² and this was increased to 7710m² with the additional floor. The plinth area for the Annex building is 8850m².The construction programme spanned from Oct 2002 to Nov 2004

The structure was one of the icons of the colonial era and very much part of Kuala Lumpur history. By reinstating the structure to its original historical context and at the same time adapting it to an auditorium, a new and significant venue for the Arts at the heart of the old city has been established. This has also helped boost tourism by adding a new historical landmark and new places of interest for local and foreign visitors.

1.3 Client Brief and Requirements

The conservation building was reconstructed to house an Auditorium, while the Annex building complemented this development by providing the space for cultural performance studios and an administrative office. The requirement was one of a re-adaptation of an existing building which required a high level of conservation knowledge and approach. The new annex building was to be constructed with modern construction methods with minimal disturbance to the existing original façade as well as the floor of the conservation building.

2 ENGINEERING FEATURES

2.1 Scope of Works

The scope of works included :

a) Condition and Dilapidation Survey undertaken in relation to the Department of Museum and Antiquities HABS requirements.
b) Structural Evaluation and Assessment.
c) Underpinning and masonry arch strengthening by a novel pinning method to minimize intervention.
d) Structural design to recreate the structure (see Figures 2 & 3) including a new roof design in keeping with the Architectural Accent of the time to fit in with the adaptive reuse requirements.
e) Construction methodology with strong emphasis on the basement area and methods to mitigate against impact of the new Annex building construction on the historical building.
f) Providing proposed remedial treatment for defects identified.
g) Supervision of civil and structural works.
h) Supervision of upgrading and reinstatement works.

2.2 Complexity of Design

There were several critical issues associated with the upgrading works which required careful engineering judgement. This included:

a) The building was badly decayed due to human, physical, environmental and fire impacts and therefore carefully planned construction methodologies for the upgrading work sequence was required.
b) Detailed monitoring and testing were required to confirm the structural strength, stability and insitu condition of the structure and the potential impact of new loads acting on the structure.
c) Ground settlement problems associated with the adjacent basement excavation works and ground water movement and its potential impact on the adjacent walls of the heritage structure was undertaken.
d) The need for a rigorous monitoring system for the heritage building and alternative design approaches were considered.
e) The need to integrate the existing structural elements with new elements while complying with the historical building and conservation guidelines.

f) In keeping with the adaptive reuse and the need to minimize external impact on the original structural elements an internal steel frame was designed to support the new roof structure. This not only eased the construction approach, it also allowed structural works to proceed as the upgrading works were ongoing.

2.3 Design Approaches

2.3.1 Design Philosophy

The approach to the conservation building upgrading was to restore where possible all elements of the structure to its original intent coupled with the introduction of a new load bearing internal steel frame structure within the inner auditorium. The latter was thought necessary for the following reasons:

a) Fire damage had weakened the masonry elements particularly at the upper levels.
b) Several years of weathering due to complete exposure of the masonry elements had accelerated deterioration.
c) Change of use of the structure requiring large spans and increased loading due to the auditorium seating.
d) Re-establishment of the Chinese roof tiles which were significantly heavier than the sheet elements previously in place.

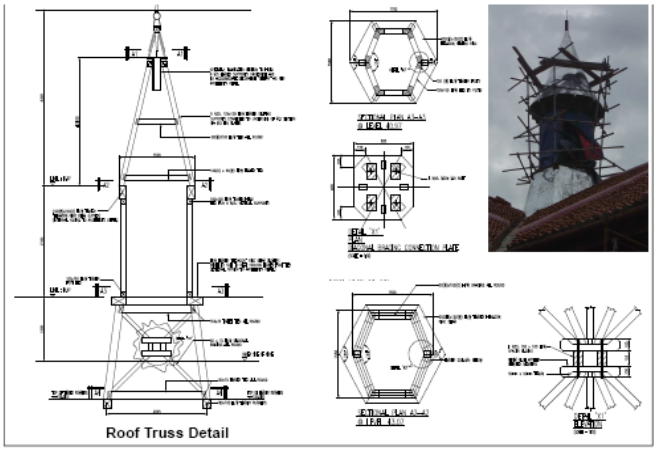

Figure 2. Roof Truss details reestablishing the original Bell Tower.

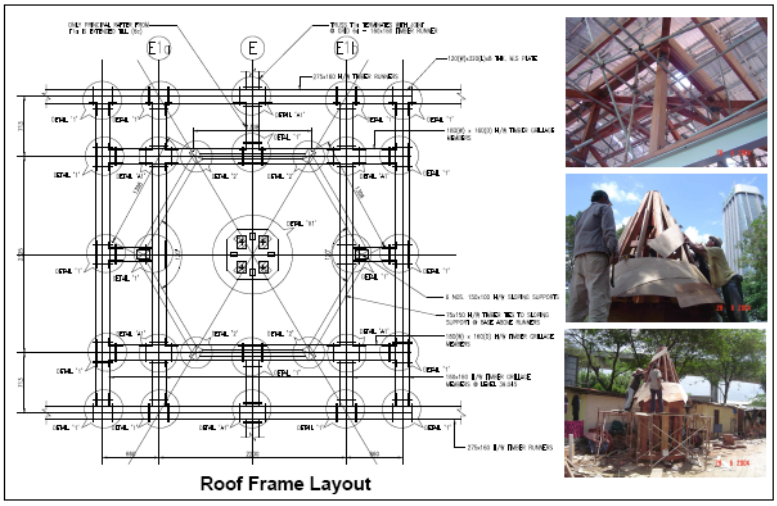

Figure 3. Roof truss Details- Timber roof to cater for new long spans for the adaptive reuse.

2.3.2 Key Design Considerations

The reinstatement of the existing structure needed to consider not only the problems of fire damage, water ingress, erosion and mould growth but also the structural strengthening needs particularly of arches and masonry elements.

Key design considerations included structural assessment and redesign, and the development of options for reinstatement, material consultancy including rising damp, timber retention and/or replacement, overall site drainage, redesign of the roofing system and conservation of ruins. The scope for the new structure involved a complete redesign. From the outset one of the parameters the team embarked upon was to introduce the timber truss system. This was deemed necessary as this constituted a primary component of the conservation building.

2.3.3 Conservation Building

Based on a detailed assessment the existing masonry walls, these were considered inappropriate as the primary structural member as outlined in Section 2.3.1.

A secondary inner steel fame was therefore recommended to be specially designed in order to take the structural loads. This required careful planning to avoid encroachment onto the existing structure with particular considerations at foundation level. This frame was also used to support the temporary roof cover during the upgrading works. To minimize the influence of the foundation works on the main structure, a cantilever strap beam arrangement was designed allowing the footing placement at > 600m away from the existing wall (see Figure 4). The footings and strap beams were designed to minimize any excavation requirements adjacent to the masonry wall foundations. A temporary support system was designed to shore the walls during construction which was also used as an access platform for the investigation and upgrading works.

2.3.4 Annex Building

The structure was designed as a conventional 3-storey concrete frame structure with a one level basement. Special attention was given to the basement works and foundation design such that any impact to the existing Conservation Building would be minimized. Of particular concern was the excavation works for the basement which required dewatering and potentially a draw down on the water table. The other was the potential uplift forces during the temporary construction phase which required anchoring of the basement.

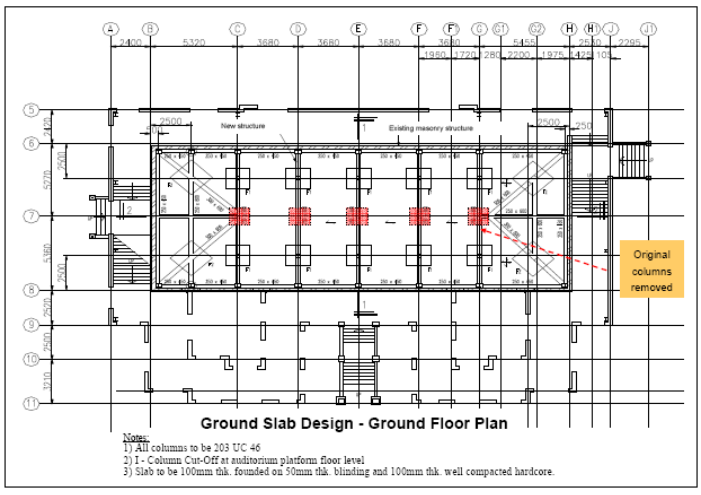

Figure 4. Ground Floor plan, central columns removed and new steel Frame structure in place

2.4 Design Solutions / Engineering Merit

2.4.1 Overview

The strategy and methodology adapted for this project consisted of the following:

a) The construction approach clearly required dividing the works into two distinct parcels. The conservation building was treated as a separate construction entity with a team of workers who were under strict guidance with skills training as deemed necessary to the conservation standards. The new Annex building was handled by a separate team of sub contractors.
b) Priority in terms of safety and stability of the existing Conservation Building was established while the construction of the new Annex Building was carried out. Adequate means and relevant procedures were observed.
c) Civil and structural works carried out positively addressed the issues of rainwater, impact and dewatering in safeguarding the Conservation Building during upgrading works.
d) All temporary works including scaffolding works and shoring works to the existing remains were handled very sensitively and in accordance to the norms of the standard practice where conservation is concerned.
e) The quality of workmanship and materials used were strictly adhered to as per specification requirements and the rigorous investigations undertaken on the conservation structure to confirm compatibility of approach.
f) The infrastructure works complemented the conservation works and where necessary conservation was given priority.

2.4.2 Conservation Building

a) Overview

Based on the historical significance of the structure and its deteriorated state due to the physical impact of the environment, the upgrading works undertaken required special attention and care. Of particular importance was the minimization of the potential impact of the adjacent annex building basement works and the new foundation and ground beam works within the auditorium which was required to house the new structural frame within the Conservation Building. Prior to any works starting the protection of the structure by temporary roof cover, bracing and shoring proceeded immediately and was fully in place. The shoring of the adjacent basement excavation against any soil collapse and the minimization of ground water seepage was established prior to the start of the works.

Ground engineering studies were undertaken to measure ground water fluctuations. In all cases permeability measurements were also taken to obtain accurate information about the soil properties and form a basis to predict ground water flow characteristics. Testing results were used to confirm suitability of the basement design and construction approach. This identified a clear danger to the conservation structure and required in-depth presentation to the client to change the original size and extent of the Annex Building basement and the introduction of a physical barrier between the Annex and Conservation buildings to minimize water flows.

b) Temporary Protection of the Structure

Footings of the conservation structure were much shallower than originally thought based on the information provided during the tender exercise. These were confirmed by measurement following excavation of the footings and were found to be only at 1m below ground level. The requirement for temporary shoring of the structure and additional protection of the masonry foundations prior to any excavations or work beginning was therefore imperative. A combination of methods was undertaken:

- the introduction of a secant pile wall and Jet Grouting as a physical barrier between the basement excavation and the conservation building.

- protection bracing of the structure using timber and/or steel elements.

c) Protection of the excavation

Following the basement excavation the sides of the basement embankments adjacent to the existing conservation building were shored by approved means. The secant pile wall socketed to rock was considered an adequate solution. The provision of a capping beam and strutting at corners provided additional measures required for stability during construction.

d) Monitoring and Instrumentation of adjacent structures

A rigorous monitoring regime was set up. This included monitoring points on the structural masonry elements closest to the basement excavation, temporary benchmarks, tilt monitoring and monitoring of building and ground settlements. The measurements were used as a basis to increase the shoring requirements as appropriate.

e) Mitigation of differential settlement

The monitoring results provided an indication of actual movement potential. A combination of construction sequencing and programming and measures to minimise ground water movement was undertaken as the mitigation approach. The adoption of secant pile provided a barrier against water flows and this minimised the risk of the associated settlement. This coupled with the reduced basement size and depth requirements as suggested by us was accepted and considered a workable solution.

f) Specialist Remedial Requirements

There were several issues concerning the upgrading of the fabric of the structure which required careful planning. This included plaster restoration, brickwork reinstatement, timber replacement (See Table 1) and the need to undertake trials, all of which impacted the overall programming of the structural framing requirements. Proposals from other specialists and contractors were incorporated into detailed method statements for the remedial treatment works.

g) Retention of Main Structure

The outer corridor structure was retained as its original design and layout with the masonry walls acting as the main structural members. In this case the actual loading on the structure could be maintained as there was no indication of any fire damage at the masonry wall levels. Random testing of the brickwork undertaken prior to contract award suggested that the strength of the bricks (See Table 2) were well above requirements and had not deteriorated despite the exposure to the environment.

Further testing of the bricks and mortar was commissioned to confirm the adequacy of the bricks for this purpose. Calculations based on the typical footing details obtained following the excavations and the expected structural loads indicated that the compressive strength required for the bricks was up to an order of magnitude below that reported following testing earlier undertaken. Steel frame trusses were used to allow the corresponding structural loads to be reduced accordingly.

A good proportion of the main masonry arches were pinned using a novel approach developed for this project and was found to be very cost effective.

3 PROJECT ACCOMPLISHMENT

3.1 Client Needs

The client needs can be outlined as follows:
a) Upgrading, conservation and preservation works need to be true to the authenticity and originality of the former design style, type and physical outlook.
b) Replacement of building materials should follow the Conservation requirements as imposed by the Museum and Antiquities Department.
c) Requirements compliance for adaptive reuse of the building to suit the new function, purpose and objectives.

3.2 Budget and Project Time Line

The project was successfully controlled due to the implementation of proper documentation in the forms of proformas and checklists undertaken at all stages of construction, i.e. pre-construction, during construction and post-construction periods. The difficulty in budget controls for conservation projects is well known due to unforeseen circumstances at the time of project procurement leading to intervention not originally considered necessary. In this case cost control was exercised, as the main issues of concern had been raised during the tender submission and the increased budget was related primarily to the need to establish protection measures against ground water movement and possible settlement of the Conservation Building. This was also one of the reasons for the delays in the original programme. The other was related to the procurement of Chinese tiles and special timber for the roof structure.

3.3 Overview

The ultimate client for the project was the Department of Museum and Antiquities of the Ministry of Tourism, Culture and Arts who controlled the budget allocation. A key Client requirement was the conservation and upgrading of the badly decayed building to suit the new function while at the same time maintaining the originality and authenticity of the building design and style. The project was completed with constraints on budget and design alternatives were constantly reviewed to achieve the most feasible and cost-effective solutions. Following engineering feedback, overall concept changes were made after award of the contract. This resulted in an improved overall development, minimization of risk to the Conservation Building and matched the client's overall objectives closely (see Figure 5).

Petros Moundoulas [3]
Eleni Aggelakopoulou [4]

T 25

ABSTRACT

During historic building restoration works, one of the most critical factors in planning syntheses for durable restoration mortars is to understand the correlation between mortar properties and raw materials.

Towards this direction, the present work aims to prove that multivariate statistics and especially Principal Component Analysis (PCA) is an invaluable tool for classifying restoration mortars in separate groups, depending on their synthesis and physicochemical characteristics. Different syntheses of restoration mortars were prepared using traditional techniques and materials such as binders (aerial and natural hydraulic lime), pozzolanic additives (natural and artificial pozzolanas) and aggregates (sand and crushed brick).

Thirty five samples in total were analysed by thermal analyses (differential thermal analysis [DTA] and thermogravimetric analysis [TGA]), mercury intrusion porosimetry and mechanical strength tests. The results give us a very useful and illustrative tool in and planning syntheses for restoration purposes.

1. INTRODUCTION

It is well known that historic building restoration interventions may cause significant failures and accelerate degradation of the building elements, if the restoration materials are not compatible to the original ones. Especially in the case of mortar restoration, cement-based materials have been proved improper for major or minor restoration works [Fassina & Borsela 1993; Moropoulou 2000]. However, the term "compatibility" is vague and not clearly defined and guidelines for compatible mortars do not yet exist [von Konow 1997].

Towards this direction, the present work aims to prove that multivariate statistics and especially Principal Component Analysis (PCA) is an invaluable tool for classifying restoration mortars in separate groups, depending on their synthesis and physicochemical characteristics. PCA is a technique for simplifying a data set, by reducing the number of variables [Davies 1986]. Due to its effectiveness in 'summarizing' data, PCA reveals similarities and differences and is usually the first step to search for groups in large data sets.

The technique has previously been used by Moropoulou *et al.* [2003] to classify historical mortars. A similar approach will be presented in here for restoration mortars. The restoration mortars presented herein belong to two different series. First is a series of sixteen (16) laboratory syntheses, made for research purposes and second a series of twenty seven (27) restoration mortars, which have been prepared for real application on historic buildings. The first series includes pastes with different pozzolans, that is natural, artificial and highly reactive pozzolans [Moropoulou *et al.* 2004). The second series includes pastes, which have been prepared for restoring the Basilica of Aghia Sophia (Istanbul, Turkey), a water-mill at Veroia (Greece) and an orphanage at Aigina (Greece).

2. MATERIALS AND TECHNIQUES

The first series of pastes includes syntheses which were prepared by mixing a commercial lime with three types of pozzolans (Table 1): a natural pozzolan (earth of Melos island, Greece - EM), an artificial pozzolan (ceramic powder of ground, handmade bricks fired at low temperatures - CP) — and an artificial highly reactive pozzolan (metakaolin - Metastar 501 of IMERYS Minerals Ltd. – MK). Mortars indicated by L and LPu are referred to lime powder and lime putty mortars. All syntheses are produced by quartz sand except the LCal and LPuCal syntheses where a calcite sand was used. The exact chemical composition of the pozzolans is given in Moropoulou *et al.* [2004]. The metakaolin is the finest pozzolan with cumulative passing percentage (CPP) at 64 μm of 100% and at 16 μm up to 95.6%, the earth of Milos shows a CPP from 64 μm up to 95.9% and the corresponding percentage for the ceramic powder is up to 88.1%. The second series of syntheses is given in Table 2. Lime putty, lime powder and natural hydraulic lime were used as binding materials. Lime putty is generally encountered in historic mortars, while lime powder was used as an alternative binding material for the substitution of lime putty due to the higher and quasi-stable percentage of $Ca(OH)_2$ content. The aggregate materials were mainly siliceous sand and crushed brick. The former has already been detected in historic mortar samples with the effect of producing lightweight mortars, due to its lower bulk density in respect to the sand aggregates, along with lower modulus of elasticity that it provides. In some of the mixtures natural and artificial pozzolanic additions (Melos earth, Ceramic Powder respectively) were used.

Samples from the pastes were analysed by Mercury Intrusion Porosimetry, Differential Thermal Analysis (DTA), Thermogravimetric Analysis (TGA) and tested by mechanical strength tests. DTA and TGA were carried out (DTA/TG, Netzsch 409EP), in a static air atmosphere with heating rate of 10 ^{0}C/min from 25–1000 ^{0}C. Measurements were done on the total sample and on the fraction smaller than 63 μm, which constitutes the binding materials [Bakolas *et al.* 1998]. A Carlo Erba 4000 mercury porosimeter was used for porosimetry measurements and the cylindrical mathematical model was employed to elaborate the results. Tests on compressive and flexural strengths were carried out at 12

months (Toni-Technik DKD-K-23301 compressive tester/load rate: 0.01 kN/s, ToniTechnik-D-70804 flexural tester/load rate: 0.05 kN/s). The results for the two series of data are given in Tables 3 and 4.

SSA = Specific Surface Area, PR = Pore Radius, Db = Bulk density, Por = Total Porosity, H = Mass loss attributed to hygroscopic water (%) for lime mortars and to water of CSH for pozzolanic ones, H-HC = Mass loss attributed to water of Ca(OH)2, CH = $Ca(OH)_2$, CH = consumed $Ca(OH)_2$, CO_2 = Mass loss attributed to CaCO3 (%), Fc = Compressive strength, Ff = Flexural strength.

3. RESULTS AND DISCUSSION

The application of PCA on the two data series gave a number of Principal Components (PCs), the two first of which are given in Figures 1a and 2a. These figures show the projection of the original variables on the PCs plane. Figures 1a and 2a are very useful because they help us understand the contribution of the original variables to each PC.

Three well defined and distinct groups are formed in Figure 1b. The lime mortars are very well separated from all the other samples. The critical variables for this separation are H, H-CH, CO_2 and Pore Radius, Porosity. Lime mortars present larger values of pore radius average attributed to the nature of binder and larger values of H-CH and H-CH since there is no addition of pozzolan in their pastes.

The group of pastes with the artificial pozzolan (metakaoline, MK) is also very compact and easily discriminated by the others. The critical variables are Specific Surface Area, Fc and H. Metakaolin is a high reactive pozzolan, leading to high values of chemical bound water, dense microstructure and high values of compressive and flexural strength.

As for the mortars with crushed brick, they are grouped very close to those with Melos earth. Altogether form another well defined group, separated from the others, with density being the critical variable. Both pozzolanic additions did not exhibit a high pozzolanic activity therefore their characteristics are analogous.

As it is shown from the plots of Figure 2b, there is a strong relation between the presence of pozzolanic additives and the high values of chemically bound water, but also the high values of compressive and flexural strength. At the same time the rates of carbonation remain high allowing the quick setting and hardening. We have also to note the development of a microstructure with greater values of specific surface area and lower values of average pore radious and total porosity.

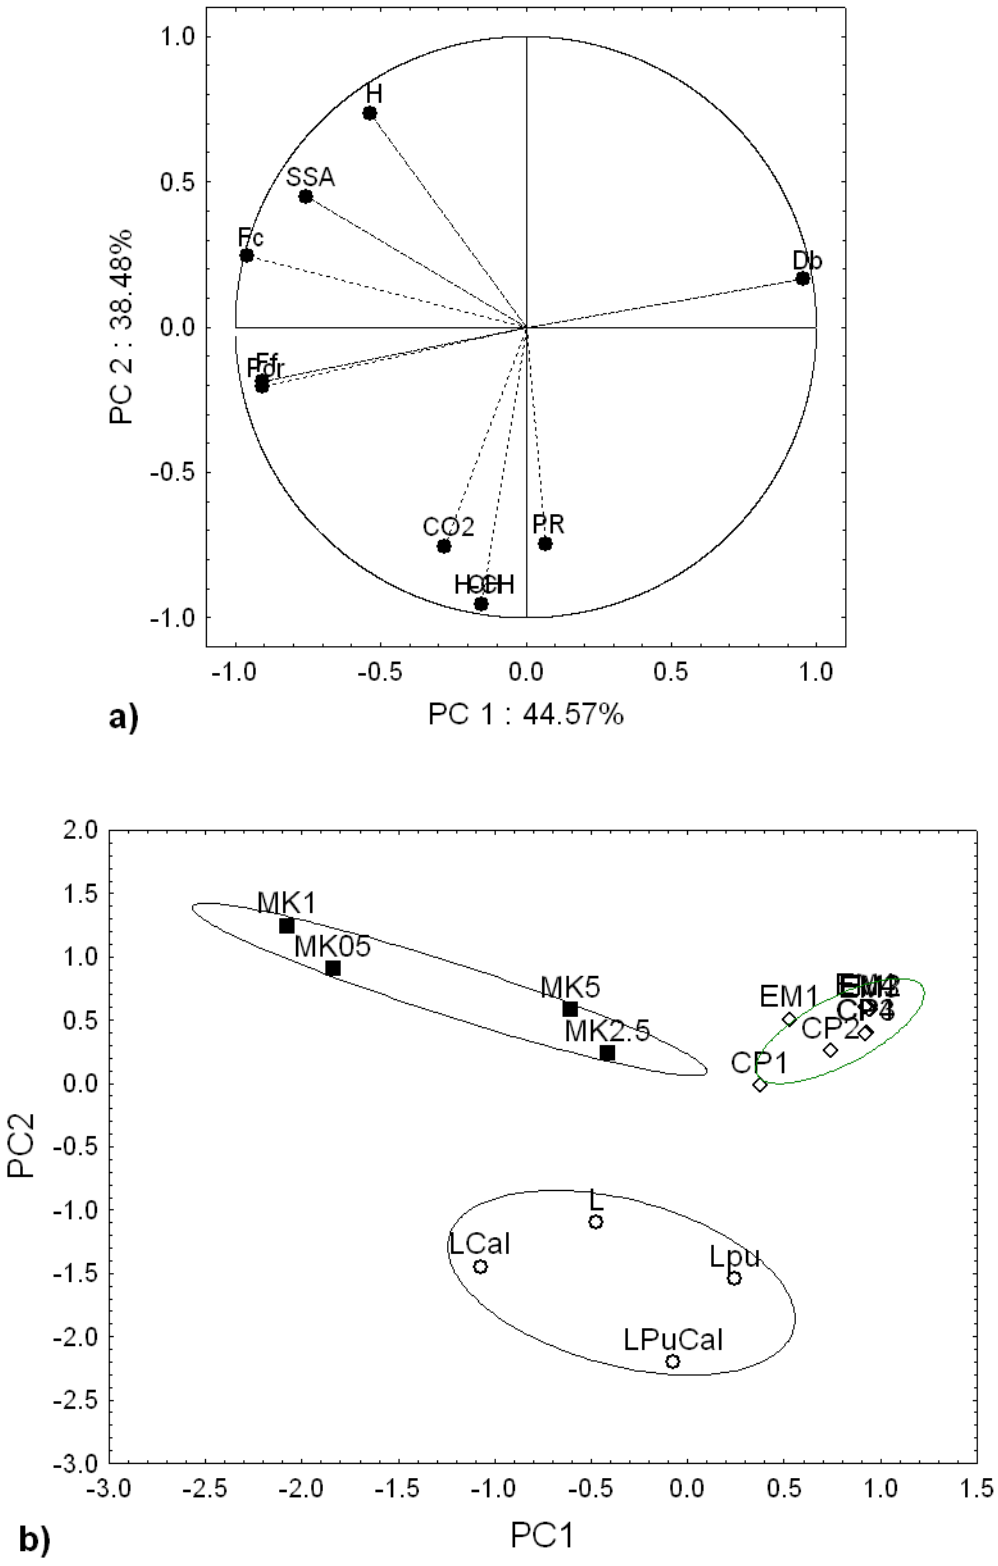

Figure 1. First series of samples: a) Projection of the variables on the plane of the Principal Components 1 and 2 and b) The PCA scores of the first series of the mortar samples

SSA = Specific Surface Area, PR = Pore Radius, Db = Bulk Density, Por = Total Porosity, CBW= Chemically Bound Water, CO_2 = Mass loss attributed to CaCO3 (%) , Fc = Compressive strength, Ff = Flexural strength.

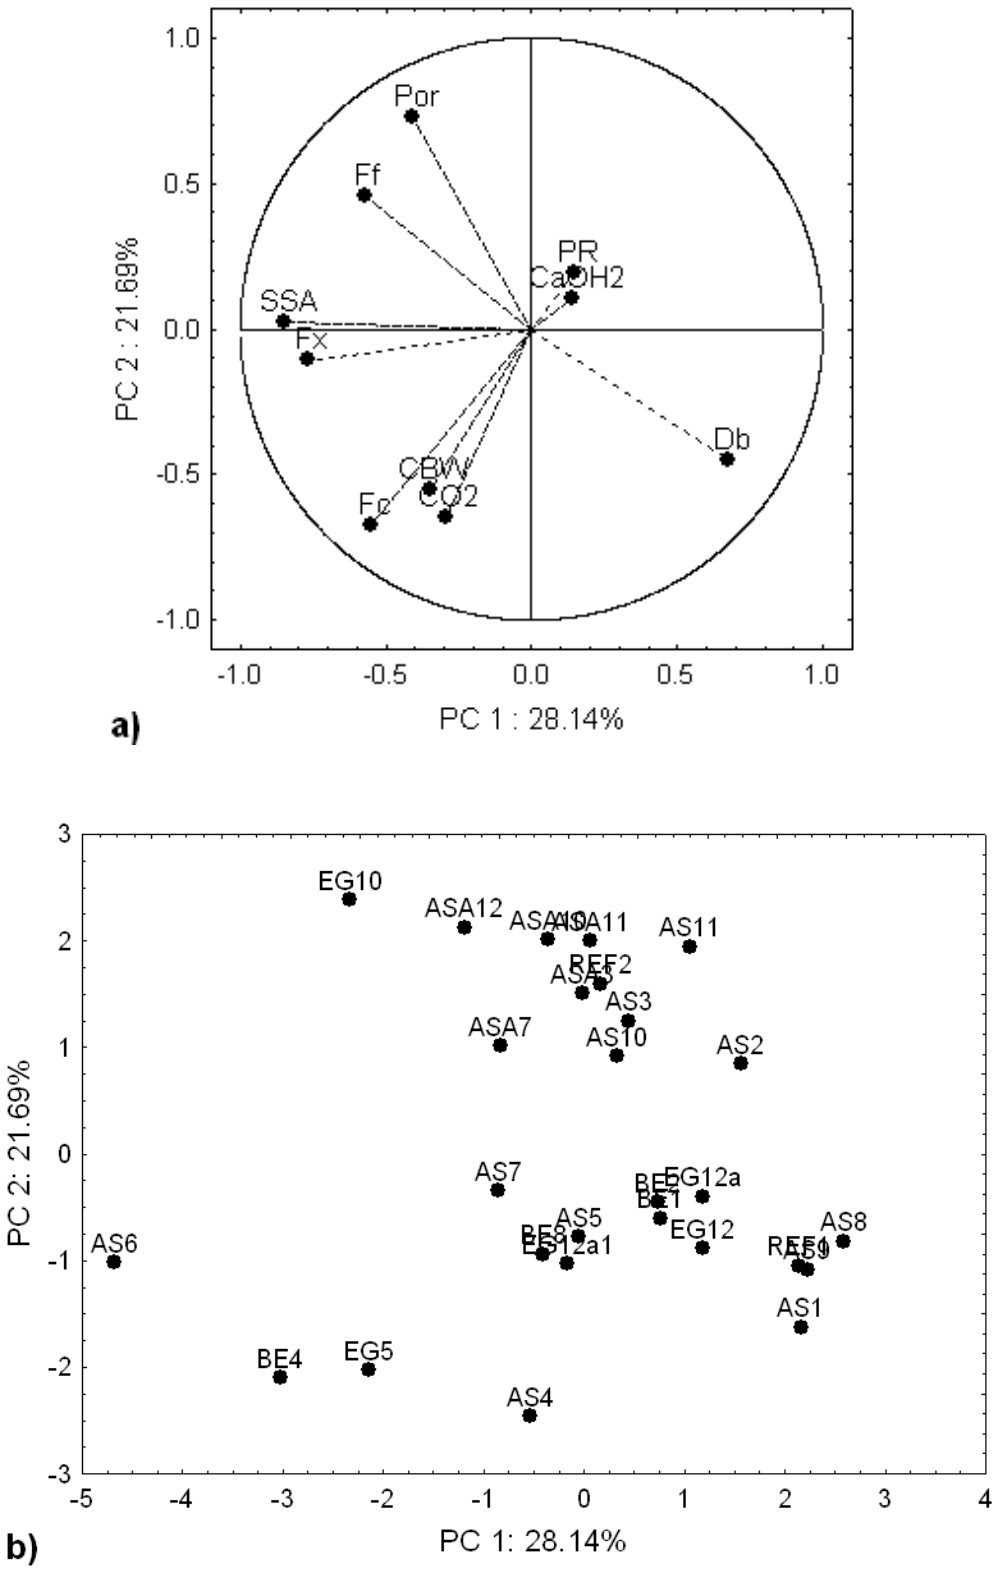

Figure 2. Second series of samples: a) Projection of the variables on the plane of the Principal Components 1 and 2 and b) The PCA scores of the second series of the mortar samples

These are the main characteristics of the restoration mortars for the orphanage at Aigina and the water-mill at Veroia. The mortars with active aggregates (crushed brick) show a different behavior, mainly because the specific microstructure of the ceramics influence the results of the microstructure reported. On the other hand and in the cases where pozzolanic additives or active aggregates were not used the main aim was the compatibility with the historic compounds. In these cases the development of high values of strength was not the main issue. In these cases there is a strong relation between the lower carbonation rate with the development of a certain microstructure (greater average pore radious, higher values of total porosity) and lower values of strength.

4. CONCLUSIONS

In order to ensure compatibility of restoration mortars the present work used PCA for classifying restoration mortars, depending on their synthesis and physicochemical characteristics. The results of Mercury Intrusion Porosimetry, Thermal Analysis and Strength Tests for thirty five mortar samples were treated with PCA. The results may contribute in the future, in developing guidelines for compatible restoration mortars.

Technological Features and Decay Processes of A "New" Building Type at The Beginning of XX Century

Fabio Fatiguso [1]
Giambattista De Tommasi [2]

T 25

ABSTRACT

Building at the beginning of the 20th century results from a "transitional" architectural knowledge, where the traditional culture (connected to Best Practice Codes) and the modern one (resulting from the Industrial Revolution), join together. From a constructional and technological point of view, a new building "type" is defined, *mixed structure building*, characterised by the combination and/or the substitution of traditional building elements with other ones made out of "new" materials and techniques. Experience shows that such buildings were subjected, during the years, to ageing due to a material and "technological" decay that was increased and not prevented at all. This study gives an overview of mixed structure buildings, as a result of a progressive transformation. Moreover, it highlights potential critical aspects and specific decay processes. The research defines material, technical, technological features of the "new" building type and it analyzes physical, technological, functional and normative decay. It classifies the material and technological decay processes and it localizes potential lacking points where decay can generate. The research aims at systematizing all the information about this heritage in order to define specific methodologies and guidelines for maintenance and renovation of performance quality.

1 INTRODUCTION

Between the end of the 19th century and the beginning of the 20th century, buildings are characterized by a progressive combination and/or substitution of traditional materials and constructional techniques with modern ones. This process is referred to a general transformation within the historical, social, economic and cultural context. The co-presence of traditional and modern elements caused evident and peculiar decay effects. This study explains the most significant results of a research funded by the Italian Ministry of University on knowledge and conservation of mixed structure buildings at the beginning of the 20th century, in terms of materials, techniques and technologies. The aim is to define maintenance guidelines and tools for recovering the lost qualities and adapting to new performance requirements [De Tommasi 2007].

2 A "NEW" BUILDING TYPE AT THE BEGINNING OF 20th CENTURY

Buildings in the first decades of the 20th century result from a "transitional" architectural knowledge, where the traditional culture (connected to Best Practice Codes) and the modern one (resulting from the experimental activities during the Industrial Revolution), join together. In that period, great trust is given to innovative materials and techniques, their possible uses and their durability. In fact, there is the progressive introduction of "modern" materials and elements in "traditional" techniques and technologies for buildings [Curioni, 1873]. The result is a new building type, *the mixed structure construction*, that shows the co-presence of materials and elements from pre-modern construction tradition – vertical bearing walls made of stone and/or bricks – and of "new" materials and elements – iron and cement, wooden and iron floors, iron and bricks floors, reinforced concrete floors and vertical elements realised with iron columns, concrete beams and pillars -. At the beginning, floors with I-shape iron beams as bearing element are widely used; they are finished with little vaults in natural or artificial blocks, with "volterrane" and "hollow flat blocks". Technical and technological solutions become more and more complex after the evolution of scientific studies and components [Formenti 1893]. Such innovation, in a construction process which was unchanged for centuries, doesn't change the constructional, technological and functional conception of the building. Progressive introduction of reinforced concrete structures, as a result of experimentations and application of static calculation theory [Morsch 1930], doesn't modify the described situation. By the way, in the reality, structural and constructional conception of building is changing. Some new building features are: increased loads and strengthening of horizontal floors, more efficient connections between horizontal and vertical elements, decreased capacity of masonry to undergo light differential assessments. The evolution of studies and technological solutions, as well as of functional requirements determines the diffusion of frame structures (beams and pillars), first only for substitution of main wall of the buildings. Only after a long time the use of frame structure concerns the building as a whole system with the consequent advantages from the function and distribution point of view.

3 THE CONSERVATION OF MIXED STRUCTURE BUILDINGS

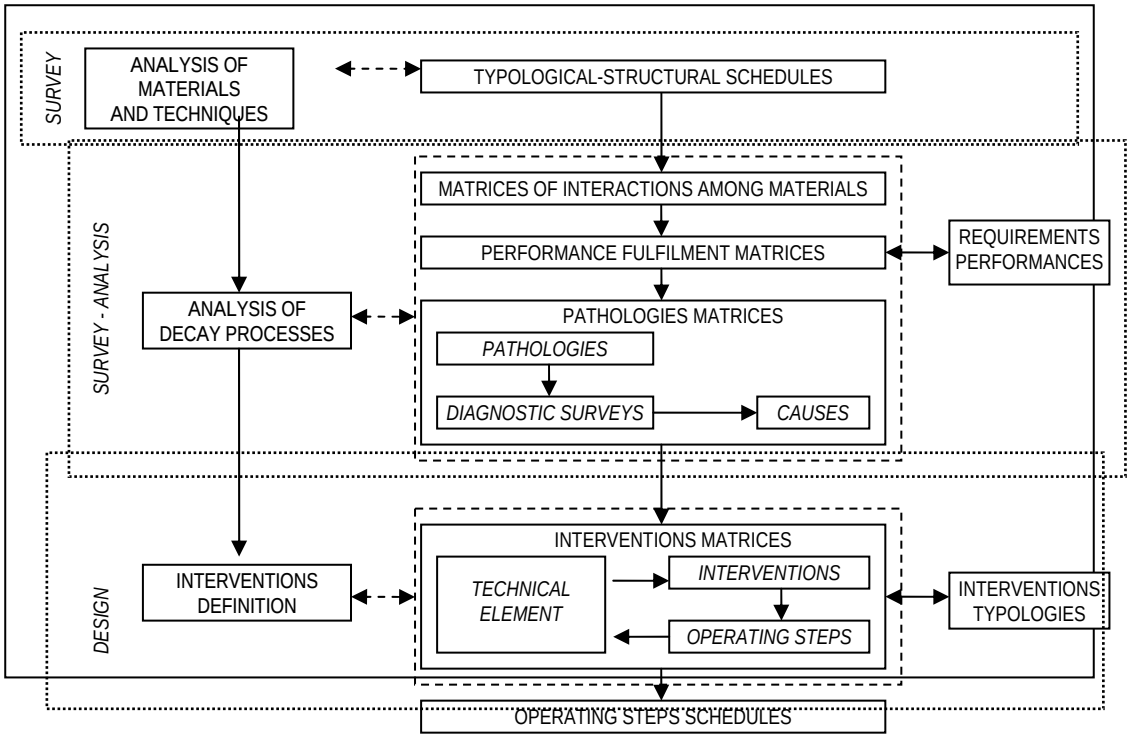
Experience has shown that such buildings – combining very different techniques and materials - were subjected, throughout the years (and they are still subjected), to ageing caused by an increasing and unpredictable material and "technological" decay. The consequent reduction of the service life and the presence of elements with decreased performances are due to the concomitant actions of physiological and pathological factors. This is mostly evident in some specific "critical points", and often determined by the overlap (and supposed integration) between traditional and modern materials and techniques or by the employment of technologies under experimentation that were not jet durable and reliable enough.
During the time the mixed structure heritage has also undergone a constant adaptation to new requirements concerning function and safety issues, as well as compliance to new codes. These adaptations and maintenance interventions were often carried out without supervision and by unskilled

operators. As a consequence, they frequently have caused a further significant decrease of the performance qualities to the technical elements/subsystems and to the whole building. Some maintenance works often underestimated decay processes and causes, so that pathologies appeared again after a short time. Moreover, the short term of transition from the traditional structure to the modern one (30- 40 years) caused a low attention towards the mixed structure building typology, which has been not too much explored. It was just seen as an extension of the masonry building tradition or as an anticipation of the modern constructional techniques and of the reinforced concrete buildings.

4 A METHODOLOGICAL APPROACH TO MAINTENANCE AND REFURBISHMENT

Then, a methodological approach is necessary that considers the specific material, technical and constructional features and the more frequent pathologies of mixed structure buildings. The approach should define appropriate and congruent activities for recovering the lost performances and meeting the actual quality standards. Nevertheless, a mature historical and architectural sensibility has recognized the relevant interest of buildings of the first years of the 20th century as a heritage to preserve through specific interventions. Certainly, it doesn't make sense the obstinate conservation and/or the re-proposition of unrecoverable materials and constructional technologies, because they did not show durability during the time, they are replaced by new and more efficient products and their production is not sustainable anymore. As a consequence, the methodological approach comes from the identification of pathologies and performance losses and from the analysis of well known intervention typologies, related to the single technical elements. This approach refers to a well established procedure of survey, analysis and design. It is specifically developed for mixed structure buildings, by the typology recognition of technical elements. It identifies frequent pathologies and performance losses, relative causes and correlated diagnostic surveys. Finally it defines possible maintenance and refurbishment works.

Table 1. Scheme of approach of analysis and refurbishment process.



The approach, whose scheme is shown in the Tab.1, is structured as an ordered multilevel sequence of schedules and synthesis matrixes, guide and control tools of the whole design path.
The initial procedural step is the typological analysis and the identification of the material, technical and constructional features. It allows, through typological and constructional schedules (par. 4.1), the recognition of the technical elements according to a taxonomic systematization from the technological point of view. The following phase is the analysis of obsolescence and decay processes. Since that, for each technical element, residual performances and pathological alterations are recognized, through the crossed exam of the matrixes, referred to the interaction of materials, the performance behaviour and the pathologies (par. 4.2).
The previous elements define the relations between the performances losses, the verifiable pathologies, the possible causes and the relative diagnostic surveys. As a consequence the diagnosis can be carried out with an acceptable level of reliability. As far as the refurbishment and maintenance works are concerned, an intervention matrix (par. 4.3) correlates the possible intervention solutions to the single technical elements, also by describing the operating phases of each intervention. The planner can choose the interventions among several typologies in the matrix, also correlating to the context specificity. Once defined the intervention and its consequent articulation, the operative phases schedules provide with the specific techniques that are congruent and appropriate.

4.1 Building Technologies

The initial research step is focused on the knowledge systematisation of buildings of first decades of the 20th century, through the analysis of the historical and technical evolution and the definition of the new building type features. Such step results from the comparison between technical information related to constructional elements in handbook literature (1850-1940), as well as from some “case studies” which, for typology, extension, morphological and constructional features, can be considered representative.
These case studies refer to the public residential state built in Apulia and Basilicata Regions between 1900 e 1940. Specifically, the research considered 23 existing building complexes (totally 110 dwellings). For all the buildings, cataloguing, technical and constructional survey and analysis of material-typological-structural features of technological units have been carried out.
The study has allowed a taxonomical systematisation of technological units, sub-systems and technical element classes as well as the definition of their typological construction, technological and structural features. The results are shown in analysis schedules (fig. 1). Analysis schedules point out some example schemes of possible basic typologies (eventually with some variants), geometry and dimensions of single elements, employed materials and techniques, technological solutions, connections with vertical bearing structures.
The research was focused on technical elements of floors, staircases and balconies, for which major variety of types, materials and solutions does exist. For instance, as far as the floors are concerned, they are characterized by different materials and techniques, even if they are in the same building. There should be traditional vaults, as well as more modern floors, realized by several technological solutions. Case studies in Basilicata Region and in Foggia city show some floors with iron beams, connected with typical lateritious elements like “tavelloni”, “pignatte”, volterrane” and “voltine”. In some building complexes in Matera city lateritious elements are replaced by tuff block, certainly less expensive and more available on the territory. Nevertheless, in Bari there are many floors made out of reinforced concrete slabs or reinforced concrete beams and light hollow flat blocks.

4.2 Decay Processes and Pathologies

The research allowed to define, for each technical element within the mixed structure system, as previously scheduled, potential critical points for decay. It also allowed characterize obsolescence processes by verifying performance requirements, coming from the actual dispositions and the survey of alterations and pathologies.

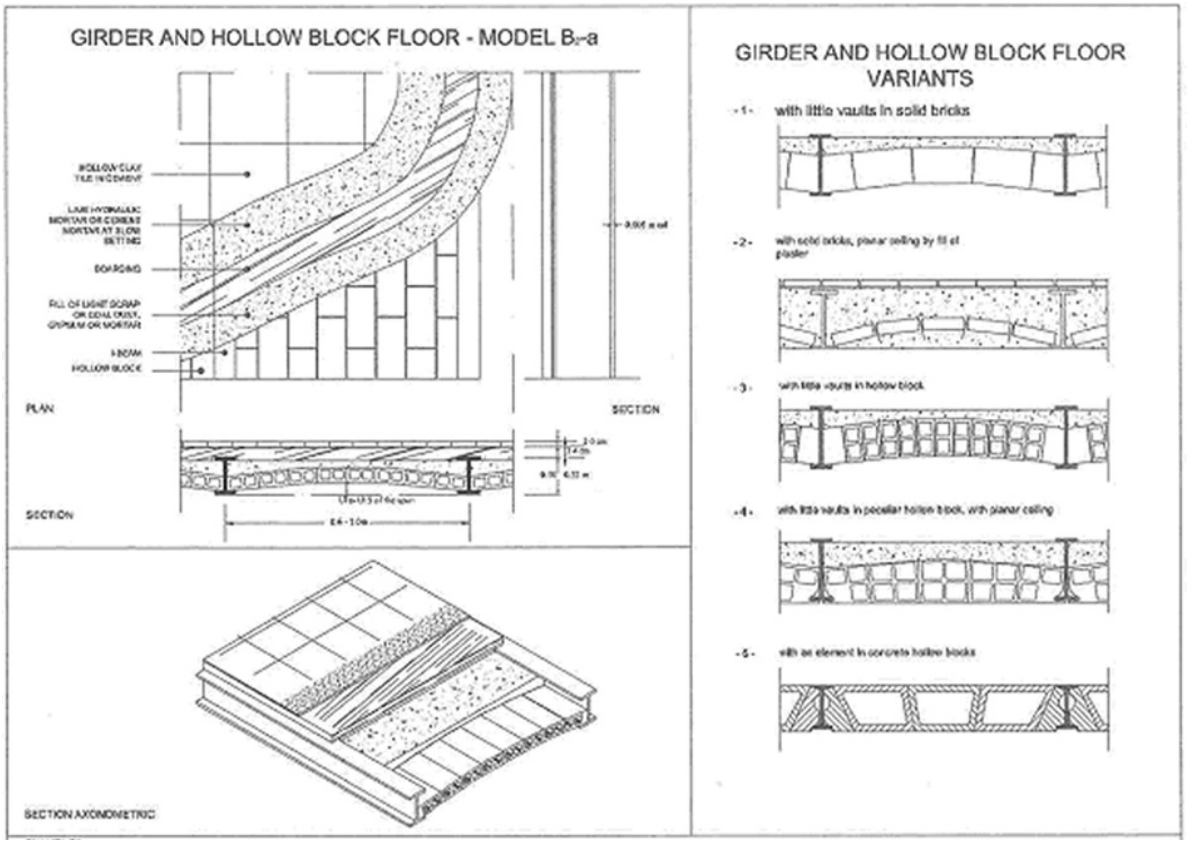


Figure 1. Example of typological-structural Schedule referred to B2b type floor.

Figure 2. B2 type floor: plaster detachment and impost brick breaking; C1 type floor: concrete elements detachment and bricks breaking.

In particular, the study has examined the processes of physical, technological, functional and normative obsolescence. Specifically, physical decay appears like a natural phenomenon in the "contact points" between different techniques and technologies. As a consequence, this decay is due to the juxtaposition of different materials, natural and artificial ones, that are not ever compatible, and it is worsen by the "ignorance", at the their construction, about the performance characteristics of the "new" materials.

Most of the decay phenomena seem to be originated from the concomitant action of physiological and pathological factors, that has reduced the service life of the buildings and/or perturbed the functionality of subsystems and components. Furthermore, natural and pathological obsolescence causes are often overlapped, whose origin is often hard to identify.

The study has assessed the quality levels of the technical elements connected to the general requirement classes from the UNI8289 and to the specific technical requirements (UNI 8290, ISO 6241, Directive 89/106 CEE). For each technical requirement, the performance levels and the minimum performance threshold of the technical element have been individuated.
Moreover, for each constructional element an analysis of the possible alterations and pathological manifestations has been conducted, by the results from the 23 existing building complexes considered as "case studies".

The general picture point out similar pathologies occurring for similar technological elements and solutions. For instance, slabs with iron bearing beams show often plaster detachment, namely surface stains and deteriorations, cracks and detachments between iron beams and filling ("voltine", "tavelloni", "pignatte/volterranee"). Possible causes are high deformability and surface corrosion of iron beams. There are cracks and detachments on the floors, as well, due to the poor mechanical compatibility between the different materials and elements. Breaking of lateritious elements, as well as section reduction and inflection/deformation of iron beams (due to the corrosion) are less frequent. Fig. 2 show some common observed pathologies on the technical element "floor", related to the plaster detachment, the breaking of tiles, the decay of bar cover and the lesions/fractures/separations of concrete elements.
Due to the presence of several anomalies and pathologies, different performance requirements and complex compatibility issues for the used materials, analysis has been summarized in order to define the relations between residual performances, failures, causes and diagnostic surveys. Such relation have been expressed under matrix form.

An example of the matrix is given in Table 2 for the technical element "floor". Such matrix is also a summarizing abacus of performance fulfilment of each element in comparison with the required performances. The matrix highlights three different levels of performance of the technical element types and explains the improvement possibility of performance levels by different intervention methods.

Table 3 shows, still as an example and referred to technical element of floor, an abstract of the matrix that specifies pathologies, failures and losses, possible causes and related diagnostic surveys.

4.3 Maintenance and refurbishment interventions

The proposed approach indicates, in general terms, that mixed structure buildings should require recovery works for the existing damage and degradation. They should require performance improvements, with the revision/rectification/removal of the incongruities determined by the union of traditional and modern constructional techniques.

The analysis of the obsolescence and degradation processes points out that, with reference to the considered technical elements, the maintenance and refurbishment intervention typologies are the superficial protection (of structural elements and not), the improvement/reconstruction of the connections and of the old/new interfaces (between traditional and modern materials), the reconstruction/remaking of decayed parts (of structural elements and not), the structural reinforcement and the compliance to actual dispositions.

The intervention typologies in the intervention matrix come from this general structure that is detailed in the research for every considered technical element. These typologies, even if they are not exhaustive of the possible different technical possibilities, resume the main technological solutions feasible for the performance losses and the existing pathologies. Once defined the intervention typology, within a decision process based on the pathology analysis and diagnosis, the interventions matrix (tab. 4) allows the individuation of the different operating phases in which the intervention is articulated. The interventions matrix synthesizes the structured relations among technical element, congruent solutions and consequent operating phases, in a practical guide tool for the project.

For each operating phase, monographic schedules have been defined, containing technical specifications. The monographic schedules are structured in informative blocks with aims (objectives and efficacy of phase in relation with the general intervention typology), preconditions (preliminary conditions that have to be verified to realize the operating phase and to guarantee the predicted efficacy), specific requirements (characteristics and prerogatives of the phase related to the mixed structure buildings specificity), techniques (detailed execution procedures), tools (instruments, utensils, implements) and materials (raw materials and products).

5 CONCLUSIONS

The research has demonstrated that the mixed structure heritage realized at the beginning of the 20th century is much more common - both in terms of "new" constructions and refurbishment of existing buildings in the historical centres – than what it was supposed to be. It is moreover characterized by "values" - historical, social, architectural, material and technological ones – that were not so much examined till now. This undervaluation was probably due to their presumed "spontaneous" origin. The study has permitted the characterization, in general terms, of the mixed structure buildings, with reference to the material, technical, technological and typological aspects, and the individuation, of the different obsolescence phenomena and consequent conservation issues. The suggested methodological approach allows the conservation, the maintenance and the refurbishment of the performances through congruent and adequate interventions. The procedural model can be considered as an intervention protocol, since it is aimed at the achievement of the expected result without the rigid imposition of a univocal possibility of satisfaction. It can be used as a tool of guide and control of the project qualities, by keeping a predefined framework of compatibilities and congruencies.
Finally, in general terms and even if further research developments are necessary, the application on real cases shows that the method is correct and offers several possibilities: the solutions seem consistent with the effective situations and, as a consequence, adaptable to different necessities. This approach also enhances rediscovery and refurbishment of materials and technologies that were

abandoned too soon, but that today can be partially reused after assessing their residual performances: this does make sense not for a simple and "romantic" re-proposition of materials and past stylistic elements, but for the execution of a "correct" refurbishment in addition to a possible contemporary reinterpretation of technological solutions that are still valid.

Chris Cloete [3]

T 32

ABSTRACT

Evaluation of environmental degradation factors forms an integral part of Service Life Prediction. External climate contribute to degradation of building components through mechanical, electromagnetic, thermal, chemical and biological agents. Although the combined effect of the macro- meso- and micro- climate should be taken into consideration, this paper illustrates how macroclimate zones can be classified, based on work by Weinert [1980] on rainfall, evaporation and the weathering of Karoo dolerite, commonly used throughout South Africa in road construction and as aggregate in concrete. Water only contributes to the degradation process if present on the surface of components or microclimate. Evaporation of surface water is determined by humidity and temperature of the surface and surrounding air. Weinert calculated an N-value based on a factored ratio between evaporation and precipitation, where $N < 5$ represents wet and $N > 5$ dry regions. Although Weinert's N-values can be used to categorise the macroclimate for degradation of building components, other degradation factors such as pollution should also be taken into consideration. Chemical and biological degradation agents are dominant in wet regions, while mechanical, electromagnetic and thermal degradation agents occur mainly in dry regions. The same macroclimate might be aggressive towards one component, but favourable for another. An evaluation of the macroclimate should therefore be based on an impact analysis of the prevailing degradation agents applicable to the climatic region and component under consideration.

1 INTRODUCTION

Exposure of buildings and components to the external, internal and operational environment contributes to degradation and effects durability and service life. [Jernberg et al, 2004]. Evaluation of environmental degradation factors therefore forms an integral part of Service Life Prediction. However, according to Eurin et al [1985] cited by Jernberg et al [2004] "every attempt in practice to measure and describe the degradation environment is an approximation and simplification."

Three of the seven factors considered in the Factor Method for Estimation of Service Life of Components and Assemblies as presented in ISO 15686 Part 1 [ISO 2000] can be classified as environmental degradation factors, namely:

- factor D: indoor environment
- factor E: outdoor environment
- factor F: in-use conditions

This paper illustrates how the outdoor or external environment (factor E) can be evaluated, based on work by Weinert [1980] on rainfall, evaporation and the weathering of Karoo dolerite, commonly used throughout South Africa in road construction and as aggregate in concrete.

2 EXTERNAL ENVIRONMENTAL DEGRADATION FACTORS

The external environment comprises of a macroclimate, mesoclimate and microclimate. The macroclimate describes the gross meteorological conditions "in terms like polar climate, subtropical climate and tropical climate. The descriptions are based on measurement of meteorological agents such as air temperature, precipitation etc." The meso climate takes "the effects of the terrain and of the built environment" into account, while "the climatological description is still based on the standard meteorological measurements." The local scale describes "The local conditions in the building proximity, such as for example in the streets around the building." The meteorological variables in the absolute proximity of a material surface are described by the microclimate, which "is crucial to understanding and estimating material degradation. The most important variables describing microclimate include relative humidity, surface moisture, surface temperature, irradiation and deposition of air pollutants. ... The actual in-use condition relevant to materials degradation is the microclimate, i.e. the prevailing environmental condition in a layer adjacent to a component surface. ... As weather does not repeat itself — i.e. every year is not a standard year — one has to be cautious in drawing conclusions from one exposure period to another." [Jernberg et al, 2004]

2.1 Weinert's Climatic N-values

According to Weinert [1980] the influence of the environment on the life and performance of a road is often greater than realized. Observed variations in the performance of weathered dolerite used in road construction in different parts of the South Africa eventually culminated into the development of Weinert's climatic N-value, which is expressed by the following formula:

$$N = \frac{12E_J}{P_a}$$

where E_J is the computed evaporation from a shallow free water surface during January (warmest month), and P_a is the total annual precipitation

There was a marked difference in the performance of dolerite when used in road pavements to the east and west of an imaginary north-south line running through the middle of South Africa. This line has an N-value of 5 as shown in Figure 1 below. To the east of this line where $N < 5$ and chemical decomposition predominates the performance was unsatisfactory, while to the west where $N > 5$ and mechanical disintegration is the predominant mode of rock weathering the performance was satisfactory.

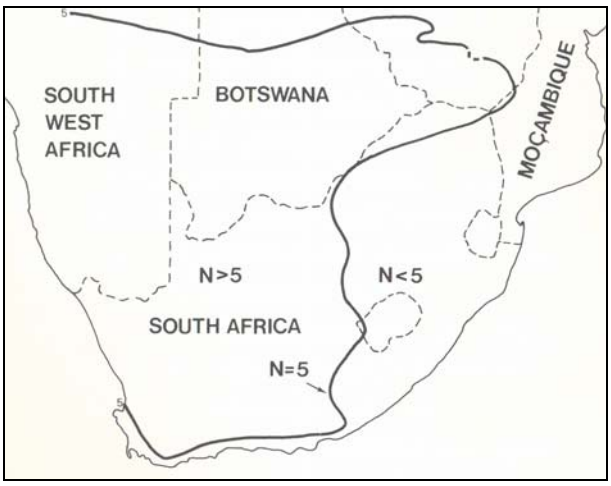

Figure 1: Weinert's Climatic N-values [Source: Brink, 1978]
[* South West Africa = pre-independence name of Namibia]

In Figure 2 below the three macroclimatic regions of Southern Africa is shown. In the western region, which has a dry climate with N > 5, mechanical degradation is dominant. The southern and central region is smaller and a transitional zone with a moderate climate, where both mechanical and chemical degradation take place. The eastern region has a wet climate with an N-value < 5, where chemical degradation is dominant. This demarcation is based on the weathering of natural road materials such as dolerite, which is a natural rock occurring throughout South Africa. Some of the materials used in the built environment are also natural materials and these three macroclimates could therefore also apply to these natural materials.

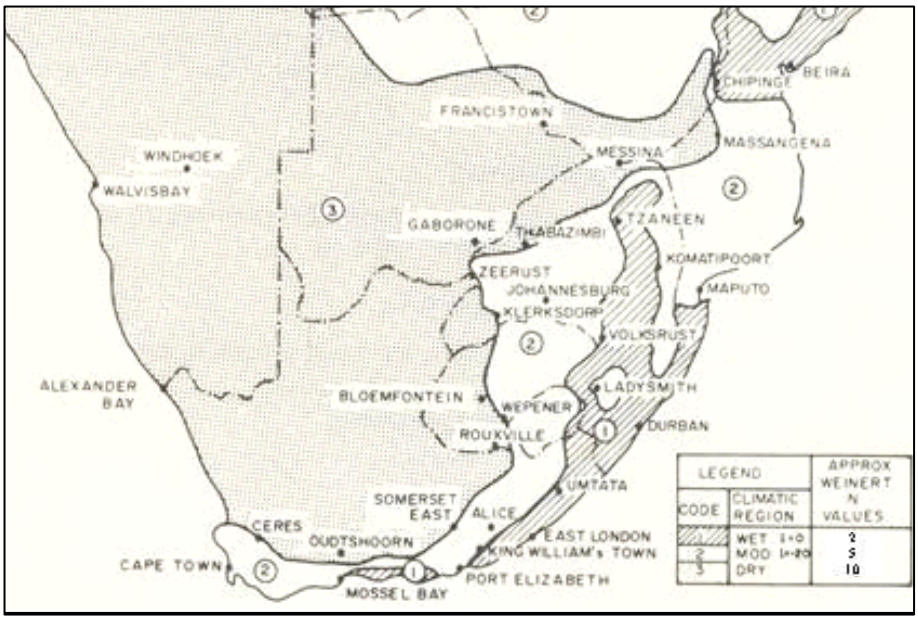

Figure 2: Macroclimatic Regions of Southern Africa [Source: CSIR, 1985]

2.3 Marco Climate Zones

The mean annual rainfall, evaporation and temperatures for South Africa are shown in Figures 3 to 5 below. It is interesting to note the correlation with the three macroclimatic zones shown in Figure 2 above.

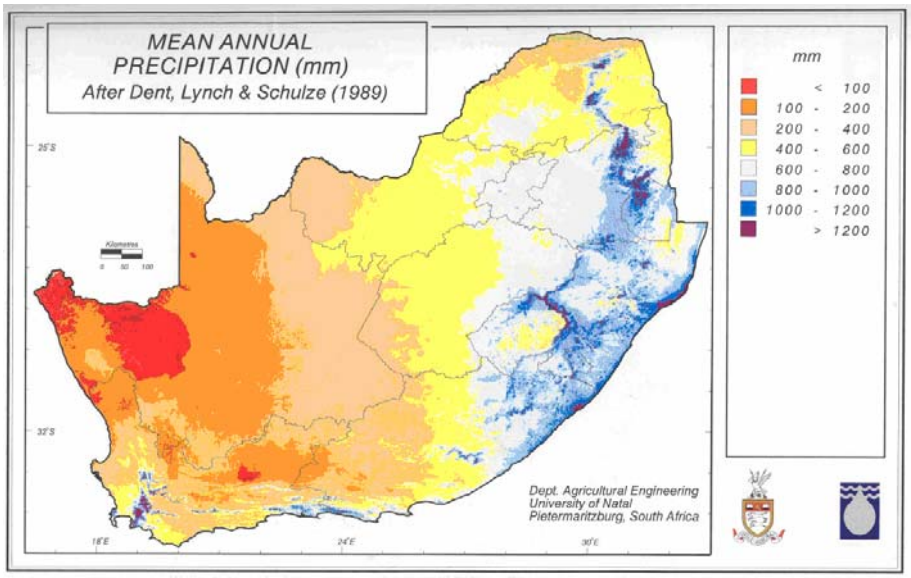

Figure 3: Mean Annual Precipitation for South Africa [source: University of Natal]

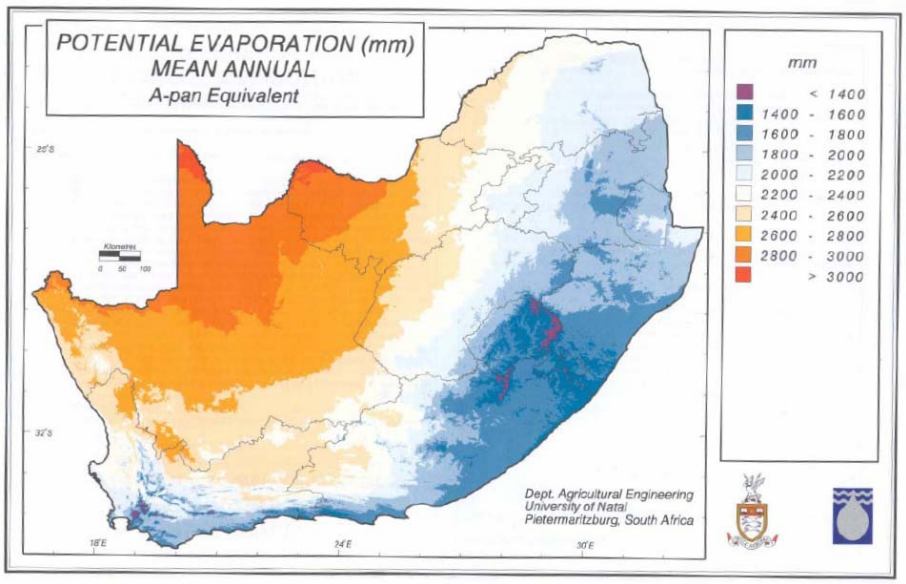

Figure 4: Mean Annual Potential Evaporation for South Africa [source: University of Natal]

The macroclimate in the South African context plays a major role in degradation, as can be seen from Weinert [1980], Brink [1978] and CSIR [1985]. Weinert's work was based on the weathering of Karoo dolerite, commonly found throughout South Africa and besides road construction, also used as aggregate in concrete. Just like dolerite most of the materials used in building construction are natural materials. Some of the materials are used in their natural state while others are processed or combined with other materials. The addition of bonding materials and chemicals during the processing of these materials could change the characteristics of the natural material to some extend (e.g. galvanising of steel, anodising of aluminium), but the base material will remain the same.

Weinert's N-values are based on rainfall and evaporation. Water can only contribute to the degradation process if it is present on the surface of material (the microclimate). The evaporation of surface water is determined by the humidity of the surrounding air and the temperature of the surface and the surrounding air.

On the wetter eastern coastline of South Africa (Weinert's N-value < 2) corrosion of metal is a major problem, while in regions with an N-value > 5, corrosion is less problematic. Mould growth is another scourge of the coastal regions, which is almost unknown in the drier regions. In regions with an N-value < 5 special attention should be given to the impact of water on the degradation process.

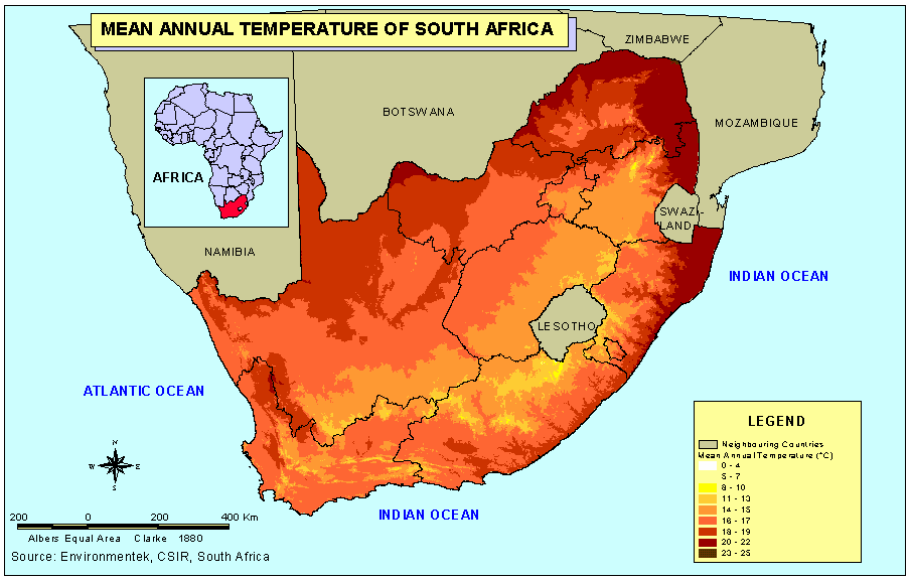

Figure 5: Mean Annual Temperatures [Source: CSIR]

There is an interesting difference between the eastern coastal areas and the Western Cape, both with an N-value < 5. In KwaZulu Natal, a summer rainfall region, there are lots of moisture (rainfall season) and heat (hot summer months), but because of the high humidity of the air, evaporation is low, resulting in an aggressive environment for buildings. In the Western Cape, a winter rainfall region, the temperatures are low during the rainfall season resulting in low evaporation of surface water; again an aggressive environment in terms of degradation processes less dependent on temperature.

Although Weinert's N-values can be used, with circumspection, to categorise the macroclimate for degradation of building components, water is not the only degradation agent found in the external climate and other degradation factors such as pollution should also be taken into consideration. Chemical and biological degradation agents are dominant in wet regions, while mechanical, electromagnetic and thermal degradation agents occur mainly in dry regions.. Electromagnetic processes, especially in the drier and hotter parts of the country (N-value > 5), could in combination with high temperatures have a very negative impact on the degradation patterns of building materials. Ultra-violet radiation is harmful not only to humans, but also to building materials, and its effect should not be underestimated.

The mesoclimate should also be considered, especially in major industrial and surrounding areas, where air and water pollution could be a problem. Acid rain, caused when fossil fuels are burnt (e.g. coal-fired power stations) and sulphur is released into the air, has a major impact on degradation of building materials and should be taken into consideration where applicable.

2.2 Rating of external environment

In general the classification of the CSIR [1985] as shown in Figure 2, could be quite useful, if the applicable degradation processes are taken into consideration. The dry regions (N-value > 5) could in general be classified as 'favourable', the moderate areas (2 < N-value < 5) as 'less favourable', and the wet areas (N-value < 2) as 'slightly aggressive'. Again, this should not be applied blindly as certain materials could be more vulnerable to degradation in dry and hot conditions.

The proposed zones for chemical and biological degradation agents in Figure 6 above correspond with the TRH4 [CSIR, 1985] zones for roads. There are three macroclimate zones (mean annual evaporation > 2600 mm, < 2600 mm and > 2000 mm, and < 2000mm), with a fourth zone along the narrow eastern and southern coastal belt, where corrosion is a problem. The broken line indicates an area where the macroclimate could be classified as 'aggressive' in the case of biological degradation.

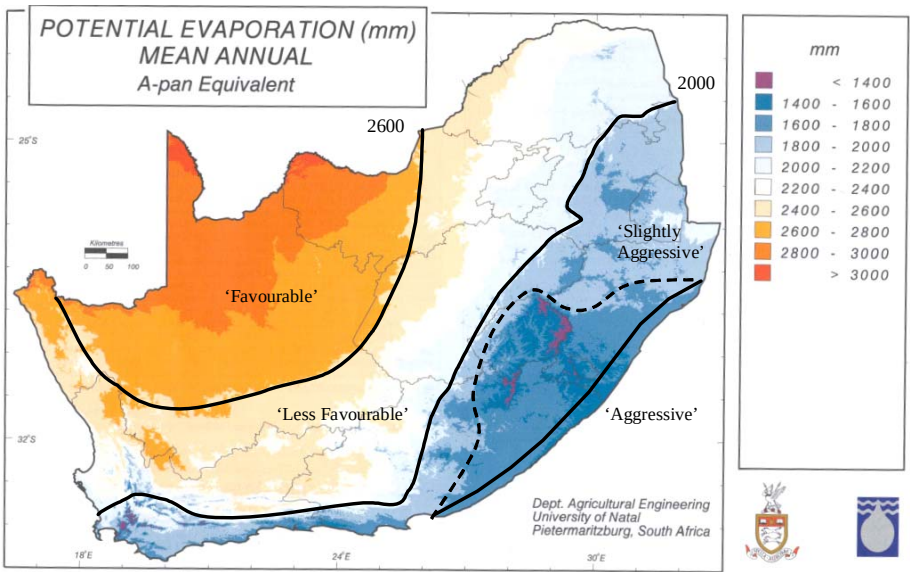

Figure 6: Proposed Macroclimate Zone Classification for Chemical and Biological Degradation Agents [Base map: University of Natal]

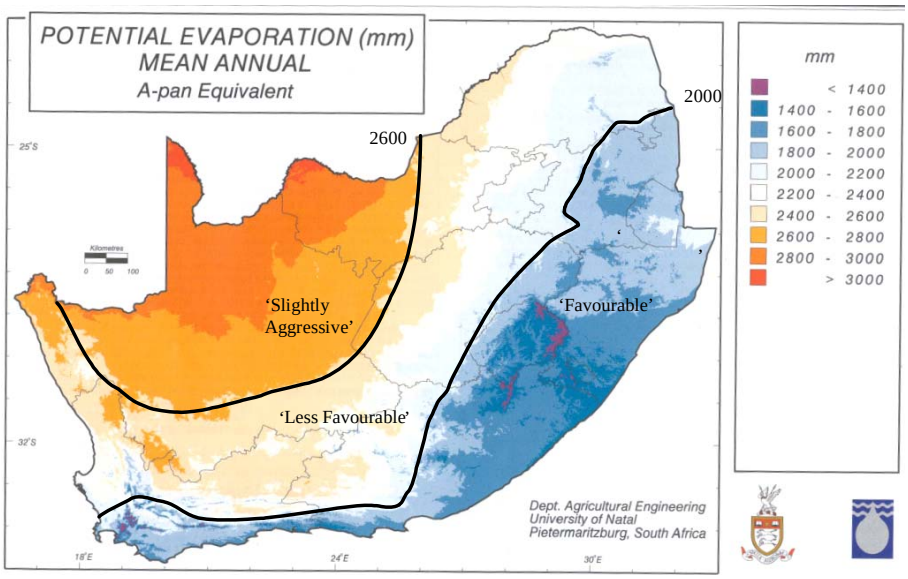

Figure 7: Proposed Macroclimate Zone Classification for Mechanical, Electro-magnetic and Thermal Degradation Agents [Base map: University of Natal]

The same macroclimate might be aggressive towards one component, but favourable for another. An evaluation of the macroclimate should therefore be based on an impact analysis of the prevailing degradation agents applicable to the climatic region and component under consideration. In the western regions mechanical, electromagnetic and thermal degradation agents are more dominant and the classifications are as shown in Figure 7 above should apply.

The external environment can be classified as 'aggressive' to 'slightly aggressive' if buildings are in or down-wind from heavily polluted industrial areas'. Should the macroclimate have a classification of 'slightly aggressive' and the mesoclimate is 'aggressive', the external environment could become 'aggressive' to 'very aggressive' depending on the microclimate or space in the absolute proximity of a material surface. Here the design level should also be considered to determine the level of protection offered by the design and installation of the component. The combined effect of all three external environmental levels (macro, meso and micro) should be taken into consideration, with microclimate being the decisive factor.

In the analysis of building degradation the opinion of domain experts and inconsistent field data are often the only sources of information. Mc Duling [2006] used a five point rating system to evaluate condition and degradation and durability factors, similar to the factors used in the Factor Method, in a Service Life Prediction model based on the Markov Chain and Neuro-Fuzzy Artificial Inteligence to translate "IF-THEN" rules based on domain expert knowledge and reasoning into crisp probability values to populate the Markovian transitional probability matrices. The following ratings are used to evaluate the external environment:

- 5 – 'Favourable': External environment has very little or no effect on the building or component.
- 4 – 'Less Favourable': The building or component is exposed to external environmental degradation agents from time to time. The dosages are relatively low and of short duration.
- 3 – 'Slightly Aggressive': The building or component is exposed to external environmental degradation agents for longer periods. Areas where large temperature variations, strong winds, heavy driving rain, hail and snow, earth tremors (mining areas) occur.
- 2 – 'Aggressive': The building or component is exposed to high doses of external environmental degradation agents (e.g. industrial areas where pollution is problematic), where a combination of degradation agents are present (e.g. moisture and heat) on the surface of the component (microclimate) most of the time.
- 1 – 'Very Aggressive': The building or component is constantly and directly exposed to very aggressive external environmental degradation agents (e.g. unprotected steel exposed to salt-spray or within 50 meters from the high water mark on the east coast)

Although this is different to the factor values between 0.8 and 1.2 proposed in the Factor Method, the above ratings can be used to minimise subjectivity in evaluating the outdoor or external environment (factor E), as shown below:

- 1.2 – 'Favourable'
- 1.1 – 'Less Favourable'.
- 1.0 – 'Slightly Aggressive' ("normal" environment)
- 0.9 – 'Aggressive'
- 0.8 – 'Very Aggressive':

3 CONCLUSION

Although Weinert's N-values can be used to categorise the macroclimate for degradation of building components, other degradation factors such as pollution should also be taken into consideration. Chemical and biological degradation agents are dominant in wet regions, while mechanical, electromagnetic and thermal degradation agents occur mainly in dry regions. The same macroclimate might be aggressive towards one component, but favourable for another. An evaluation of the

macroclimate should therefore be based on an impact analysis of the prevailing degradation agents applicable to the climatic region and component under consideration.

Until such time when a more scientific based method can be developed the proposed process can be used to evaluate the effect of external environmental degradation agents for service life prediction purposes. Figures 6 and 7 are however only indicative of macroclimate zoning and need further investigation, development and refinement.

Climatic Comparison to Analyse Different Degradation Levels in External Walls' Outdoor Exposure

Bruno Daniotti [1]
Sonia Lupica Spagnolo [2]

T 32

ABSTRACT

In the last few years the Durability of Building Components Group is carring out an experimental programme to evaluate Reference Service Life of self supporting external walls made of a double masonry with thermal insulation inside. In parallel with the accelerated ageing tests it was planned an outdoor exposure in order to evaluate the existing time re-scaling factor between the two kind of ageings.
Analysing the different agents' stresses which characterize the specific outdoor environment the importance to compare different degradation and performance levels on different reference outdoor exposure sites brought to realize a coupled outdoor exposure in different climatic contests.
The paper deals in particular with the results obtained in exposing some specimens, analogous to the ones tested under accelerated ageing, in two cities: Milano (Italy) and Lugano (Switzerland). The two weathering conditions lead to different degradation levels.
The analysis of the different climatic loads allows to relate the degradation effects with the actions. This is useful to define different Service Lives related to different outdoor weathering conditions and looking toward a better definition of accelerated ageing cycles, selecting the relevant loads, determining durability differences. To simplify and make the comparison more immediate, degradation levels have been classified using an evaluating dimensional scale from 0 (no visible damages) to 3 (presence of relevant damages such as detaches).

1 INTRODUCTION

The chief objective of the experimental programme on self supporting external walls, undertaken since 1999, has been to define the Reference Service Life of some double masonries with thermal insulation inside protected by different kind of paints (acrylic and vinylversatic) prepared with different concentration of resin (PVC40 and PVC60), following the methodology proposed in ISO 15686-2:2001 "Building and constructed assets – Service life planning: Service life prediction procedures". According to the ISO standard the comparison between long – term and short – term exposure results should be used in the assessment of building components' service life, once it has been verified that there is the same degradation level in each one of the samples: the experimental programme needed on one side laboratory accelerated tests and on the other side natural outdoor exposure because it was then necessary to understand the existing correspondence between the two studied ageing conditions [Daniotti *et al.* 1999]. It was, therefore, necessary to realize some specimens, analogous to the ones tested under accelerated ageing, to expose to natural environment. Starting from the monitoring results related to outdoor samples this paper reports about the climatic comparison between the two exposure contexts: Milano (Italy) and Lugano (Switzerland).

2 THE OUTDOOR EXPOSURE FOR NATURAL AGEING

In the experimental phase of natural ageing, 8 partial samples for each site (Milano and Lugano) have been tested; they are composed of, perforated brickwork coated by a layer of plaster and then a protective film of paint. These specimens are totally analogous to the one used in accelerated proofs, in order to permit the comparison between the two ageing conditions, obtaining the so-called time-rescaling factor.

The following variables have been adopted, in order to gain as more information as possible:

- *Different kind of painting protection (Acrylic paints, Vinylversatic paints)*: in order to study both the degree of waterproofing and the degradation's mechanisms;
- *Different resin ratio (PVC 40, PVC 60)*: Powder Volume Concentration (PVC), which measures the powders' percentage inside the paint, so that the resin ratio in the paint is given by the complement to 100 of the PVC-value;
- *Double exposure (Milano – I, Lugano – CH)*, to evaluate the effects due to different weathering and pollution conditions (in both sites they were exposed toward South);
- *Different slope (90°, 45°)*: the 45° configuration should accelerate the degradation and make the effects on the masonry more evident.

Figure 1. Natural ageing asset in Lugano (picture on the left) and Milano (picture on the right).

The comparative analysis between the two contexts is related most of all to the pollution level, and to temperatures and radiation levels.

2.1 Pollution Comparison Between Exposure Sites

An important information to take into consideration for a durability prevision is the pollution level of the site with particular attention to the concentration of pollutants such as SO_2, PM10 and NO_2 which are considered the most damaging agents for external walls. A time course of 6 years (from 1999 to 2005) has been studied. Three graphics underlining the course of concentration of polluting agents in Milan, where the pollution is higher, are here reported.

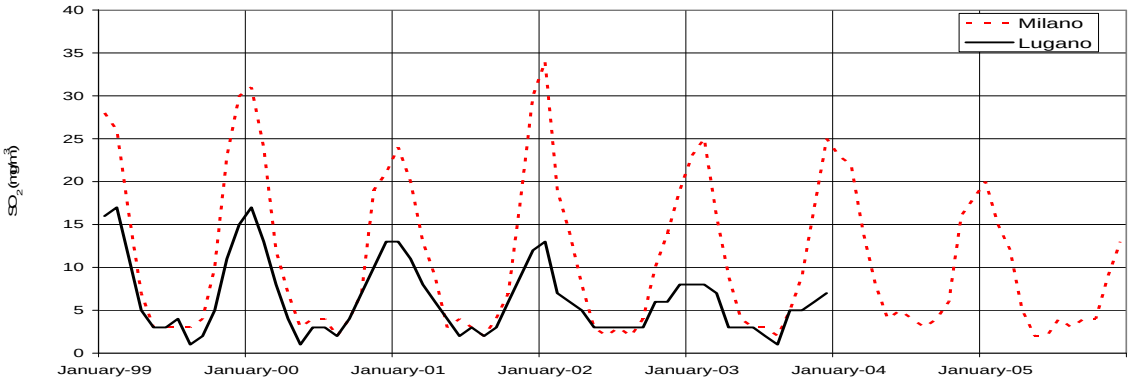

Figure 2. SO_2 concentration course in Milano (Italy).

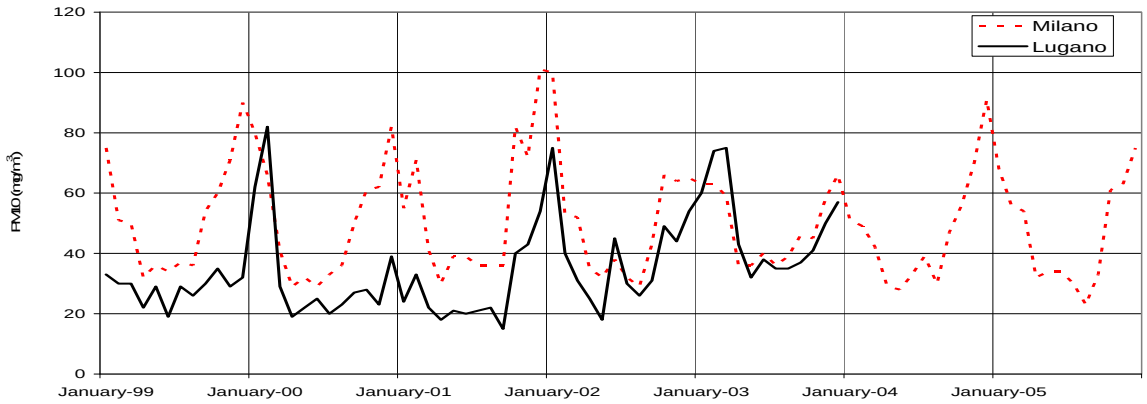

Figure 3. PM10 concentration course in Milano (Italy)

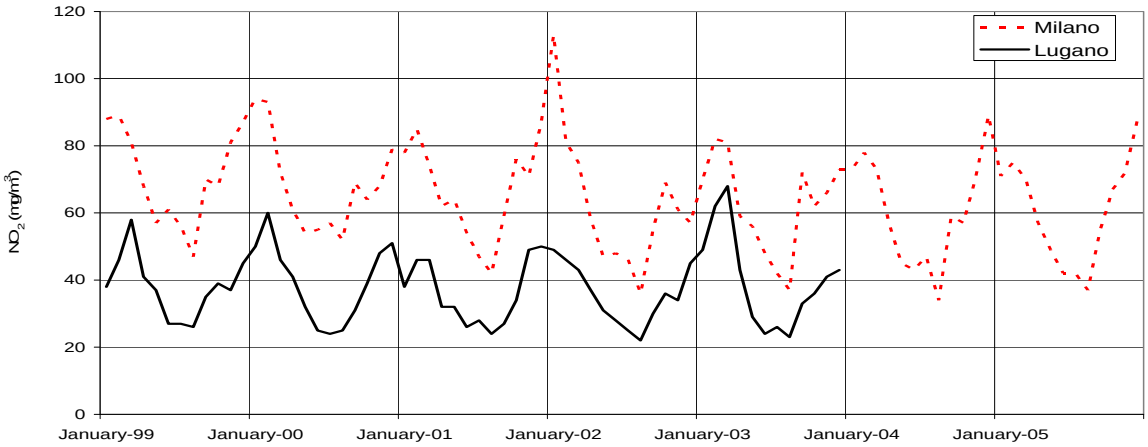

Figure 4. NO_2 concentration course in Milano (Italy)

In particular, the graphic about SO_2 concentration shows a swinging course with an important increase in winter and an evident decrease in the summertime. An Italian standard imposes that the concentration of SO_2 cannot exceed the value 125 µg/m³ for more than three times in the year. In Milan it is possible to notice that the highest registered values never exceed 34 µg/m³, widely below

the limit. In Lugano SO_2 concentration remains below the admissible thresholds too. Moreover, the concentration of SO_2 in the considered period has notably decreased in Lugano and it shows a swinging course in Milan with a light decreasing in the last two years (2004 and 2005).

Considering PM10 it is possible to notice the same swinging course found out with SO_2 concentrations, but in this case PM10 concentration is often near the admitted level, overcoming it most of the times, especially in winter. The admissible thresholds for PM10's concentration are, in fact, overcome in both the climate contexts: in Lugano there is an increase in the considered last year, while in Milan there is a light diminution.

An identical behavior is showed by NO_2 concentration course during the year, with an overcoming of the admitted levels in both the climates: in particular in Milan a light decrease can be noticed while in Lugano there was a progressive increasing of their concentration.
The annual mean values for the considered range of time and for the three polluting agents can be eventually compared with the admitted thresholds: the synthesis of such comparison is shown in the table below.

Table 1. Syntesis of the annual mean values for the considered polluting agents compared with the legal maximum values for both the climatic contexts

	SO_2		**PM10**		**NO_2**	
	Annual mean value [μg/m^3]		**Annual mean value [μg/m^3]**		**Annual mean value [μg/m^3]**	
	Measured	**Legal Maximum**	**Measured**	**Legal Maximum**	**Measured**	**Legal Maximum**
Milan	11,72	80	51,03	40+1,6	65,32	40+12
Lugano	6,23	30	35,35	20	37,71	30

2.2 Temperatures Comparison

Therefore, to better define the climatic differences between the two context it is necessary to analyze daily values of temperatures (maximum, minimum and mean ones) and of solar radiation.

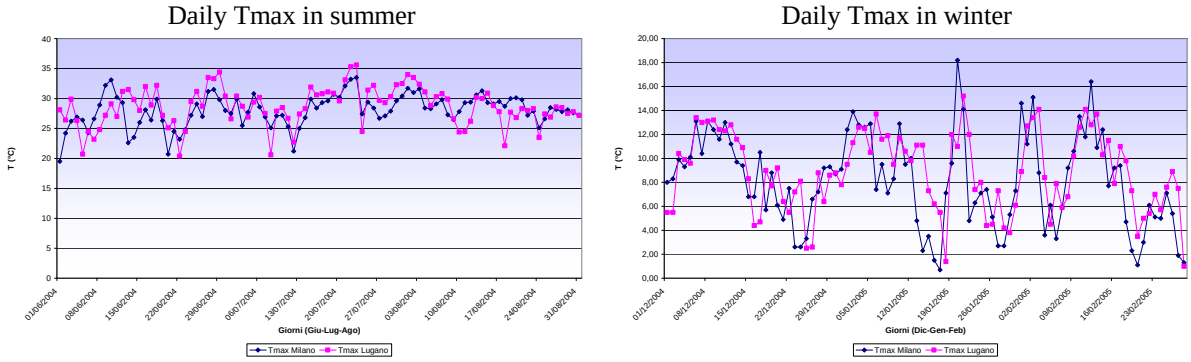

Figure 5. Comparison between daily maximum temperatures in summer and in winter.

Maximum temperatures are reached more frequently and with higher values in Lugano. In particular, the difference between the two localities is more evident in June and in July. Looking at the hourly course for the most significant days in summer it is possible to notice this difference.

Figure 6 shows in particular that daily maximum temperatures are nearly always reached in Lugano and not in Milan.

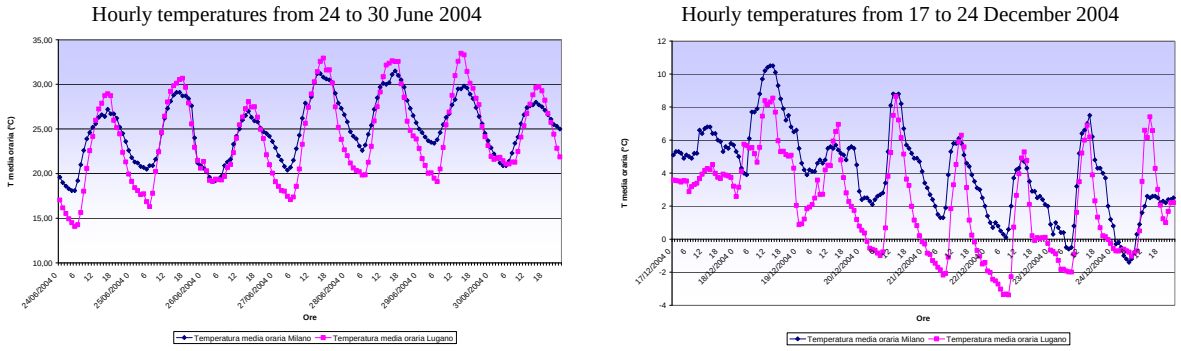

Figure 6. Comparison between hourly temperatures in relevant days in summer and in winter.

Taking into consideration the course of minimum temperatures, it is possible to notice that they are higher in Milan than in Lugano: in the Swiss city there are frequently temperatures under zero, while in Milan it seldom happens.

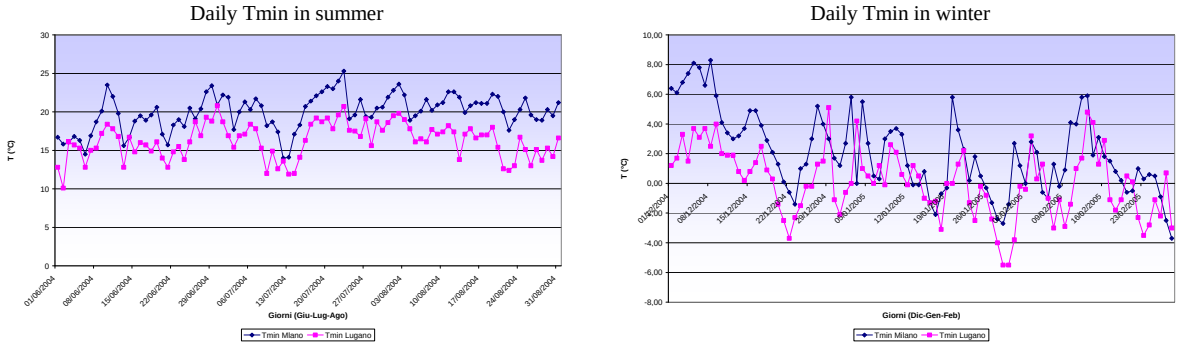

Figure 7. Comparison between daily minimum temperatures in summer and in winter.

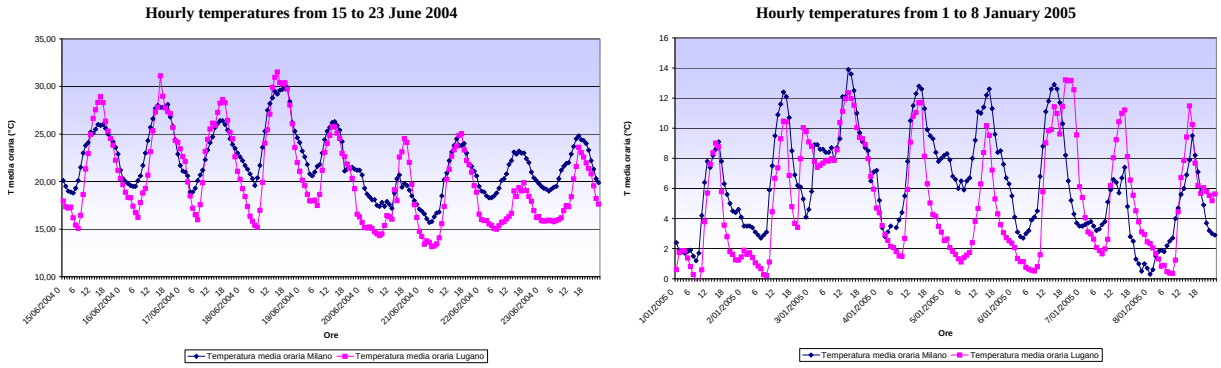

Figure 8. Comparison between hourly temperatures in significant days in summer and in winter.

Climatic conditions in Lugano are characterized by high daily ΔT values: in fact in Milan maximum temperatures are lower while mean ones are higher than in Lugano.

2.3 Solar Radiation Comparison

In Milan the daily course of solar radiation is characterized by a higher number of hours of exposure and a higher intensity of these values. The maximum value registered in Milan is 1000 W/m^2, while in Lugano it is 894,2 W/m^2, with a maximum daily solar energy received equal to 8223 Wh/m^2 in the Italian city and 7442 Wh/m^2 in the Swiss one.

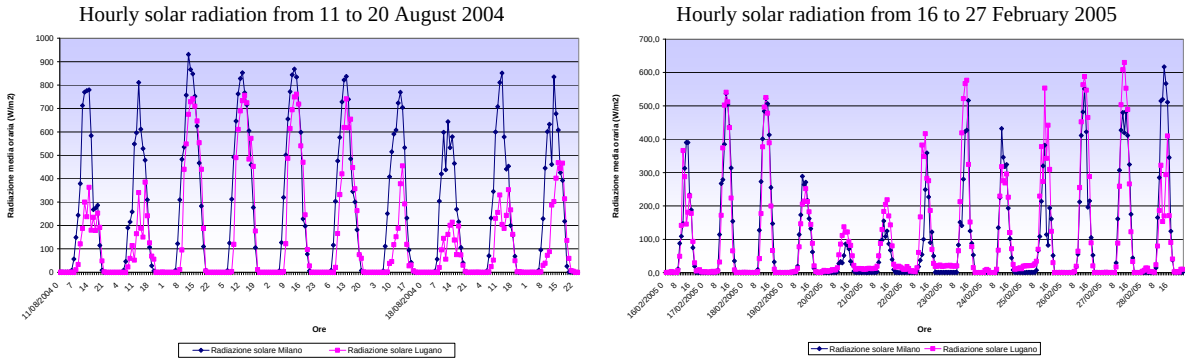

Figure 9. Comparison between hourly solar radiations in significant days in summer and in winter.

2.4 Degradation Comparison

To evaluate the decay during time for the different specimens, a classification of degradation levels through a dimensional scale (from 0 to 3), based on a photographical analysis, has been defined:

- **DL0**: undamaged protecting layer, there can be microcracks due to the presence of air during the applying step and following drying of the paint, but there are not cracks or swellings;

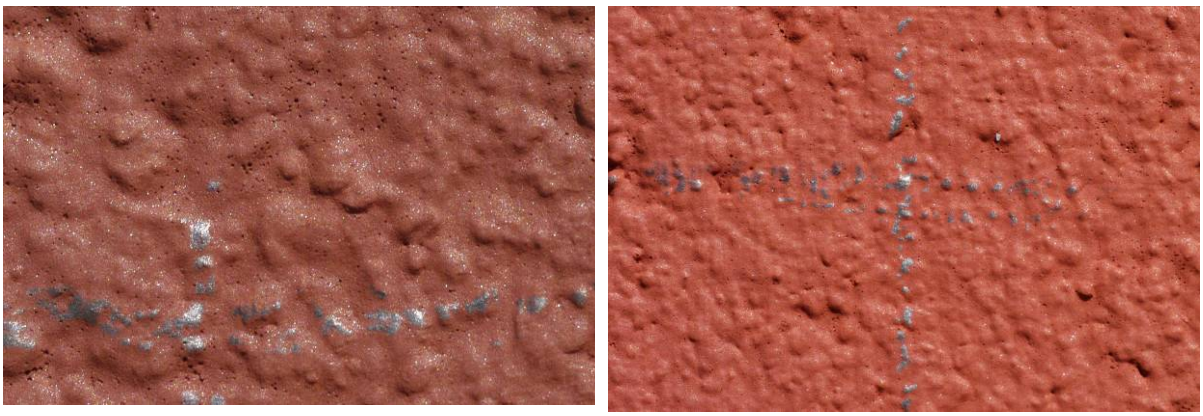

Figure 10. Photographs which show two examples of degradation level 0.

- **DL1**: broken swellings or local cracks;

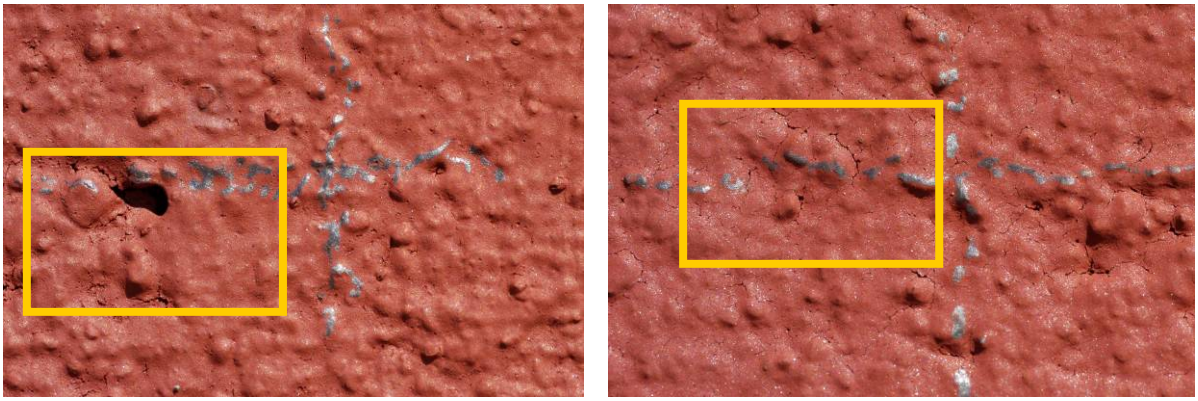

Figure 11. Photographs which show two examples of degradation level 1 (broken swelling on the left, local cracks on the right one).

- **DL2**: many microcrackles and cracks;

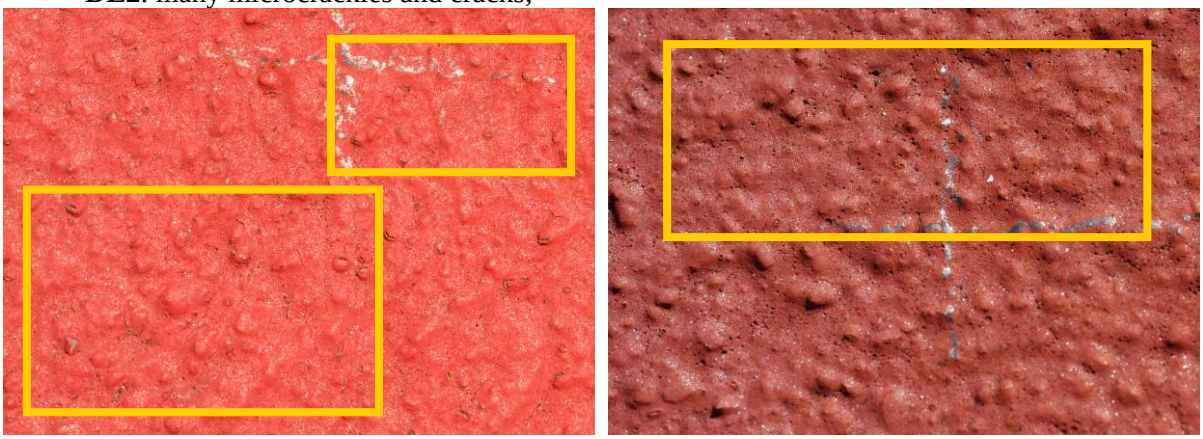

Figure 12. Photographs which show two examples of degradation level 2 (broken swelling on the left, local cracks on the right one).

- **DL3**: torn bubbles, detaching and saline crystallisation of surface.

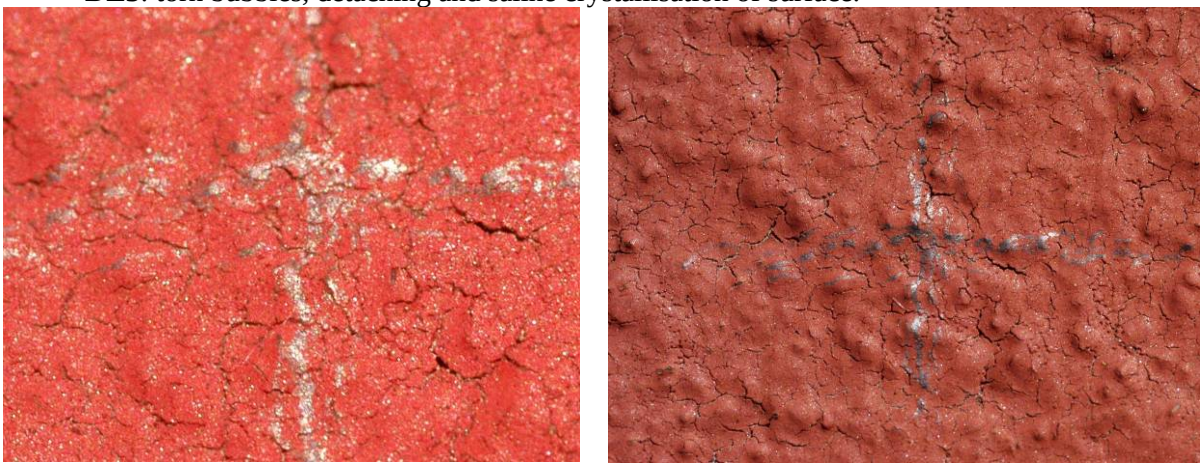

Figure 13. Photographs which show two examples of degradation level 3.

This kind of classification allowed the behaviour comparisons during time and will be used in developpng diagnostic cards in order to define inspection procedures; thanks to the comparison among degradation levels found in Milano and in Lugano for the two slopes it is possible to sum up the following considerations:

- ageing of 90° sloped specimens is quite similar for the two exposure sites; the only important difference is for VL90 specimens (V= vinylversatic resin, L=low concentration of resin) because they are more damaged in Milan than in Lugano;
- ageing of 45° sloped specimens is faster than for 90° sloped ones.

Table 2. Synthesis of Degradation Levels for 90° sloped specimens in Milano

2006	DL 2	DL 3	DL 1	DL 2
2007	DL 3	DL 3	DL 1	DL 2

3 CONCLUSIONS

Comparison between accelerated ageing results and outdoor ageing ones (analysed on the surface through optical microscope) has given the possibility to define Reference Service Life for considered paints: after 4 years of outdoor exposure and 150 cycle of artificial one; specimens covered by acrylic paint show a relevant level of water protection, while specimens covered by vinylversatic paints have lost their performance levels , then reaching the end of their service life.
In particular, acrylic paints show a better protection than vinylversatic ones, high concentration of resin increases the protection and vinylversatic paints with low concentration of resin end their service life after 4 years of outdoor exposure. In order to correctly interpret the results obtained, an analysis of the climatic conditions and pollution concentrations in the two cities (Milano and Lugano) was carried out during the exposure period, with such results:

- In Lugano the quantity of rain and daily thermal difference are higher;
- In Milano values of pollution (PM10, SO_2 and NO_2), solar radiation and medium temperature are higher than in Lugano.

As a first hypothesis based on materials' information, vinylversatic paints degrade themselves more quickly in Milano than in Lugano due to solar radiation stresses: this hypothesis will be verified with specific tests. The paper underlines the importance to study climatic data, and pollution levels focusing on agents which can provoke degradations on the studied building component, while analysing the results from outdoor exposure experimental programmes.

Climatic Data Analysis to Define Accelerated Ageing for Reference Service Life Evaluation

Bruno Daniotti [1]
Sonia Lupica Spagnolo [2]
Riccardo Paolini [3]

T 32

ABSTRACT

In order to define accelerated ageing cycles useful to evaluate reference service life is very important to analyse the "reference" climatic conditions to be simulated. In this paper we will report the activities developed by Durability of Building Components Group of Politecnico di Milano to set up the accelerated ageing cycle for ETICS, based on a national agreement within the Italian Network of Durability Evaluation laboratories. Statistical climatic data as Test Reference Year and standardized data have been considered to determine the most severe climatic conditions relevant for ETICS durability aspects. The considered agents have been selected taking into account the degradation and failure modes for the specific ETICS component. The most severe thermal shock events in summer and winter conditions have been analysed to define the temperatures during sub-cycles. Rain ,freeze and UV conditions have been defined taking into account their statistical occurrence and the ratio between summer and winter cycling have been defined on the base of statistical probability of such events. This analysis allowed to obtain lab ageing cycles calculated on the base of statistical data for the considered Reference climatic and geographical conditions. This will be useful to compare results based on lab accelerated ageing and outdoor exposure results.

1 INTRODUCTION

One of the most important issues concerning laboratory durability evaluation is the choice of ageing cycles and so the main goal of this study is to set a procedure appropriate for pre-design accelerated ageing. First of all it's important to remember that different kinds of accelerated cycles exist, which have different aims:

- torture cycles – their purpose is to get a first evaluation of durability of the component in extreme conditions, much harsher than those ever encountered in use. These kind of tests couldn't be considered as proper durability tests;
- "standard" cycles – their aim is to test a building component and release an approval (such as in case of cycles of ETAGs) or a certificate (such as in case of cycles in specific standards). In both cases the result of the test should be valid over all the territory where the standard or the technical guide is applied. For this reason only one cycle is designed to reproduce ageing conditions in a very wide area: it's an envelop cycle of the extreme durability conditions all over Europe. That's why they cannot be considered service life prediction tests;
- real ageing accelerated cycles – their aim is to assess the durability of a building component in order to get a value of Reference Service Life and assess the overall performance decay and degradation evolution.

The aim of pre-designing ageing cycles is to avoid a large number of trials (up to convergence of degradation got with long-term and with short-term exposure) and to get an ageing cycle suited for the climatic context.

1.1 Avoiding a Large Number of Trial Tests

ISO 15686-2 sets a procedure for service life prediction of building components where a milestone is the comparison between degradation got with artificial accelerated ageing (i.e. laboratory tests and, only for walls, natural exposure with inclined surface) and degradation got with long-term exposure. If there is a great difference in degradation levels, pre-testing cycles must be re-designed and the procedure repeated. That means that a bad pre-design could cost a large number of trials. On the other hand, in the experimental programme about accelerated ageing tests on paintings carried on by Politecnico di Milano in collaboration with SUPSI, the methodology of time re-scaling has been proposed. This means that when the same degradation level is got, a comparison is set between long-term ageing time (field exposure with specimens of the same size of the ones used in short-term ageing) and the ageing cycles reproduced in laboratory tests, in order to gain the rate of ageing cycles per year. This kind of comparison could be implemented only if there is not a big initial error in pre-designing the cycle (the ageing cycle reproduces the climatic ageing phases in a similar proportion and, by means of time re-scaling, the correct proportion will be achieved) or the transport error will produce misleading results.

1.2 Ageing Cycle Suited for The Climatic Context

Ageing in different contexts cannot be assessed with the same ageing cycle. EOTA Guidance Document 3, in Annex A, individualizes four climatic conditions for Europe, different meso-climatic conditions (orientation and position of the building) and several internal environment conditions. This means that only one ageing cycle is not obviously sufficient in order to assess the behaviour in all Europe, but a large number of agents combinations should be taken into account. All combinations couldn't be reproduced and so the most representative and diffuse conditions may be chosen.

The need for more ageing cycles for the same building component is highlighted by the need for evaluating the Estimated Service Life. In ISO 15686-8 is suggested that data concerning RSL should be rejected "when the degradation agents deemed to be significant for the expected degradation process(es) are not all encompassed" and it is also recommended that "data based on reference in-use

conditions similar to the object-specific in-use conditions should always be sought", in order to "keep the modifying factors as unified as possible, thus minimizing the probability of error in the ESL due to uncertainty in the way mechanisms of degradation are affected by the modifications; and minimize the probability that a critical property not encompassed by data becomes the terminal critical property".

This involves that not only one value of RSL for a building component should be sought, but a set of Reference Service Lives may be taken into account and the nearest RSL to in-use conditions should be chosen as starting value for calculating ESL. In particular, in order to get different RSL values, different ageing cycles should be designed and so reduce the transport error from RSL to ESL.

2 AGEING CYCLE PRE-DESIGN

In this paragraph a first overview of different possibilities in ageing cycles pre-design is portrayed, while in the third paragraph examples cases are given.

2.1 Ageing Cycle Pre-designing Tools

Both determining the intensity of agents and determining the rate between ageing phases is fundamental in planning accelerated ageing tests and, in order to do this, three main different ways (at different analysis level) of pre-designing ageing cycles could be set:

- standard reference - if a standard for hygrothermal tests exists (even if not suited for durability assessment) it could be assumed as first hypothesis (e.g. see point 3.1);
- environmental data analysis - pure statistic analysis or analysis of environmental data beyond a critical threshold, got with the degradation factors and failure mechanisms analysis;
- preliminary degradation model - the weight of every ageing event (every event over the critical threshold) is determined thanks to a preliminary degradation simulation model (it doesn't simulate the whole ageing cycle, but only the first cycle).

2.2 Environmental Data Analysis

The aim of an environmental analysis is both to set the intensity of agents to be reproduced and their frequency in one year, in order to get a basic cycle corresponding just to one year. In case of several ageing phases (or sub-cycles) included in the ageing cycle, the aim of this analysis is to get their rate too, in order to design the cycle as close as possible to the environmental and stress context that has to be reproduced (e.g. the rate of UV phase on freeze – thaw phase will be different in assessing the service life of the same component in Norway or in Greece).

2.2.1 Basic climatic data analysis

No information is available concerning neither critical thresholds values nor frequency of critical events. In this case studying the environmental conditions in order to reproduce a "typical" ageing condition could be a first analysis tool.

2.2.2 Analysis of conditions of probability for critical events happening

No complete data are available that could allow to assess the real happening of critical events. In this case it's possible to assess when there is the probability (i.e. suitable conditions for happening) of a critical event. In order to operate this analysis preliminary data concerning critical values are needed. Critical thresholds could be defined by means of two different methods:

- standard reference for that specific degradation mechanism;
- preliminary tests suited for determining the critical value (e.g. trough the repetition of only one phase of whole ageing cycle).

2.2.3 Critical events counting

The aim of an accelerated ageing cycle is to "compress" ageing time and so reproduce only critical events. This criterion consists in searching for critical intensities of ageing factors, beyond which the studied material or building component is subject to fatigue or ageing. This method needs suited data. For instance, in case of assessing ageing due to summer thermal shock the occurrence of high external surface temperatures values and followed by a storm should be recorded. On the other hand in case of winter thermal shock the cloud index value should be measured in order to take into account different conditions that can cause low surface temperatures.

Different methods of collecting environmental data suited for durability analysis – and their importance – are discussed in Haagenrud *et al.* [2005]. The most important part of available data on demand for durability concerns agents relevant in corrosion process (both for steel and reinforced concrete structures), for wood and for paintings, while for several other building components, among those ETICS, there is a lack of information.

Another point is that even the statistic analysis method of climatic data in terms of energy approach and in terms of durability is different: mean data in the first case, while the complex of data (over a period of time corresponding to the foreseen RSL of that class of building component) in the second case. This means that in counting the number of critical events a mean year (as TRY) is an approximation that excludes peak values.

2.3 Degradation Model

Thanks to an environmental data analysis only the frequency of events over the critical threshold can be taken into account. In fact critical events (i.e. events beyond the critical threshold) have not the same intensity (see Fig. 1) and so produce not the same effect. Due to this fact their influence in ageing the material should be weighed by use of a model which simulates the real behaviour of the material under defined conditions (e.g. real stress - strain curve). In case of materials or building components with a low critical threshold (in comparison with average environmental conditions), this kind of study is relevant. In order to use this analysis tool a large amount of data is required.

2.3.1 Preliminary degradation model

A preliminary degradation model could assess only the first event of the degradation chain and only the mutual weight of critical events (it could be a basic dose-response function).

2.3.2 Complete degradation model

A complete degradation model is able to build up a degradation hypothesis by cycling the phenomenon and up-dating the material properties after each degradation events. This kind of complex analysis is very useful in case of non stochastic distribution of critical events, in order to assess the influence of different distributions of ageing events.

In case of ETICS, for instance, a degradation analysis tool could be a time-variant nonlinear stress – strain model of base coat (the thin exterior plaster applied on insulator) and its failure process (considering the degradation of the whole system linked to the failure of base coat). A complete degradation model would need both a proper description of the element and proper input data concerning material properties and actions applied.

A description of the geometry of the problem could be a finite element discretization of a plate of indefinite width with in of plane loading due both to temperature and moisture change and to the contribute to prevented deformation, even if small, given the insulator material (that could be reproduced considering a continuous elastic constraint parallel to the plate). On the other hand, several properties of the mortar should be obtained by preliminary tests: the real stress – strain curve both in dry and in wet conditions, the Poisson's coefficient, thermal and moisture expansion coefficients, the rigidity of the constraint given by the insulator, etc.

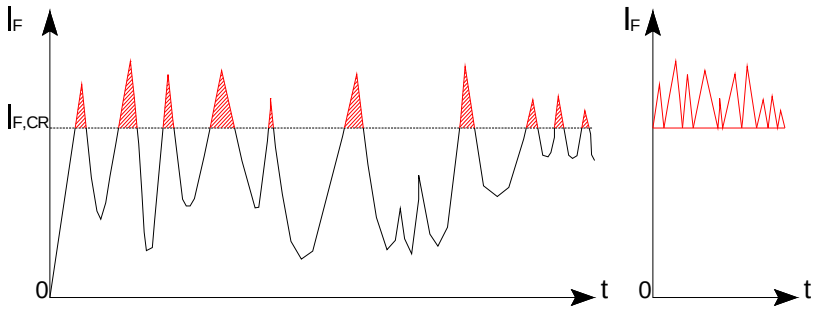

Figure 1. Acceleration of ageing time is based on the idea of excluding not ageing parts of one year.

3 A CASE OF AGEING CYCLE PRE-DESIGN: ETICS EXPERIMENTAL PROGRAMME

Since 2004, a research activity concerning durability of ETICS has been carried on by Durability of Building Components Group (DBCG) at Politecnico di Milano. This research programme involves accelerated ageing of specimens in order to survey the behaviour over time of the most external layer: base coat (a cement mortar with acrylic or vynilic resin as additive) and finishing layer (1.5 mm finishing coat with sand and acrylic resin as binder or acrylic painting).

In defining the cycle to submit the specimens to, both information from standard reference and statistic elaborations based on Milan's TRY (Test Reference Year) input data have been carried out.

3.1 Standard Reference: ETAG 004

As first reference value, the rate between the number of summer cycles and the number of winter ones designed in ETAG 004 (see Tab. 1) has been studied. This proportion corresponds to 2,29.

3.2 TRY Input Data Elaboration

3.2.1 About TRY

Efficient heating and cooling is largely dependent on building design and on the design of the heating and cooling system. Comparison of heating and air-conditioning systems in a locale needs a consideration of the effects of the weather. This weather information must be in great detail. With this aim, American Society of Heating, Refrigeration and Air-conditioning Engineers, (ASHRAE) established a task group on energy requirements for heating and cooling large structures.

Simultaneously, in the interest of energy conservation, the National Bureau of Standards (NBS) and the National Oceanic and Atmospheric (NOAA) were attempting to develop climatic data packaging most useful for building design applications. Joining forces, the three groups established a working group to develop the concept of a TRY. TRY consists of hourly weather data values (dry temperature, for global, diffuse and direct normal solar radiation, and for wind velocity) typical for the location for a selected reference year to be used by engineers in a given area to compare different heating and air-conditioning systems in the same building or in different buildings and, in general, to study thermal behaviour of technological and technical building's components. At the same time, the Federal Energy Administration (FEA) - as a member of the Steering Group on Climatic Conditions and Reference Year of the NATO Committee on Challenges of Modern Society - was also working on the problem. A consolidation of both efforts resulted in the development of a selection process for the Test Reference Year, an international format for presentation of the TRY data, and TRY calculations for 60 cities within the U.S. The ASHRAE approved procedure was chosen for selecting a TRY. The principle of selection is to eliminate years in the period of record containing months with extremely high or low mean temperature until only one year remains.

Table 1. ETAG 004 – Hygrothermal behaviour and freeze – thaw tests

Heat - rain cycles [80 cycles]
1. heating to 70°C (rise for 1 hour) and maintaining at (70 ± 5)°C and 10 to 15 % RH for 2 hours (total of 3 hours);
2. spraying for 1 hour (water temperature (+ 15 ± 5)°C, amount of water 1 l/m^2 min);
3. leave for 2 hours (drainage).
After at least 48 hours of subsequent conditioning at temperatures between 10 and 25°C and a minimum relative humidity of 50 %.
Heat-cold cycles [5 cycles]
1. exposure to (50 ± 5)°C (rise for 1 hour) and maximum 10 % RH for 7 hours (total of 8 hours),
2. exposure to (- 20 ± 5)°C (fall for 2 hours) for 14 hours (total of 16 hours).
Freeze – thaw [30 cycles]
1. Exposure to water for 8 hours at (+ 20 ± 2)°C by immersion of the samples, render face downwards, in a water bath, by the method described in 5.1.3.1 Capillarity test.
2. Freezing to (- 20 ± 2)°C (fall for 2 hours) for 14 hours (total of 16 hours).

3.2.1 Analysis on TRY for defining ageing cycles for ETICS

Starting from the TRY store for Milan Linate, the elaboration of climatic input data was conducted by DBCG in order to individuate the most stressing actions for the chosen building component and calculating how many times these stressing conditions happen in the Test Reference Year. Thanks then to a statistical elaboration of these data, it was possible to give an analytical validation to the defined cycle and, in particular, to the chosen ratio between summer cycles and winter ones.

The following tables show the results of elaborations developed using Milan Linate's TRY and taking into consideration, above all, the highest probability of stressing conditions both in winter and in summer, according to the "agents-actions-effects" analysis previously undertaken for ETICS.

In particular, in winter season, has been considered as ageing event the contemporary presence of low (under zero) temperatures and high relative humidity percentage, assessing the highest risk of superficial condensation that can provide water to be absorbed by the finishing coat and then, due to freezing, it can create cracks in the layer. In summer season, instead, it has been assessed the probability of thermal shocks, considering the occurrence of high air temperatures (or high air sun temperatures) and contemporary high relative humidity percentage (in order to take into account the probability of summer storms, in lack of precise data concerning it).

Despite this, it must be underlined that TRY is a collection of mean values of hourly mean data: it doesn't take into account peaks which can be relevant critical actions.

According to this statistical analysis it was then possible to observe the distribution of the ratio between summer and winter cycles: this rate is always higher than the one proposed by EOTA (equal to 2,29, as indicated at point 3.1).

In order to assume a more realistic rate value, without getting too far from the value suggested by EOTA, it was decided to repeat ageing sub-cycles maintaining the proportion 2.5: in each complete cycle CX there are 25 UV cycles, 10 winter cycles and 25 summer cycles. Complete ageing cycles CX therefore are assembled in groups of five so to get a macro-cycle TX. The overall duration of a macro-cycle is more or less one month.

Table 2. Daily elaborations for winter and summer seasons

Cycle	*t daily*		*RH max daily*	*Number of days in one year*	*Percentage in one year (%)*
WINTER	$T_{AIR\ MIN}$	≤ 0°C	≥ 80%	85	23,29
		≤ 0°C	≥ 90%	77	21,10
		≤ -5°C	≥ 80%	13	3,56
		≤ -5°C	≥ 90%	10	2,74
SUMMER	$T_{AIR\ MAX}$	≥ 25°C	≥ 80%	85	23,29
		≥ 25°C	≥ 90%	39	10,68
	$T_{AIR\ SUN\ MAX}$	≥ 50°C	≥ 90%	33	9,04
		≥ 55°C	≥ 90%	11	3,01

Table 3. Hourly elaborations for winter season

Cycle	*t hourly*	*RH hourly*	*v wind*	*Number of hours in one year*	*Percentage in one year (%)*
WINTER	≤ 0°C	≥ 80%	---	600	6,85
	≤ 0°C	≥ 90%	---	354	4,04
	≤ 0°C	≥ 80%	> 4 m/s	43	0,49
	≤ 0°C	≥ 90%	> 4 m/s	32	0,37

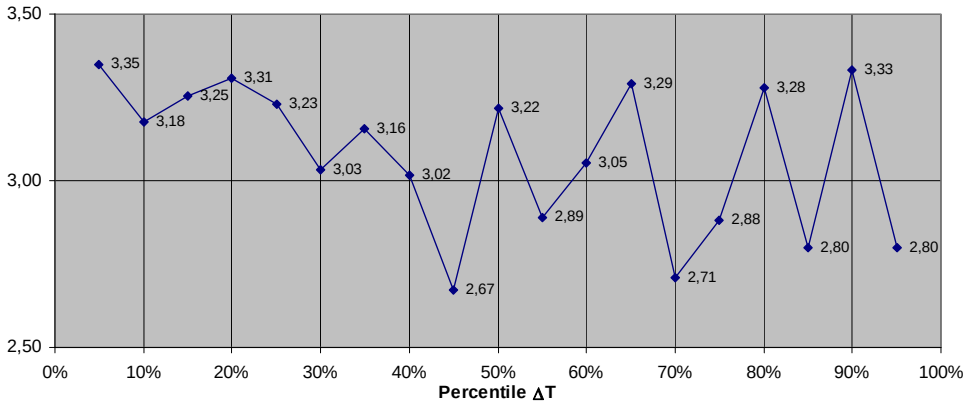

Figure 2. Ratio between summer and winter cycles, according to different percentiles

Table 4. Ageing sub-cycles or basic cycles (in bold set point values).

Basic cycle	Repeat	n°	Phase	Climatic chamber				Laboratory		
				T_{air} [°C]	T_{sup} [°C]	T_{H20} [°C]	RH [%]	$T_{op,i}$ [°C]	RH [%]	Duration [min]
UV	25	1.1	UV	***35***	-	-	15 ± 2	26 ± 3	60 ± 5	60
Winter	10	2.1	Rain: 1 [lt/m^2]	***5 ± 1***	-	5 ± 1	100	19 ± 2	60 ± 5	60
		2.2	Freeze	***-20 ± 2***	-	-	-	19 ± 2	60 ± 5	180
		2.3	Winter heat	***30 ± 2***	-	-	50 ± 2	19 ± 2	50 ± 5	60
Summer	25	3.1	Dry heat	***70 ± 5***	70 ± 5	-	15 ± 2	26 ± 3	60 ± 5	60
		3.2	Rain	*20*	-	20	100	26 ± 3	60 ± 5	60

4 CONCLUDING REMARKS

Lack of knowledge of environmental exposure data and models is an important barrier for further progress towards Service Life prediction.

The methodology for defining accelerated ageing cycles adopted by DBCG and applied to the ETICS experimental programme could be considered a first step in establishing a procedure for choosing the most proper ageing cycle for the studied building component: this is a topic emerged as a methodological problematic in particular during the last Italian national meeting in Favignana (TP). The necessity underlined is to adopt a common proceeding methodology for defining ageing cycle which better simulate the real climatic context to which they are associated.

T 32

ABSTRACT

Results are presented from an extensive research project on the hail impact resistance of various building materials and components including tiles, metal sheets, skylights, wood, glass, flexible sheets, exernal thermal insulation and finished systems, window shutters. The data established by impacting specimens with simulated hailstones made of plastic balls and ice spheres are correlated to each other. The results are discussed and recommendations are given for a new testing practice which will be implemented in Switzerland. In the project, it became evident that high speed hail tests can not be replaced by a dart impact test using falling steel balls to achieve the same kinetic energy. The values of hail impact resistance (HIR) show a marked difference between high modulus and low modulus materials, and their structural stiffness and surface properties.

A new classification system for the hail impact resistance of building materials is proposed. This system considers the five predominant damage categories experienced during impact; specifically, loss of functionality, deformation, fracture, aesthetics, and damage affecting aging. The results also show that requirements of certain standards such as that for solar modules do not comply with the hail size observations made during naturally-occurring hail storms.

1 INTRODUCTION

In Switzerland, each year hailstorms cause substantial damage to building envelopes and over time, total losses show an upward trend. The use of a plastic ball to simulate hail impact started in Switzerland in 1970 when roofing membranes were competing against traditional roofing materials like roof tiles. Standards such as SN 564 280 [1], recommendations of building authorities and insurance companies referred to such procedures. In determining hail impact resistance (HIR), a 40 mm plastic ball is shot at a specified speed at the test specimen. Temperature sensitive materials are cooled at the surface to 5° C and positioned on a rigid and/or flexible support. Facade elements are fastened at an angle of 45° or 90° with regular fasteners, and jointed to each other. The resultant damage is assessed for leakage and /or visual deficiencies.
Constant projectile properties, reproducibility, instant damage assessment, time and costs savings are the advantages of the current test procedures. There are, however, various disadvantages in this procedure in regard to the natural weather influences. In general, the density of plastic balls is higher than that of natural hailstones and the fracture behaviour is brittle for ice, elasto-plastic for plastic balls. This means that a plastic ball exerts higher energy than that occurring with a natural hail stone.

2 HIGH MASS - LOW SPEED VERSUS LOW MASS - HIGH SPEED

The approach to this problem with reference to natural environmental condition demands knowledge of the impact speed of a hailstone. It can be calculated from analytical evaluation or – as in recent times – from the use of measuring devices during a hail storm. If a high speed camera is available, the impact speed can be indirectly established by video-recording the impact.

2.1 Evaluation of Impact Velocity

At impact on the ground, hail appears to be of white colour. This fact leads to the conclusion that the amount of trapped air in the ice is apparently rather high. With increasing size, however, sliced hailstones often show a shell-like structure. Within this structure, clear ice alternates with porous ice resulting from many ups and downs in the turbulent air circulation within a storm super cell. Size of hailstone and aerodynamic drag c_w as determined by the hailstone shape has the strongest influence on impact velocity.

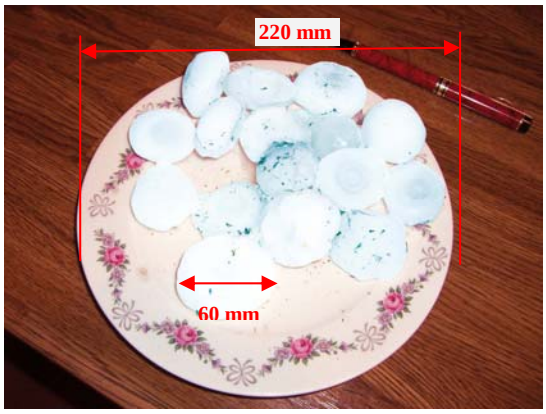

Figure 1. Shapes and dimensions of collected hailstones that fell from a super cell near Lugano on June 21, 2007 (photo by F. Terrasi)

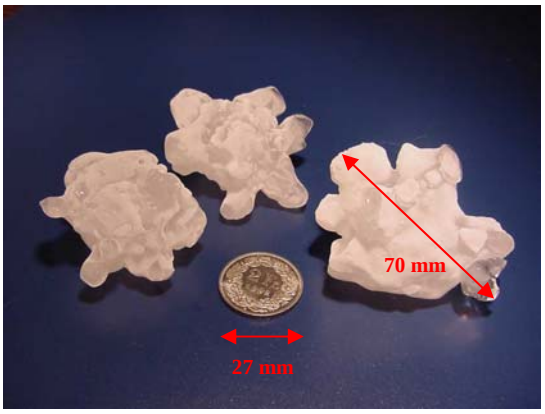

Figure 2. Shapes and dimensions of collected hailstones that fell from a super cell in the city area of Zurich on June 24, 2002 (photo by U. Spreiter; the diameter of the 2-Swiss Francs coin is 27 mm.)

These shapes vary from round, egg-shaped, disk-like, smooth, warty, bulgy, and even extremely jagged surfaced. Recently, bulgy, pointed forms were detected also in smaller-sized hailstones (Figure 1 and 2). Therefore the aerodynamic drag coefficient, c_w, can range from 0.45 for a smooth surface to 0.8 for a rough surface. In turn, the density, ρ_{ice}, may range from 0.60 to 0.91 kg/dm^3.

In the past, various scientists have reported on the hail impact velocity and its destructiveness. As an example: In 1937, Bilham and Relf [2] studied differences between small (< 10 mm) and large hailstones. Motz [3], Kawashita/Flüeler [4], and others evaluated the most cited equations for terminal velocity. Figure 3 shows the range of the calculated terminal velocity, v_{tH}, for hailstone diameters ranging from 20 to 100 mm. As a rule, factors in the calculation include the sphere diameter, d_H, the density of the ice, $\rho_{ice,}$ the density of the air, ρ_{air}, and the coefficient of aerodynamic drag in air, c_w. The following formula is most frequently used:

$$v_{tH} = \sqrt[2]{\frac{4 \cdot d_H \cdot g \cdot \rho_{ice}}{3 \cdot c_w \cdot \rho_{air}}} \qquad (1)$$

$$E_{kin} = m \cdot v^2/2 \qquad (2)$$

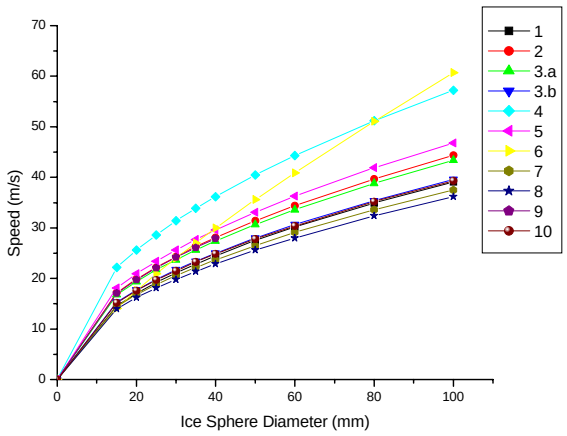

Figure 3. Calculated terminal velocity for round hailstones from different authors: 1. Bohm, 2. ASTM 1038-05, 3a. EMPA with c_w 0.5, 3b. EMPA c_w 0.6, 4. Motz ρ_{air} 0.9,kg/m^3, 5. Motz ρ_{air} 1.23,kg/m^3, 6. Heymsfield, 7. Pflaum, 8. and 9. Matson, 10. Lozowski, Guastala and Flüeler

In this present study, the following constants are used (Figure 2, curve 3a): Ice density, ρ_{ice} : 875 kg/m^3, air density at 20 ° C, ρ_{air} : 1.226 kg/m^3, and coefficient of aerodynamic drag, c_w: 0.5 kg/m^2.

2.2 Test Practices of Common Standards

Since the beginning of recorded history, Australia, South America, the United States, and Central Europe have known the effects of hailstorms. To toughen materials against hail impact, test procedures were first established in South Africa in the 1950s and in the United States at NIST in the 1960s. In Switzerland, the plastics industry provided evidence in the early 1970s that polymer roofing membranes are equal or even superior to classic roofing materials such as clay tiles. Initial impact testing was conducted using ice spheres. Nevertheless, for practical and economical reasons, a 40 mm polyamide (PA) sphere was chosen. Comparisons of in-service hailstone damage on polymer roofing membranes to that obtained with the PA spheres showed similar damage patterns. Due to this fact, SIA established a test protocol in 1977 [1] with the requirement of a velocity of 17 m/s when shooting at a chilled waterproofing membrane supported by a steel plate and soft thermal insulation board (EPS).

This velocity equates to a kinetic energy of 5.6 J. In comparison, good classic clay tiles become damaged at a velocity of 9 m/s which is equal to 1.6 J.

3 TEST PROGRAM

To simulate the conditions of natural hail and its impact on the building envelope, an extensive experimental investigation was performed. A comparative study was carried out on 50 types of materials originating from 11 fields of application using laboratory-made ice spheres and plastic balls.

3.1 Test Apparatus and Parameters

The test apparatus consisted of a pneumatic gun positioned vertically (Figure 4). This apparatus was originally designed for use with plastic balls only. In the course of expanding our technical investigations, the apparatus was modified to launch 15 to 50 mm ice spheres. By using a light beam, the projectile velocity is instantaneously measured at the end of the gun barrel in a distance of 30 cm. Target and distance are exactly aimed at by two focussing lasers (Figure 5). The velocity is set by the pneumatic pressure corresponding to calibration values enabling a repeatability of < 1 m/s.

Figure 4. Test apparatus and tilted steel frame with mounting for a wood framed window glass

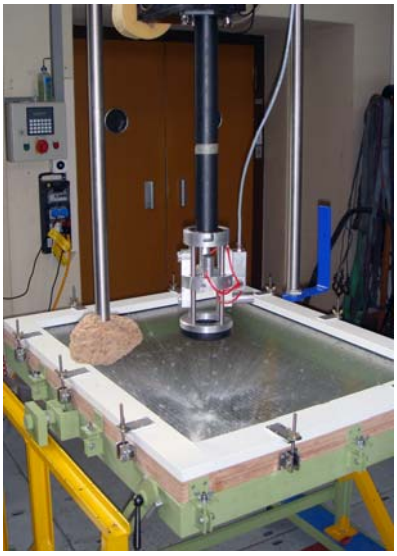

Figure 5. Edge impact of a 50 mm ice sphere on a 6 mm thick wire glass window

For the project, the following parameters were chosen:

Set-up of test specimen:	Condition new, as installed in building, custom-designed
Size of test specimen:	0.8 to 1.1 m^2 with jointing, possible overlaps, original fasteners
Surface treatment:	Temperature sensitive materials: chilled with ice granules for 3 min.
Test temperature:	Room temperature and humidity, approx 23° C/50 % r. h.
Impact angle:	Roofing 90°, façade 45°, both applications 45° and 90°
Type of impact:	Single shot mode
Impact speed:	Appropriate speed for size of projectile

3.2 Projectiles and Properties

For projectiles, precision balls made from PA 66 (density of 1.16 kg/dm^3) and laboratory ice spheres (density 0.875 g/cm^3) were used. The ice spheres were made in silicon moulds using demineralised water. The production of crack-free and essentially pore-free ice spheres required approx. 17 hours at -20° C in a freezer. Freezing of the water was induced by a freezer plate at the bottom of the mould, thus facilitating slow growth of the ice core from bottom to top. Due to time-dependent changes of ice,

a shelf time of less than 3 weeks was observed for the newly made ice spheres. The important properties of both types of projectiles are listed in Table 1:

Table 1. Mass of ice spheres and plastic balls for various diameters.

Type of sphere	Unit	Diameter (mm)				Failure behaviour
		20	30	40	50	
Mass of ice	(g)	3.8	12.3	30.2	58.3	brittle
Mass of Polyamide	(g)	4.8	16.1	38.8	74.9	tough

3.3 Procedure

To investigate the damage mechanism and weak points, test specimens were first impacted using PA-balls fired within the velocity range observed for real hailstones at impact. At a damage velocity considerably higher or lower than natural velocities, test specimens were impacted by sphere sizes 10 mm higher or lower. Then, the procedure was applied by using ice spheres.

4 DAMAGE ASSESSMENT AND EVALUATION

Assessment of damage in regard to insurance codes of practice was the most challenging task. The diversity of materials, supports, substrates, and fastenings along with the wide-ranging damage characteristics at impact demanded very close examination of each application. Therefore, the damage characteristics due to impact were grouped within the following general categories:

a) Loss of a main function: such as water tightness, breakdown of mechanical/electrical properties, loss of load bearing property etc,
b) Deformation: indentation, dent formation, deformation of defined depth,
c) Cracking and fracture: visible cracks, spontaneous fracture, delamination,
d) Aesthetics: change of appearance, loss of light transmission, change of aesthetical appearance, view in back light from a distance of 5 m, and
e) Damage affecting aging: inherent cracking, face separation, de-bonding, damage of surface layers.

After impact, the damage category was assigned based on the lowest velocity (i.e., kinetic energy according to Eq. 2) that resulted in damage. For ductile materials such as metallic sheets, the formation of a dent was judged to be aesthetic damage. In general, aesthetic damage was not observable until the depth of the indent reached about 0.5 mm.

5 RESULTS

The diversity of the investigated materials and their uses generated a wide range of results. Nevertheless, these results could be classified into three material categories according to load bearing behaviour, i.e. stiffness (Tables 2.1 – 2.3). A condensed report is provided by [6], also in French.

Figure 6 is a plot relating depth of indentation to projectile kinetic energy for the case of a 0.7 mm zinc-plated, corrugated steel sheet impacted using 40 mm PA balls and 40 mm ice spheres. Figure 7 shows a photo of the indentations at projectile velocities of 26, 30, and 36 m/s. At a 90° impact angle, both projectile types caused circular indentations that increased in size with increasing velocity. At an angle of 45° mainly ellipsoidal indents resulted. Upon impact, PA balls remained intact and showed no cracking. In contrast, ice spheres tended to split - even at a velocity as low as 10 m/s - depending on the nature, mass and surface topology of the specimen. A clear observation from the testing was that, for heavy mass specimens such as clay tiles, the ice fragmentation pattern was distinct and more diverse changing with increasing velocity in comparison to the fragmentation of compliant specimens. A heavy mass specimen is one for which the ratio of the test specimen mass to the projectile mass is

greater than 50. Another observation was that low HIR values (i.e., < 3 J) were in general found for specimens where the damage was categorized as aesthetic rather than functional.

Table 2.1. High stiffness, tough materials

Material/Component	Element stiffness	E·I (kN·mm²/mm)	Angle (°)	E_{kin} (J)	HIR-class	Lowest values for Product	Ø (mm)	E_{kin} (J)
Tiles	high	2330-2635	90	13.7 - 27.3	4	clay tiles	50	13.75
Glass	high	370 - 3000	45	5.5 - 46.7	3 - 5	wire glass 7	40	5.5
Fibre cement	high	140-252	45/90	17.6 - 38.2	4 - 5	corrug. plate 5.5	40	17.6
Polymer plates	high	0.3-9.6	90	6.4 - 38.8	3 - 5	PMMA 4	30	6.4
Skylights	high	5.3 - 7.4	90	0.8 – 3.1	2 - 3	PMMA 2.5	30	0.8

Figure 7: Indentations caused by 40 mm projectiles; impact using PA balls (left) and ice spheres (right) at velocities of 26, 30 and 36 m/s

6 CORRELATION OF DATA FROM POLYAMID AND ICE SPHERES

Test data from two projectile materials - ice versus Polyamide - allow a correlation of the tested materials. A ratio (I/P) can be calculated between the values of velocity (and also kinetic energy) of ice (I) spheres and Polyamide (P) balls sphere. Figure 8 shows the relationship between the primary kinetic energy data for various specimens tested using 40 mm PA balls and 40 mm ice spheres.

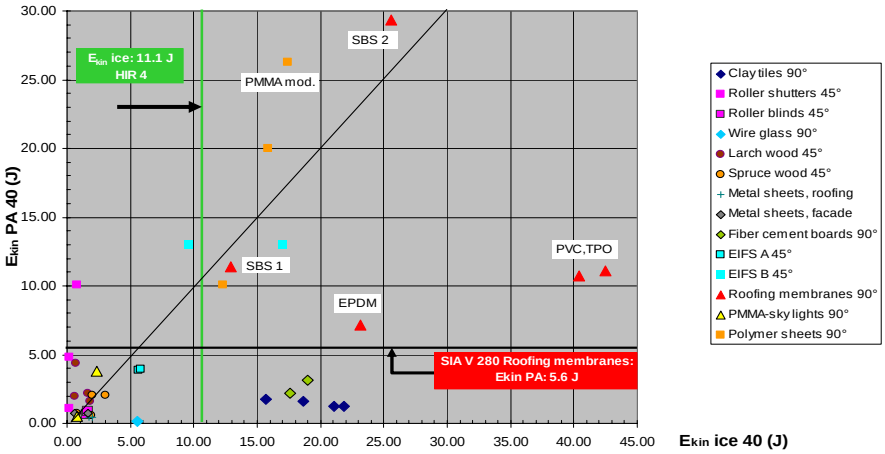

Figure 8. Kinetic energy in J for ice spheres and PA balls causing damage. Actual reqirement (red) for roofing membranes in Switzerland

This figure confirms clearly that many specimens experienced damage at very low kinetic energies. It is noted that hailstones having diameters less than 30 mm generally have kinetic energies of less than 3.5 J. Most important from Figure 8, it is evident that the data points for many specimens fell well below or above the correlation line indicating for these cases that testing needs to be conducted with ice spheres and not with PA balls. This is especially the case for roofing membranes tested on rigid substrates and for clay tiles.

7 CLASSIFICATION AND DESCRIPTION

A classification of building materials should be understood not only by material scientists and professionals in the building business but also by users. So, it should be ease to understand and related to the observed weather phenomena. In a 1991 publication, Flüeler [5] made an attempt to define a classification system including 5 levels of hail impact resistance. It is now stated to classify hail impact resistance into classes 1 to 5 (Table 3) that corresponds to hailstone diameters of 10 to 50 mm at which the building materials remain damage-free. It includes the corresponding terminal velocity of an impacting hailstone, as calculated using equation 1, curve 3a of the plot in figure 2 and calculated kinetic energy using equation 2. An examination of Table 3 shows that for each HIR class, the range of kinetic energy corresponding to that given HIR Class is rather large, for example, ranging from 11.1 J to < 27.0 J for HIR Class 4. This realization dictates that, for a more precise description differences in kinetic energy sustained without damage must be taken into account in the proposed classification system. The classification thus signifies not only the HIR class designation, but also the highest kinetic energy achieved without damage for the given sized ice sphere. Table 4 provides HIR Class designations (without kinetic energy) for the specimens in this study.

Table 3: Classification of hail impact resistance (HIR) and calculated kinetic energy

HIR-Class	Ice Sphere diameter (mm)	Mass (g)	Terminal velocity (m/s)	Kinetic energy (J)
1	10	0.5	13.8	***0.04***
2	20	3.6	19.5	***0.7***
3	30	12.3	23.9	***3.5***
4	40	29.2	27.5	***11.1***
5	50	56.9	30.8	***27.0***

Table 4: HIR-guide values of tested building materials and predominant damage category

HIR Class	Material/Component	Type	Thickness (mm)	Predominant Damage Category
1	Roller shutters, roller blinds	aluminium, folded	< 0.5	Deformation, aesthetics
	Metal sheets	cupper, tin	< 0.6	Deformation, aesthetics
	GRP-panels	light, shaped	> 2	Fibre matrix defect
2	Metal sheets façade and roofing	Fe, Cu-Fe, Ti plated	>0.5 - 0.7	Deformation, aesthetics
	Roller shutter reinforced	aluminium profile	0.9	Deformation, aesthetics
	Wood panels	planed, coated	25	Indent, cracked paint
3	Skylights	PMMA	2.5	Fracture, leakage, transparency
	GRP-double face panels	structural	20	
	EIFS (EPS and rock wool)	reinforced glass web	>3	Fibre matrix defect
	Wire glass	wire net 10 mm	7	Cracking, de-bonding Fracture
4	Roofing membranes	EPDM, SBS	4	Leakage
	Polymer sheets	PMMA modified	4	Transparency, defect
	Roof tiles	clay, structured surface	15	Internal fissure (sound check)
	Fibre cement boards/roofing	flat, undulated	6	Indent, surface crack, fissure
5	Roofing membranes	TPO, PVC-P	>1.5	Leakage
	Polymer sheets, skylights	PC, plain + structured	4	Deformation
	Safety glasses	single, laminated	6	Splitting, fracture
	Window glasses	insulated, alum. framed	4/16/4	Splitting, fracture

Note: HIR Classes in this table are examples achieved in the study and should not be taken as requirements or guide values.

8. CONCLUSIONS

1. This study confirmed field observations particularly from insurance companies that indicate that considerable hail damage payment (> 80 %) is made for the materials that fall within the HIR Class 1 and 2. They experience damage at kinetic energies of 0.7 J or less.

2. Impact of stiff, high-mass construction materials by a PA ball provokes considerably higher kinetic energy than that of an ice sphere of the same size. The fragmentation energy is not available for the damage process. For very stiff and high-mass materials, ice spheres have a kinetic energy up to 15 to 20 times greater than that of a PA ball to inflict damage.

3. With the exception of mass difference, lightweight elastic materials behave almost similarly with the two types of projectiles because of low fracture/deformation energy absorption.

4. For materials with structured cross sections with thin faces (e.g., double face plate, < 1 mm), a smaller projectile diameter might provoke damage while a larger diameter causes no damage.

5. Very often, hail damage resulting in loss of functionality or other physical characteristics is not as disconcerting as aesthetic damage. As an example, car bodies dented by hail are still roadworthy.

6. The effect of hail impact on the aging behaviour must be sufficiently taken into consideration.

7. Due to the diversity of materials and systems used for building envelopes, HIR evaluations have to be performed using ice spheres impacting at natural terminal velocity. Moreover, the kinetic enegy sustained during these evaluations has to be taken into account in an HIR classification system.

Prediction of Atmospheric Corrosion Rate Using An Artificial Neural Network

Gülşah Doğan [1]
Emrah Gökaltun [2]

T32

ABSTRACT

Atmosphere is the environment to which the building materials are naturally exposed. Air pollution which is formed due to polluting this environment in an uncontrolled way causes undeniable negative results for both living beings and building materials. One of these unfavorable results is the atmospheric corrosion damage to the metal building materials. The weight loss as a consequence of the atmospheric corrosion significantly affects the performance and lifetime of the metal building materials and it results in big economical and social costs.

In order to quantify the impact of the corrosion on the metal building materials, the corrosion rate is often measured, if possible, or predicted using a mathematical model or an artificial neural network (ANN). Motivated from the proven performance of the ANNs in modeling the corrosion dynamics, in this study, an artificial neural network (DYSA) was developed to predict the atmospheric corrosion rate. When compared to the ANNs proposed in the literature for the corrosion rate estimation, the DYSA distinguishes itself from the rest by its unique data clustering technique together with Levenberg-Marquardt training algorithm using Bayesian regularization. The prediction performance of the DYSA was compared against the well-known MICAT network presented in the literature. The fact that the DYSA can predict the corrosion rate better than the MICAT network in the statistical sense was based on the following encouraging simulation results: DYSA decreased the mean square error by 84% and 54% for the training and test data sets, respectively; increased the correlation coefficient by 10% for the training data set as compared to the MICAT network.

1 INTRODUCTION

The sustainability of life for all living beings on the world is only possible provided that there is synergy between them and their environment. This is because the environment is composed of living and nonliving elements and there are sophisticated relations and interactions between these elements. Human being, which depends on its environment like all other living beings for maintaining its life, is affected by its environment and affects it as well. The multi-faceted and uninterrupted interaction between human and its environment lasting throughout has started to impair in time due to the fact that humans have exploited the environment in an unconscious way for meeting their unbounded needs. Human originated effects like developing technology, population growth and its accompanying result of unplanned urbanization have started to damage the environment balance. As a result, the environment has been used for the consumer society's needs. Ignoring the environment in the production and consumer operations has caused many environmental problems. One of these problems is the air pollution which is due to the combustion of fossil fuels for supplying increasing energy demand from day to day. The air pollution, which has become a global environmental issue due to the transportation and dispersion processes, damages living as well as nonliving environment.

Buildings, depending on their ambient conditions, are exposed to a variety of effects in their life. These effects, in time, cause deterioration of and damage to the inner structure or surface of the building materials. The deterioration of materials forming the building affects the comfort and health of its users and decreases the lifetime of the building. Thus, it is required that effects and factors that can cause a damage to the building materials be understood in order to take the proper protective measures, that is, maintaining the health of the building, increasing the service lifetime of the building structure, avoiding the economical and social costs due to the damages/deteriorations. The air pollution among these factors plays an important role in forming a variety of damage mechanisms or speeding up the damage mechanisms. Thus, the air pollution has become a research topic in the field of architecture in which the possible impact of the air pollution on monuments, historical buildings and nowadays buildings is investigated [Atkinson 1970].

In this study, the impact of the atmospheric corrosion, which is one of the results of the air pollution, on the building materials is addressed. Atmosphere is the environment to which metal building materials are often exposed, and it is quite corrosive due to its nature. However, in the existence of pollutants like SO_2 and NO_2 which are released into atmosphere as the combustion wastes of fossil fuels used in production, heating and transportation and which play an important role in forming the air pollution, the corrosivity of the atmosphere highly increases. These pollutants, combined with other factors (temperature and humidity), affect the metals as well as all other materials by means of *Dry and Wet Deposition Mechanisms* [Dehri 1994].

In order to quantify the impact of the corrosion on the metal building materials, the *corrosion rate* is measured or predicted where the corrosion rate can be defined as the amount of substance dissolved per unit time at a specified surface. Determining the corrosion rate is important for understanding the durability of the metals and alloys to the corrosion. Furthermore, knowing the aptness of the material to the corrosion depending on the corrosivity of the ambient is very important for selecting the most suitable materials to be used in the building and taking the required protective measures for them. In the literature, a variety of methods has been developed to find out the corrosion rate: artificial neural networks [Pintos *et al.* 2000], power function and linear regression [Hou & Liang 2004], and D/R (Dose/Response) equation [Knotkova 2005]. In particularly, artificial neural network's proven success in modeling the nonlinear and complex systems and its ability of producing results even for the unseen examples based on its past experience make it an ideal choice for predicting the corrosion rate as compared to the linear regression techniques. Some of the studies which used the artificial neural network for predicting the corrosion rate in the literature are as follows: [Cai *et al*. [1999]; Cottis *et al*. [1999]; Pintos *et al*. [2000]; Parthiban *et al*. [2005]].
Based on the success achieved by the artificial neural networks for predicting the corrosion rate in the literature, an artificial neural network (DYSA) was developed to predict the corrosion rate in this study

as well. The DYSA's distinguishing features include its unique data clustering technique together with Levenberg-Marquardt training algorithm using Bayesian regularization. The prediction performance of the DYSA was compared against the well-known MICAT network (Pintos *et al.* [2000]) presented in the literature. The fact that the DYSA can predict the corrosion rate better than the MICAT network in the statistical sense was based on the following encouraging simulation results: DYSA decreased the mean square error by 84% and 54% for the training and test data sets, respectively; increased the correlation coefficient by 10% for the training data set as compared to the MICAT network.

The rest of the paper is organized as follows. Section 2 presents the MICAT network model proposed by Pintos *et al.* [2000]; Section 3 introduces DYSA network developed in this study; Section 4 compares the prediction performance of MICAT and DYSA networks; Section 5 concludes the paper.

2 MICAT ANN MODEL

The Mapa Iberoamericano de Corrosión Atmosférica (MICAT) project includes seventy-two test sites exposed to the atmosphere in fourteen countries throughout Iberoamerica. These countries are Argentina, Brasil, Chile, Colombia, Costa Rica, Cuba, Ecuador, Portugal, Peru, Mexico, Venezuela, Panama, Spain, and Uruguay. The MICAT project has three main objectives: (i) construct the corrosion map for Iberoamerica, (ii) provide a better understanding of atmospheric corrosion phenomena, (iii) identify mathematical models that could predict the corrosion rate of metals in the atmosphere as a function of meteorological and pollution variables for Iberoamerica [Pintos *et al.* 2000].

According to Pintos *et al.* [2000], the third objective of the MICAT project can be attained by means of an artificial neural network (ANN). Thus, a database, which will be used for training and testing the ANN to be developed, was established by collecting data from seventy-two test sites in fourteen countries during the MICAT project. Based on this database, Pintos *et al.* [2000] predicted the corrosion rate of carbon steel (Fe, μm/year) as a function of six different metereochemical variables using a three layer ANN. The metereochemical variables constituting the database are temperature (T in ^{o}C), relative humidity (RH in %), time of wetness (TOW), precipitation (P in mm), sulfate deposition rate (SO_2 in mg/m^2/day), and chloride deposition rate (Cl^- in mg/m^2/day). Technical features of the ANN model developed by Pintos *et al.* [2000] are presented in Table 1.

Table 1. Technical features of MICAT artificial neural network developed by Pintos *et al.* [2000].

ANN model	Multi-layer perceptron (one hidden layer)
Number of input/hidden/output layer neurons	6/6/1
Activation function	Sigmoid
Training algorithm	Gradient descent
Method for avoiding over-training	Early stopping

3 DYSA ANN MODEL

In this section, DYSA ANN, which was developed to predict the corrosion rate better in the statistical sense than the MICAT ANN, and its design process will be presented.

3.1 DYSA Network Model

In order to define an ANN with multi-layer perceptron network topology, it is required that the number of layers and the number of neurons together with an activation function for each layer in the

network be determined. DYSA, similar to MICAT network, has three layers: input layer, hidden layer, and output layer. The rationale behind three layer network topology can be explained as follows. Predicting the corrosion rate as a function of some variables is truly a *function estimation problem*. According to Demuth *et al.* [2006], for the function estimation problems, a three layer perceptron network topology is enough to predict any function with an arbitrary accuracy provided that the number of hidden layer neurons, the activation functions of the hidden and output layer, and the weights are determined appropriately.

After the specification of the DYSA network topology, the number of neurons in each layer and the related activation functions are determined as follows. The number of input layer neurons is six, which is equal to the number of metereochemical variables in the database; the number of output layer neurons is one, since only corrosion rate will be predicted. In the literature, there is no known method that can be used to set the number of hidden layer neurons as well as the hidden layer and output layer activation functions. Thus, the trail-and-error approach was followed for setting them so that the prediction performance of the DYSA is maximized. As a result, the number of hidden layer neurons was fixed to be eight; both hidden and output layer activation function was determined to be the hyperbolic tangent [Doğan 2006].

3.2 DYSA Training Algorithm

Various training algorithms have been proposed for multi-layer perceptron ANNs. These algorithms can be classified into four groups: Gradient descent, conjugate gradient descent, Newton, and Levenberg-Marquardt [Haykin [1994]; Demuth *et al*. [2006]]. It is a fact that the training time and prediction performance vary from algorithm to algorithm. For the function estimation problems, Levenberg-Marquardt algorithm, as compared to the other ones, takes less time to complete training and shows better estimation performance [Demuth *et al*. 2006]. Thus, the training algorithm of the DYSA was chosen to be Levenberg-Marquardt algorithm.

Table 2. Technical features of DYSA artificial neural network.

ANN model	Multi-layer perceptron (one hidden layer)
Number of input/hidden/output layer neurons	6/8/1
Activation function	Hyperbolic tangent
Training algorithm	Levenberg-Marquardt
Method for avoding over-training	Bayesian regularization

During the training of an ANN using any training algorithm, it is possible to experience some common disadvantages of ANNs which may lead an ANN to producing unacceptable results. One of these disadvantages is the *loss of generalization due to over-training* [Danaher 2004]. There are a few techniques that can be applied to alleviate this disadvantage. One of them is *early stopping* used by the MICAT ANN. In the early stopping, database is split into three groups, namely: training, validation, and test. A down side of the early stopping is that it is unknown how to form the validation group, which is used to check for the over-training during the training. Another technique is *Bayesian regularization*, which does not need a validation group. Thus, DYSA has adopted Bayesian regularization. Technical features of the DYSA are presented in Table 2.

3.3 Preprocessing Data For DYSA

In the training and test of the DYSA, the MICAT database of Pintos *et al.* [2000] was exploited. The database needs to be split into two as training and test group. However, in the literature, there is no method proposed for creating training and test groups for a multi-layer perceptron ANN from a

database. Furthermore, the training group affects the training time as well as the training and test performances of an ANN. Thus, how the database is partitioned is a crucial to the performance of any ANN. One of the important and distinguishing contributions of this study is the method developed to partition a database into training group and test group. This method is explained below.

- There are 130 observations in the MICAT database. Each observation is a 1 × 7 vector of measurements, where six of them correspond to the metereochemical variables (T, RH , TOW, P, SO_2, Cl^-) and the last one is the corrosion rate (Fe). It was decided for the DYSA that the training group includes 105, and the test group contains 25 observations. Thus, the training group is a matrix of 105 × 7 and the test group is a matrix of 25 × 7. It should be noted that the MICAT ANN has a training group of 105 observations and a test group of 9 observations. Thus, the size of the training group is the same for the DYSA and MICAT; yet, DYSA will be challenged with a greater test group.
- The observations in the database were split into 20 disjoint groups using MATLAB's clusterdata function so that each group has at least one observation. Clusterdata function, first, computes the distance between any two observation pair by means of Mahalanobis distance function and then, groups the observations using based on these distances. Specifically, each observation is included in the group with the minimum average distance among twenty groups, where the average distance is the average of distances between the observation at hand and the observations in a group. As a result, Clusterdata function groups observations close to each other into the same group.
- After the grouping, the number of observations in the groups can be arbitrary. It is possible that a group includes just one observation, while another one has 20 observations. Thus, in order to make it possible to represent each group in the training data set, a maximum number of 130/20 ≈ 6 observations from each group is randomly selected. In this way, 68 observations were chosen in the first round. Remember that the training group should have 105 observations. Thus, the remaining 105 – 68 = 37 observations were randomly selected among 62 observations. Finally, the test group is formed using the rest of the observations.

Following the procedure explained above, the training and test groups were determined. In order to use the training group for training the DYSA, the training group must be scaled. This scaling is accomplished in two steps as follows:

- The training group is a matrix of 105 × 7. Each row of this matrix corresponds to an observation and each column to a variable. For example, the fourth column includes only precipitation data. When this column is studied, it is seen that the precipitation data varies in a highly wide range (between 13.0 and 4656.0 mm). Thus, when this column is scaled down into the range [-1,1] in the next step, there will be a great loss of accuracy. In order to avoid this situation, the fourth column is logarithmically scaled between 2.56 and 8.44. In the MICAT ANN, the fourth column is not logarithmically scaled.

- Demuth *et al*. [2000] stated that Levenberg-Marquardt algorithm using Bayesian regularization gives the best results if the training group is scaled in the range [-1,1]. Thus, each column of the training group is separately scaled in the range [-1,1]. In the MICAT ANN, each column is separately scaled so that the column mean is zero and the column standard deviation is one.

4 RESULTS

As stated above, the training group is a matrix of 105 × 7. The first six columns of this matrix correspond to metereochemical variables and the last column to the corrosion rate. In the framework of the *supervised learning*, the scaled training group is split into two as *training input matrix* and *training target vector*. The training input matrix (105 × 6) is composed of the first six columns of the training group; the training target vector (105 × 1) is the last column of the training group. In a similar way, the

test group of 25 × 7 is first scaled as described above and then, it is split into two as the *test input matrix* (25 × 6) and the *test target matrix* (25 × 1).

The performance of the DYSA for both the training and test input matrices was measured by using two different metrics, namely, mean square error (*mse*) and correlation coefficient (*R*). These metrics are defined below:

$$mse = \frac{1}{N}\sum_{k=1}^{N}(y_k - \hat{y}_k)^2 \tag{1}$$

$$R = \frac{\sum_{k=1}^{N}(\hat{y}_k - \bar{y})(y_k - \bar{y})}{\sqrt{\sum_{k=1}^{N}(\hat{y}_k - \bar{y})^2 \sum_{k=1}^{N}(y_k - \bar{y})^2}} \tag{2}$$

In these two equations: N denotes the number of elements in the training/test target vector; y_k is the kth element of the training/test target vector; $\hat{y}_k$ represents the kth element of the corrosion rate vector predicted by the DYSA; $\bar{y}$ is the average value of the training/test target vector. Based on these metrics, the DYSA has the following goals: (i) the difference between the predicted corrosion rate vector by the DYSA and the target vector must be minimized by minimizing the mean square error. (ii) The correlation coefficient must be maximized in order for the DYSA to account for the variations in the target vector.

The training and test of the DYSA was accomplished by a program written in MATLAB language. The training process of the DYSA can be summarized as follows: The training input matrix is applied to the DYSA whose weights are randomly determined for the first iteration. The prediction error vector is computed by subtracting the training target vector from the DYSA's output for the training input matrix. If the computed error is smaller than an acceptable error value, the training is stopped. Otherwise, the training algorithm computes a new set of weights so that the prediction error gets smaller, and then it starts over. The test process of the DYSA includes the computing DYSA's performance based on the output vector obtained after applying the test input vector to the DYSA and the test target vector. In the MATLAB program, in order to minimize the probability of converging a local solution, the training process was repeated for 500 times with different initial weights at each time and then, the ANN showing the best performance in terms of the mean square error and correlation coefficient is determined to be DYSA. The DYSA's weights can be found in [Doğan 2006].

The training and test performances of the DYSA and MICAT networks are presented in Table 3. Note that the training and test input matrices used for the DYSA are different from the ones used by MICAT. Thus, the performance of the DYSA was measured for the DYSA input matrices obtained by the procedure developed in this study as well as the MICAT input matrices in Pintos *et al.* [2000]. According to Table 3, the DYSA shows much better performance for both its input matrices and the MICAT input matrices than the MICAT. The DYSA decreases the mean square error as much as 84% for the DYSA training input matrix and 54 % for the DYSA test input matrix, while it increases the correlation coefficient by 10 % for the DYSA training input matrix. Furthermore, the DYSA decreases the mean square error as much as 73% for the MICAT training input matrix and 89 % for the MICAT test input matrix, while it increases the correlation coefficient by 9 % for the MICAT training input matrix. According to these encouraging results, the DYSA developed in this study is capable of predicting the corrosion rate better than the DYSA in the statistical sense.

Table 3. Performance comparison of DYSA and MICAT networks.

	DYSA				MICAT	
	DYSA input matrices		MICAT input matrices			
	mse	***R***	***mse***	***R***	***mse***	***R***
Training	21.15	0.99	37.31	0.98	140.0	0.90
Test	100.28	0.75	23.65	0.99	220.0	□

The performance of the DYSA in predicting the corrosion rate is studied by means of sensitivity analysis for each metereochemical variable as well. This analysis consists of two steps: (i) Forming a test input matrix for each metereochemical variable, (ii) Observing the output of the DYSA while applying these input matrices one by one to the DYSA. For the sensitivity analysis, the test input matrix was formed as follows. The minimum and maximum values of the variable for which the sensitivity analysis will be made are found in the database. In the test input matrix, this variable takes values between it minimum and maximum values with equal intervals. For the other variables, in the test input matrix, their average values computed from the database are used. In this way, six different test input matrices are prepared and the output of the DYSA for each of these matrices is determined. In this study, because of the space limitations, the sensitivity analysis for the temperature and the relative humidity are only presented for the DYSA in Fig. 1.

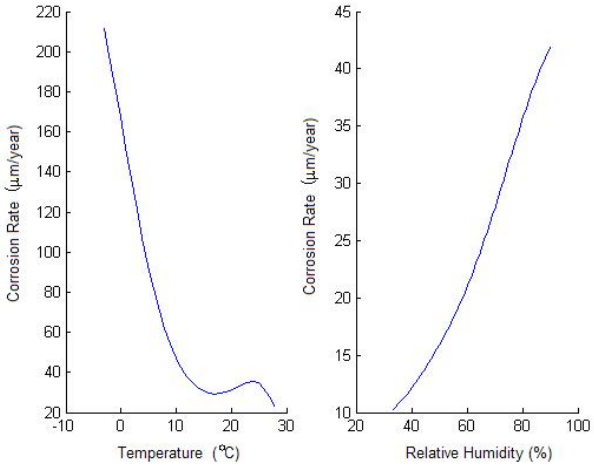

Figure 1. The sensitivity analysis of the DYSA for the temperature and relative humidity.

According to Fig. 1, while the temperature is rising, the corrosion rate is decreasing. The impact of the temperature on the corrosion rate can be in two different ways: (i) Rising of the temperature increases the reaction rate, thereby increasing the corrosion rate as well. (ii) Rising of the temperature decreases the time of wetness of the metal due to the increased vaporization, thereby decreasing the corrosion rate [Dehri, 1994]. As a result, the DYSA reacts to the rising of the temperature in the framework of (ii). As far as the relative humidity-corrosion rate relation is concerned, increasing the humidity results in more amount of electrolyte layer on the metal, thereby increasing the corrosion rate. This relation is clearly shown in Fig. 1.

5 CONCLUSIONS

As an essential building material, metals are affected the most by the destroying effects of the atmospheric pollution and the most important damage mechanism due to the interaction with the atmosphere is the atmospheric corrosion. The atmospheric corrosion with high economical losses is a

very complex matter due to the fact that many factors including environmental and atmospheric ones affect the corrosion reactions. Thus, the determination of the atmospheric corrosion rate of metals is a sophisticated and intriguing problem as well. In this study, an artificial neural network, DYSA, was developed for the solution of the problem, and it was shown that it can be used to predict the atmospheric corrosion rate with higher accuracy than the MICAT network.

Predicting The Initial Rate of Water Absorption in Clay Bricks

Guia Guarini [4]

T 33

ABSTRACT

In this work the capillary suction behaviour of fifteen clay bricks was investigated (UNI 10859) in order to assess the effect of product characteristics and processing conditions and to verify the reliability of the available models. The suction behaviour of bricks, in terms of both total amount of liquid absorbed and kinetics of the process, can basically be brought back to the models of Gummerson et co-workers and Hoffman and Niesel; these latter, however, do not make provision for the effect of product microstructure and water physical properties on the liquid-porous solid interactions. Even if experimentally the liquid suction presents a first dependence on the amount of porosity - a less dense ceramic body is undoubtedly able to absorb a larger liquid amount - other characteristics of the porous structure (size, tortuosity and internal specific surface of the capillary system, as well as the presence of mineralogical phases) request to be more deeply investigated since they could affect the process kinetics.
According with the Beltran's model, which revealed to be sufficiently reliable, the values of capillary coefficient K_s were calculated and their correlation with the experimental ones has been provided. The results obtained indicate that, for a given liquid and in the same experimental conditions, varying in a controlled way the product microstructure (i.e. decreasing the pore size, increasing the pore tortuosity and/or controlling the amorphous/new formed phases ratio) should allow to design materials having a more suitable behaviour.

1 INTRODUCTION

In the structural design of masonry, the suction behaviour of clay bricks has to be strictly controlled in order to optimize the mechanical performances and to prevent deterioration processes. Clay bricks capacity of absorbing liquids and moisture, from both the immediate surrounding and the other building materials, can be referred as their "capillarity". Since clay bricks have to satisfy many requirements (i.e. thermal and acoustic properties, load-bearing capacity and ecological impact), the relationship between these properties and capillarity phenomenon goes through their microstructural characteristics and, in particular, amount, size and shape of pores.

In the literature, a time dependent law of fluid absorption by porous materials, taking the form:

$$m = K_s \cdot t^{1/2} \tag{1}$$

has been proposed [Gummerson *et al.*, [1981]]: the water absorbed by a porous solid per surface unit area (m) increases as the square root of the elapsed time (t), with K_s being defined as the capillary coefficient. In the last years, other mathematical functions were empirically derived [Hoffman *et al.* [1985, 1990]] and the simple relation (1) was replaced by an exponential one:

$$m = a\,[1-\exp(-bt^{1/2})] \tag{2}$$

where a is the maximum moisture content and b a factor influencing the suction kinetics; multiplying a per b, the liquid absorption coefficient is obtained. Equation (1) was furtherly developed [Beltrán *et al.* [1988]] considering that the capillary coefficient K_s must depend on both properties of liquid and of porous solid. Accordingly, the capillary coefficient can be expressed by the formula:

$$K_s = \rho\left(\frac{\gamma}{\mu}\right)^{1/2} \frac{OP}{\lambda}\, r_0^{1/2} \left[\cos\vartheta/2\right]^{1/2} \tag{3}$$

where ρ, γ and μ are, respectively, the density, the surface tension and the viscosity of the liquid, while OP represents the open porosity accessible by the liquid, r_0 the median pore size and λ the pore tortuosity of the solid; θ is the liquid-brick contact angle.
For a given temperature, grouping the liquid properties and the contact angle term into a constant C, the equation (3) is reduced to:

$$K_s = C \cdot \frac{OP}{\lambda} \cdot r_0^{1/2} \tag{4}$$

while equation (1) can be written in the form:

$$m = \left[C \cdot \frac{OP}{\lambda} \cdot r_0^{1/2}\right] \cdot t^{1/2} \tag{5}$$

When the experimental results are represented graphically in the form of m versus $t^{1/2}$, a straight line with a slope K_s should be observed.

The aims of this work are: i) giving a representative survey of the suction behaviour of clay bricks and ii) assessing the influence of the main microstructural and compositional parameters of clay bricks on the absorption process. The results pursued could allow to improve the evaluation of the effects of product and processing conditions on the capillary suction of porous bodies, thus representing an important starting point in the structural design of masonry components.

2 MATERIALS AND METHODS

Fifteen samples of clay bricks were collected in different brickworks, representing the Italian production. Products were characterized by the determination of phase composition, open and total porosity, bulk density, pore size distribution and pore specific surface. Phase composition was quantitatively determined by X-ray powder diffraction (Rigaku Miniflex, CuKα radiation) with the Reference Intensity Ratio method (Al_2O_3 as internal standard, experimental error is within 5% relative). Open porosity (OP) and bulk density (BD) were quantified according to ASTM C373. Specific weight (SW) was measured by He pycnometry (Micromeritics MVP 1305, ASTM C329), while total porosity (TP) was calculated by the equation: TP = (1-BD/SW) ·100.
Pore size distribution (in the 0.01 – 100 μm range) was determined by MIP (Thermo Finnigan Pascal 140/240) with an experimental uncertainty of about 1% relative. Porosimetric data are expressed as r_0 (median pore radius), amount of micropores (P50) having a diameter < 0.05 μm (i.e. < 50 nm) and amount of macropores (P3) having diameter > 3 μm. Pore specific surface (SS) analyses were performed by nitrogen absorption (Micromeritics FlowSorb II 2300) following the B.E.T. single point method.

The capillary absorption of samples was determined according to UNI 10859 on circular disks (20.0 ± 0.1 cm diameter, thickness between 1.5 and 2.0 cm). Samples were dried in an electric oven at 60 ± 2°C for 7 days and, after cooling, their weight (m_0) was measured. A basal face of each disk was put into direct contact with a 1 cm layer of paper, filled with distilled water at 20°C, in a closed vessel. The mass of specimens (m_i) was recorded after 10, 20, 30 minutes and 1, 4, 6, 24, 48 and 72 hours and the liquid mass absorbed per surface unit area (m) was calculated by the formula:
$m = (m_i - m_0)\, A^{-1}$ (6) where A is the area of the specimen in contact with the paper layer.
The capillary absorption of each sample was described plotting m versus the square root of the elapsed time (Fig.1). The graph obtained presents an initial straight line, whose slope is the experimental capillary coefficient K_s, and a final stage characterized by an asymptotic trend.

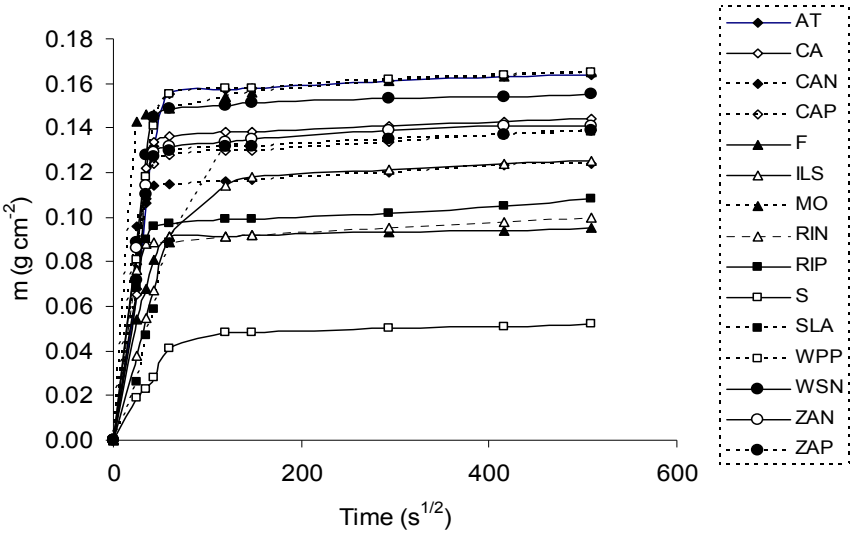

Figure 1. Suction behaviour of clay bricks.

In order to verify equation (3), the following physical properties of water at 20°C were utilized (3): density ρ = 0.998 g cm^{-3}; surface tension γ = 72.7 mN m^{-1}; viscosity μ = 1.0 mPa s. The capillary tortuosity factor λ, which is an empirical dimensionless parameter, was calculated as the ratio:

$$\lambda = \frac{r_0 \cdot SS \cdot BD}{2 \cdot OP} \qquad (7)$$

The water-brick contact angle was measured on the brick surface (DataPhysics Instrument OCA15) obtaining an average value of θ = 87± 3°. A statistical elaboration of data was performed by linear binary correlation and multivariate analysis techniques (factor analysis, scree test for eigenvalues) using the StatSoft Statistica 6.0 software.

3 RESULTS AND DISCUSSION

3.1 Physical Properties

Samples show a great variability of their physical and microstructural parameters [Table 1]: total porosity is in the 19-43 %vol. range, mostly represented by open porosity (19-40 %vol). The median pore size r_0 is between 0.1 and 1.0 μm, while specific surface varies in the 0.6-2.4 $m^2\ g^{-1}$ range. An exception is represented by the sample SLA, which has the smallest pores (r_0 = 0.09 μm) developing a high specific surface (12.3 $m^2\ g^{-1}$). The fraction of pores having dimensions under 50 nm (P50) is quite significant in sample S (13.4 %vol), despite being the less porous material. On the other hand, the amount of the larger pores (P3) is maximum in samples RIN, MO and WPP.

Table 1. Open (OP) and total (TP) porosity, bulk density (BD), median pore radius (r_0), specific surface (SS), amount of pores having a diameter smaller than 0.05 μm (P50) and greater than 3 μm (P3), pore tortuosity (λ) and thickness of clay bricks.

As far as phase composition, samples are mainly made up of quartz (17-45%), with residual K-feldspar and plagioclase up to 25 and 17%, respectively. Illite/mica is also present in most samples, with AT and SLA showing a content as high as 20%. The amorphous phase ranges from 6% (samples CAP and ZAP) to 45% (sample S), while the total amount of pyroxene, wollastonite and melilite fluctuates between 2 and 46%.

3.2 Initial Rate of Water Absorption

The suction behaviour of samples is illustrated in Fig.1. Most of them reach saturation conditions after less than 3 hours, showing then an asymptotic trend involving very small variations of the liquid mass absorbed; nevertheless, the total amount of water absorbed varies from 0.05 g cm^{-2} of sample S to about 0.16-0.17 g cm^{-2} of samples AT, MO, WPP and WSN [Table 2]. On the whole, samples seem to follow two main trends; most present an initial water uptake characterized by a steep slope (K_s values

between 0.6 and 5.9 $\cdot 10^{-3}$ g $cm^{-2}s^{-1/2}$, Fig. 1 and Table 2) that suddenly develops towards the asymptote, while samples S, ILS and SLA exhibit a more gradual behaviour (K_s between 0.6 $\cdot 10^{-3}$ and 1.5 $\cdot 10^{-3}$ g $cm^{-2}s^{-1/2}$, Fig. 1 and Table 2). These different trends can be brought back, respectively, to the models proposed by Gummerson and co-workers [1981] or Hoffmann and Niesel [1988]. In particular, the resistance (in terms of both m and K_s) offered by S, ILS and SLA to capillary suction has a first correspondence with their pore size and amount: the very low porosity and the significant percentage of micropores of sample S, as well as the smaller pores, when compared to the mean pore size of the other products, present in both ILS and SLA, confirm somehow the conclusions of the literature [Latridou and Ozouf [1978] [Vos and Tammes [1969]].

3.3 Capillary Suction vs Microstructural Properties

Since physical parameters of water can be considered constant in the experimental conditions, liquid absorption and K_s should depend only on the solid characteristics.
A positive correlation of both OP (Fig. 2A) and TP (Fig. 2B) with K_s seems to exist though with a quite low statistical significance (r^2 = 0.524 and 0.347, respectively) mainly due to the sample MO, which presents a "capillary capacity" much higher than expected on the basis of its porosity. Hence, if it is true that a less dense ceramic body is able to absorb a higher liquid amount, for the same porosity the influence of other parameters characterizing the capillary structure is not obvious.

Table 2. Total amount of absorbed water (m), experimental (K_s) and predicted (K_s*) values of capillary coefficient.

Samples	m (g cm^{-2})	$K_s \cdot 10^3$ (g $cm^{-2}s^{-1/2}$)	$K_s^* \cdot 10^3$ (g $cm^{-2}s^{-1/2}$)
AT	0.164	3.1	15.4

ZAP	0.139	3.1	13.9

Concerning the relationships of K_s with r_0 (Fig. 2C) and P50 (Fig. 2D), the following conclusions can be drawn: i) the suction kinetics is not dependent on the pore size (r^2 = 0.015) since, for most samples, very different pore dimensions correspond to quite similar values of K_s; ii) the correlation of K_s with P50 gives rise to a cloudy distribution of data (r^2 = 0.269) also because, among the samples, there are not big differences in the relative amount of micropores; at all events, the behaviour of sample S (P50 as high as 13.4%) suggests that such micropores could represent an effective restriction to the liquid uptake. In addition, when K_s is plotted against P3, a correlation with low statistical significance is obtained, so that the statement that larger pores should be the most involved in the suction phenomenon [Beltrán *et al.* [1988]] was proved to be not completely reliable.

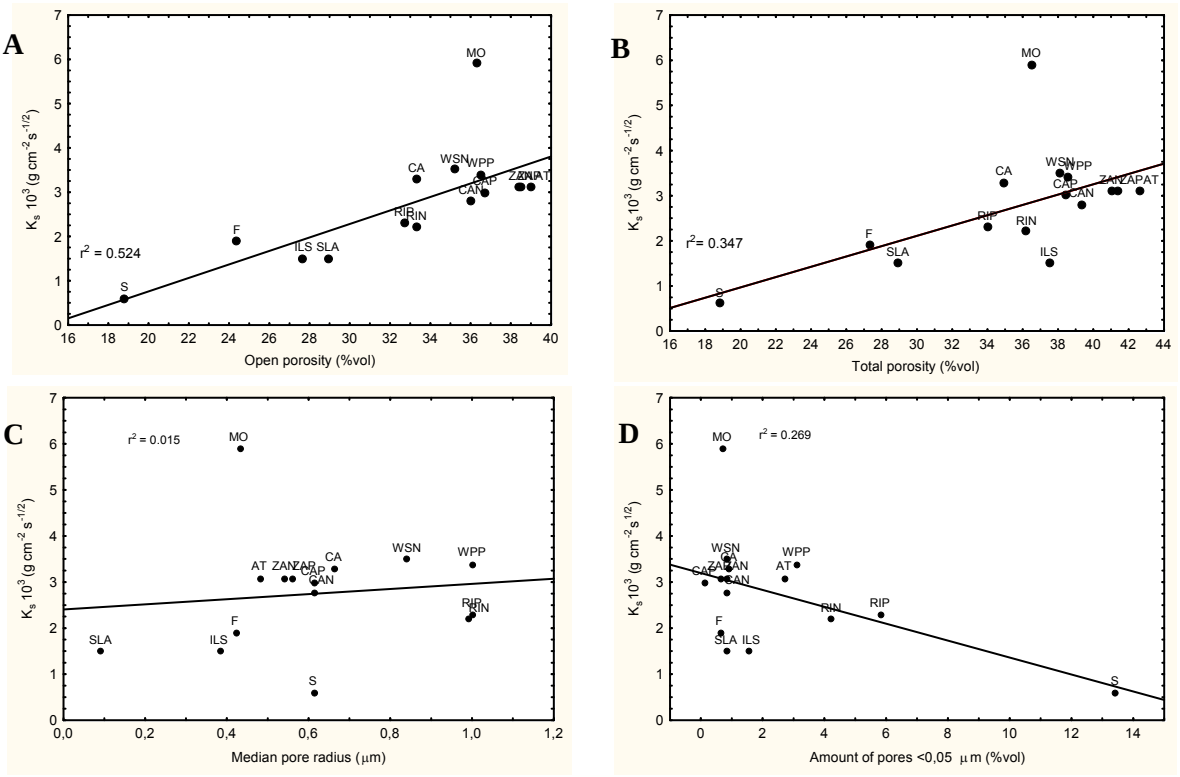

Figure 2. Experimental capillary coefficient K_s vs. (A) open porosity, (B) total porosity, (C) mean pore size and (D) amount of pores < 0.05 μm of clay bricks.

3.4 Predicting the Capillary Coefficient K_s

The reliability of the model proposed by Beltràn and co-workers [1988-1999] was checked introducing into the equation (3) the physical data of water at 20°C and, for each sample, the experimental values of open porosity, median pore size, water-brick contact angle (θ = 87°) and tortuosity factor as calculated in the present work. The predicted K_s values obtained range from 3.4 $\cdot 10^{-3}$ (g cm^{-2}s$^{-1/2}$) of sample SLA to 25.1 $\cdot 10^{-3}$ (g cm^{-2}s$^{-1/2}$) of sample MO (K_s*, Table 2) and their correlation with the experimental ones being illustrated in Figs. 3A and B; fitting the results by linear regression, the straight line going through the origin (r^2 = 0.692) provides the following relationship: the value of the capillary coefficient K_s^* predicted on the basis of equation (3) has to be multiplied by 0.212 to obtain the experimental one so that the real suction kinetics of all samples is proved to be lower than expected on the basis of model.

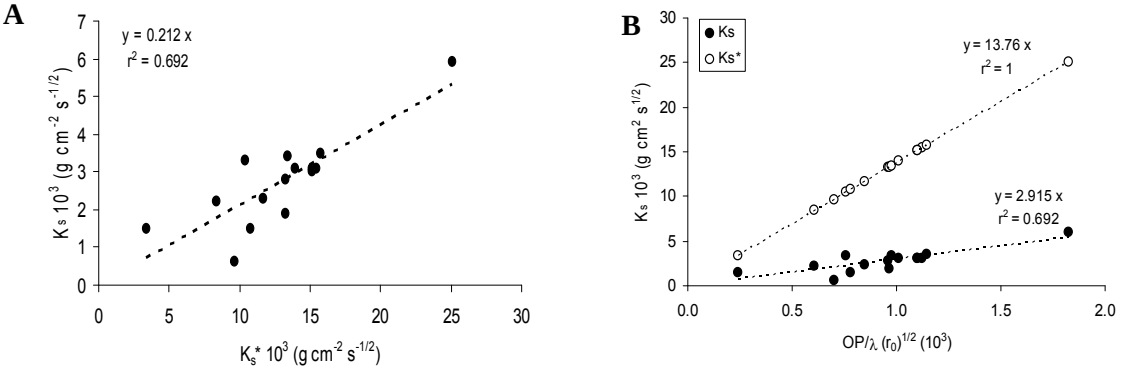

Figure 3. (A) The experimental K_s vs. the predicted K_s* values of capillarity coefficient and (B) the capillary coefficients vs. the term OP/λ□$(r_0)^{1/2}$.

Focusing our attention on these aspects, both predicted and experimental values of the capillary coefficient were plotted as function of the term OP/λ $(r_0)^{1/2}$ (Fig. 3B); the linear fitting provides straight lines having, respectively, the form:

$$K_s = 2.915 \frac{OP}{\lambda} (r_o)^{1/2} \qquad (r^2 = 0.692) \tag{8}$$

and

$$K_s^* = 13.760 \frac{OP}{\lambda} (r_o)^{1/2} \qquad (r^2 = 1) \tag{9}$$

The ratio between the slope values (2.915/13.760 = 0.212) coincides with the slope of the straight line fitting the experimental/predicted K_s relationship. Moreover, the slope value of equation (8) must correspond to the term: $\rho(\frac{\gamma}{\mu})^{1/2}[\cos\vartheta/2]^{1/2}$ which, considering constant the physical data of water at 20°C, provides the value of the water-brick contact angle fitting the experimental results: θ = 89°, very similar to the experimental average value (θ = 87°) utilized in the present work.
Looking back at equation (8) and Fig.3B, it is reliable to conclude that, besides some exceptions, the Beltràn's model is sufficiently satisfied: for the same value of open porosity, decreasing the pore size and/or increasing the pore tortuosity means to limit the suction rate and, hence, the capacity of clay bricks of absorbing moisture. At any event, this also means that, varying in a controlled way the product $OP/\lambda\ (r_0)^{1/2}$, it could be possible to design clay bricks having a more suitable suction behaviour and, at least, to bound the structural deterioration of masonry optimizing the performance of its components.

3.5 Capillary Suction vs Phase Composition

During firing, the decomposition of $CaCO_3$, with the formation of Ca-silicates by reaction with the clay minerals and release of CO_2, promotes a greater amount of porosity; theoretically, this circumstance it is expected to cause higher values of K_s as it is somehow confirmed (Fig. 4A). On the other hand, the amount of amorphous phase, together with the low sintering degree achieved at the brick firing temperature (900-1000°C), involve the presence of a smaller porosity, which, in turn, seems to be a restriction to the liquid suction phenomenon (Fig.4B).

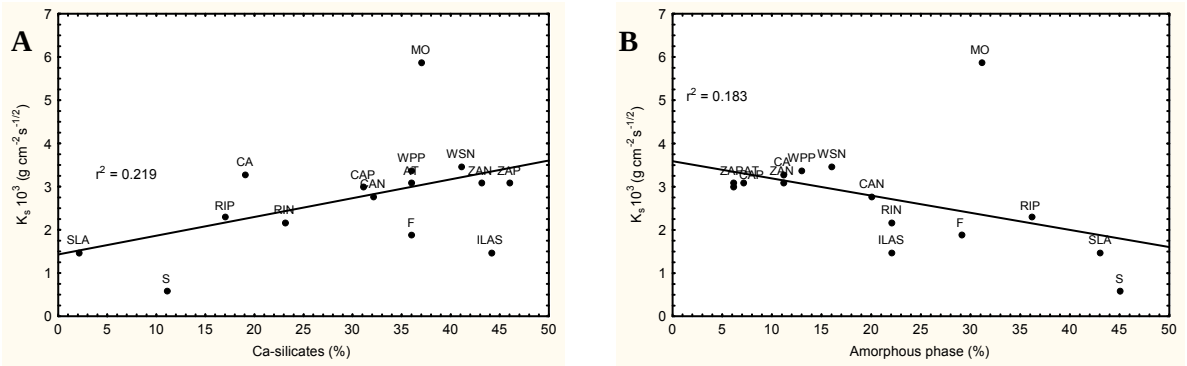

Figure 4. Experimental capillary coefficient K_s vs. amount of (A) Ca-silicates and (B) amorphous phase of clay bricks.

A statistical treatment of data was also undertaken through the extraction of the principal components: in the procedure, the amount of Ca-silicates and amorphous phase, other than K_s, were also considered as variables in addition to the microstructural ones (OP, TP, r_0, P50, P3, SS, λ). The positive or negative influence of each variables on K_s clearly stands out when the factorial weights are plotted grafically (Fig. 5): a higher porosity, in terms of both open and total values, makes the liquid uptake faster. The restrictive role played by the amount of micropores and the amorphous phase on the water

suction rate is also underlined by the statistical procedure, as well as the opposite role played by the new formed Ca-silicates.

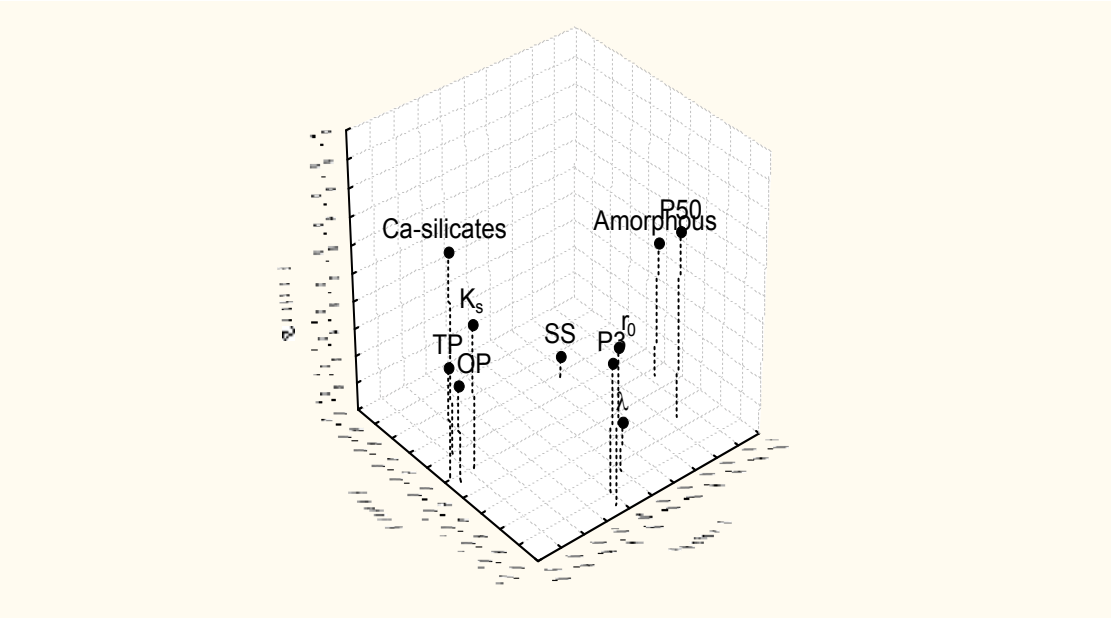

Figure 5. Principal components analysis: factors extracted.

4 CONCLUSIONS

On he whole, the suction behaviour of clay bricks follows the models of Gummerson et al. [1981] and Hoffmann et al. [1988]; however, they do not provide any information about the liquid-solid interactions, so that no prediction of the material behaviour in working conditions can be done. The suction capacity of bricks, in fact, is expected to depend on their microstructural characteristics, in particular, amount, size and shape of pores. Besides some exceptions, the linear relationships between the capillary coefficient K_s and these microstructural variables substantially confirm the role played by open porosity in increasing the absorption capacities of clay bricks, while the influence of pore characteristics on the suction kinetics does not clearly stand out.
The values of the capillary coefficient K_s were also calculated on the basis of Beltrán model [1988], whose effectiveness in predicting K_s values proved to be quite good. This means that, varying in a controlled way the term $OP/\lambda\ (r_0)^{1/2}$, it is possible to design materials having a predictable suction behaviour, hence to bound the damages in terms of structural deterioration. The capillary coefficient K_s, together with the microstructural variables and phase composition, finally underwent a statistical procedure that confirmed the influence of porosity, as well as of a coarser pore dimension (in terms of both radius and percentage of pores greater than 3 μm) in increasing the liquid adsorbing rate with the highest statistical significance. In addition, the sintering pattern of products, leading to a different amorphous/crystalline phases ratio, proved to be relevant on the definition of the most suitable microstructure: the higher porosity, promoted by the complete $CaCO_3$ decomposition, and the smaller pore size, connected with the low sintering degree of clay bricks, work in the opposite way.

ABSTRACT

The moisture tolerance of building assemblies is becoming a major durability issue worldwide because it is almost impossible to create perfectly tight building assemblies. Alerted by numerous cases of severe moisture damage caused by rain water penetration through stucco clad walls in North-America, the American Society of Heat Refrigeration and Air-conditioning Engineers (ASHRAE) has recently put out a standard on moisture design criteria for public review. This new standard forms the basis for hygrothermal performance evaluations by numerical simulation that should ultimately lead to better moisture control in buildings. In this paper the moisture behaviour of stud walls with leaks in the exterior thermal insulation system (EIFS or ETICS) is simulated by applying the procedure described in the ASHRAE standard. In a parametric study the different assembly modifications and outdoor climate conditions in North America and Europe are considered. The results show severe problems dealing with exterior insulation systems based on polystyrene insulation. Only in some cases increasing the drying potential toward the interior by replacing the vapour barrier by a smart retarder helps to solve the problem. However, when the polystyrene insulation is exchanged by mineral wool the penetrating rainwater rapidly dries out through the exterior insulation system and the humidity conditions in the wall always remain below the critical threshold.

1 INTRODUCTION

Approximately 50 years ago, the first exterior wall insulation systems – nowadays called **E**xternal **T**hermal **I**nsulation **C**omposite **S**ystems (ETICS) in Europe and **E**xterior **I**nsulation **F**inish **S**ystems (EIFS) in North America – were installed on buildings. Despite being exposed to higher hygrothermal loads than most façade systems, EIFS on concrete or masonry have a satisfactory track record in Europe. They seem to be at least as durable as conventional façades with render or stucco [Künzel et al. 2006]. However, there is only little long-term experience concerning the application of EIFS on wood frame structures in Europe where these systems are increasingly installed to alleviate thermal bridging caused by the framework or to retrofit existing buildings. Therefore, it makes sense to analyze the situation in North America where EIFS on wooden structures have a mixed track record due to numerous failures related to elevated moisture in the construction. Since it is unlikely that the reported damage cases will remain confined to North America, this paper focuses on investigating the hygrothermal behaviour of EIFS on wooden structures under selected climate conditions in America, and Europe.

2 INTERNATIONAL EXPERIENCES

2.1 Composition of EIFS (ETICS)

EIFS in North America usually closely resemble those in Europe. The original composition – recent versions may also include a drainage layer – of an EIFS is shown in Figure 1. The EIFS is glued or mechanically fastened to the exterior sheathing that might consist of OSB, plywood, gypsum sheathing or wood fibreboard. Expanded Polystyrene (EPS) normally serves as insulation material. The use of mineral fibre insulation, also quite common in Europe, is practically unknown in North America. On top of the insulation a polymer modified base coat including a reinforcing glass fibre mesh are applied, followed by a finish coat. The reinforced base coat together with the finish or top coat is called lamina which is usually approximately 5 mm thick.

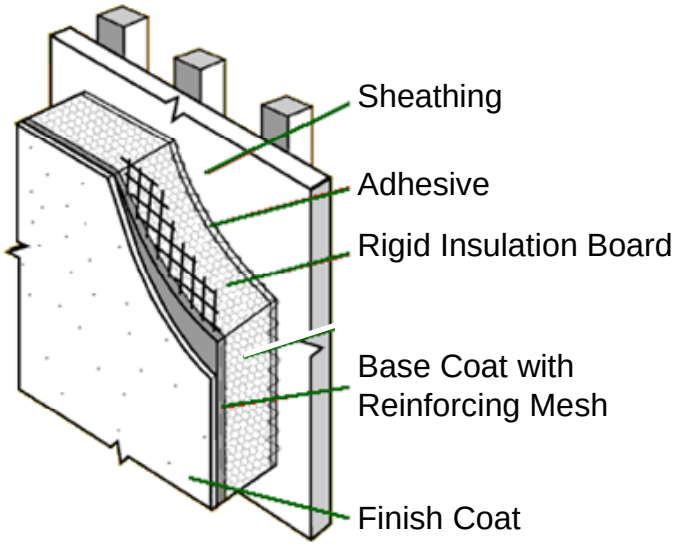

Figure 1. Composition of a typical **E**xterior **I**nsulation **F**inish **S**ystem

2.2 Damage Cases in North America and Lessons Learned

In the middle of the 90s the first substantial damage cases associated with EIFS were reported from North Carolina [Crandell & Kenney 1996] and similar reports from other regions with high precipitation intensities (e.g. Seattle, Vancouver) followed [Desjarlais et al. 2001]. Usually moisture

problems occurred mostly at the exterior sheathing boards that served as substrate for the EIFS. Pictures of rotten OSB or disintegrated gypsum board quickly spread among the building community and forced manufactures to react [Nisson & Best 1999]. A comprehensive literature review of Cheple & Huelman [2000] analysing more than 10 investigations carried out on several objects each, comes to the following conclusions: The main reasons for moisture damage are leaks around windows and joints where rainwater penetrates beneath the insulation layer. However, problems due to air convection or diffusion of indoor air may also have caused elevated moisture in some cases. An aggravating factor is the low drying potential of the construction. Moisture can neither dry-out quickly to the exterior because of the vapour retarding foam insulation nor to the interior due to the usual presence of a polyethylene vapour barrier. The solutions proposed by Cheple & Huelman [2000] are limited to managing rain water penetration by proper sloping and flashing of joints and wall openings and by applying drainable insulation systems. Sheathing materials such as untreated gypsum board, are very sensitive to moisture uptake and hence are considered inappropriate as EIFS substrates. Other work has shown that enhancing the drying potential towards the interior spaces by an innovative vapour control strategy may also alleviate the problem [Karagiozis & Kumaran 1997].

The moisture problems that occurred on North American constructions in the 90s were not limited to walls having EIFS. Buildings with normal stucco façades (render applied on building paper over OSB or plywood) were also affected [Lawton 1999]. This resulted in a new design approach that aimed at better detailing to reduce rainwater penetration and at increasing the drying potential of the whole assembly. It has been realized that it is difficult to set-up a perfect building that will never leak. Therefore the building envelope should be designed in such a way that small leaks can be handled. Consequently the ASHARE Standard 160 [2006] on criteria for moisture design states that in the absence of performance proofs it should be assumed that 1% of the wind driven rain hitting the façade is deposited on the weather resistive barrier (WRB) behind the cladding. If there is no WRB, another layer should be selected where the penetrating rainwater is likely to go (e.g. the sheathing beneath the EIFS in Figure 1).

2.3 Experiences with EIFS (ETICS) in Europe

EIFS (ETICS) in Europe have a track record of about 50 years. More than 40 million square meters of EIFS are installed on new and existing buildings every year in Germany and severe problems or damage cases have been rare [Künzel et al. 2006]. In contrast to North America where EIFS are mainly considered as a finish system, the purpose of EIFS in Europe is to provide adequate thermal performance of external walls that usually consist of masonry or poured concrete. Therefore the average insulation thickness is higher in Europe (approx. 100 mm in 2006) than in the U.S. (25-50 mm). EIFS in Europe require a Technical Approval as a system that ensures harmonized system components and trained installers. However, it is doubtful that better quality control and workmanship alone can explain the huge difference in past performance of EIFS between Europe and North America. An important reason is probably the sensitivity of the substrate. While concrete and masonry readily absorb and redistribute small quantities of leakage water without any signs of degradation, the same amount of water may severely damage typical sheathing materials such as OSB or gypsum board that are used in wood frame walls in North-America. Since EIFS have more recently been applied to wooden wall structures in Europe as well, there may also be an increase in moisture problems such as those described by Schulze & Radovic [1992] and by Schumacher [2006]. Therefore it makes sense to investigate the moisture tolerance of wooden structures with EIFS for European construction types and climate conditions in order to prevent moisture-related problems.

3 HYGROTHERMAL SIMULATIONS

The transient temperature and moisture distributions in external wall assemblies with EIFS are calculated using version 4.1 of the hygrothermal simulation model WUFI® [Künzel 1995] which has been validated many times by comparison with experimental building envelope investigations

including measurements on wall structures with EIFS (e.g. [Künzel 1998a]). In order to cover North American and European building practice the following wall assembly has been selected.

- EIFS: 10 mm lamina (exterior rendering) on 60 mm EPS
- Sheathing: 15 mm OSB
- Cavity insulation: 160 mm glass fibre batts
- Vapour retarder: polyethylene film (s_d = 20 m) or polyamide film (0.1 m < s_d < 5 m)
- Interior panelling: 12 mm gypsum board (installation gap 40 mm)

The material properties are taken from the WUFI® database. The polyethylene (PE) film represents a standard vapour retarder with a diffusion resistance (s_d) of 20 m which is equivalent to 0.16 U.S. perm. The polyamide (PA) film is a humidity controlled vapour retarder whose diffusion resistance varies with ambient humidity conditions [Künzel 1998b]. It has been developed to enhance the drying potential of building assemblies [Künzel 2005]. The colour of the exterior stucco is assumed to be bright (solar absorptivity 0.4).

3.1 Selected Locations and Loads

The first location considered is North Carolina where the EIFS problems started. As representative weather conditions the meteorological data for a cold year in Wilmington are selected from the WUFI® climate database. For Europe a sample of four locations is chosen: Hannover in the middle of Germany's Northern plain, Lisbon at the Atlantic South-West Coast of Europe, Locarno in the Southern part of the Swiss Alps and Vienna at the edge of the East-European plain. The average temperatures and humidities as well as the annual sum of wind driven rain hitting the middle of a low-rise building at the most exposed orientation are displayed in Table 1 for all selected locations. While the average relative humidity does not differ much from one location to the other, the average temperatures range from approximately 17°C to 25°C in summer and from 0°C to 10°C in winter. Hannover is the coldest place and Wilmington and Lisbon, which are the warmest locations, experience the highest wind driven rain loads.

Table 1. Driving rain load at the surface of the most exposed façade orientation and average hygrothermal conditions at the selected locations in North America and Europe.

Location	Driving rain load (façade orientation)	Rel. Humidity	Temperature (annual/monthly mean)		
		(Annual mean)	Year	January	July
Wilmington	186 l/m²a (S)	73%	16,1 °C	5.7 °C	24,9 °C
Hannover	160 l/m²a (W)	80%	8,6 °C	-0,1 °C	17,1 °C
Lisbon	193 l/m²a (W)	75%	15,6 °C	9,8 °C	20,7 °C
Locarno	133 l/m²a (E)	72%	11,5 °C	2,1 °C	22,2 °C
Vienna	112 l/m²a (W)	73%	10,4 °C	0,1 °C	20,6 °C

The hygrothermal simulations which begin in October of the representative year are continued over a period of three years by repeatedly running through the same meteorological data-set. The initial conditions in all material layers of the building assembly are set to EMC_{80} (equilibrium moisture content at 80% RH). If rainwater penetration through imperfections cannot be ruled out, 1% of the wind driven rain load from Table 1 is deposited on the exterior surface of the OSB sheathing. In practice rain water will penetrate at joints or windows. Leaks will therefore be concentrated at these locations. However for the purpose of a one-dimensional analysis it is assumed that penetrating rainwater will be evenly distributed over the entire surface of the wall's OSB sheathing.

4 SIMULATION RESULTS

The North American damage cases have shown that the substrate layer, to which the EIFS is applied, experiences the most critical moisture conditions in the assembly. Therefore the moisture content of the OSB sheathing is monitored in the present study. Moisture contents below 20 M-% are considered to be safe, i.e. the OSB will not face any moisture-related durability problems. Figure 2 displays the temporal changes in OSB moisture content (average over the thickness of the OSB) under three different scenarios. Assuming perfect workmanship (no leaks) results in permanently dry conditions (MC < 13 M-%) no matter what vapour retarder is applied to the interior side of the stud wall. If rainwater leaks are present the OSB moisture content will rise in wintertime with extended drying spells in summer. However, when there is only very little vapour diffusion towards the interior because of the rather impermeable vapour retarder (PE-film), the drying potential is limited and long-term moisture accumulation may occur (MC > 25 M-% after 3 years). By replacing the PE-film with the humidity controlled PA-film the drying potential is enhanced enough to assure long-term OSB moisture conditions below 18 M-%.

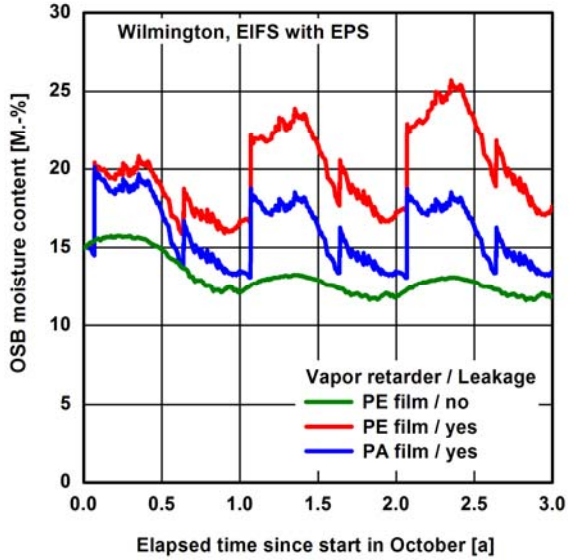

Figure 2. Temporal changes in simulated moisture content of the OSB sheathing beneath the EIFS in Wilmington for the standard case with and without rainwater leakage and with a PA-film replacing the PE-film as vapour retarder of the stud wall.

When the simulations are repeated for the coldest location considered (Hannover), a different picture develops (Figure 3). As was shown in the previous case for Wilmington, when there is no leak there is no problem. However, when there is a leak the OSB moisture content will repeatedly exceed 20 M. -% even if the dying potential to the interior is enhanced by the PA-film. An explanation for the different behaviours obtained from building assemblies investigated under different climate conditions lies in the divergence in vapour gradients. The high summer time temperatures in Wilmington result in a considerable inward vapour drive making efficient use of the drying potential provided by the humidity controlled vapour retarder. Without such a strong inverse vapour pressure gradient the drying rate towards the interior cannot compensate the rainwater leakage and damage may occur.

A good indicator of potential problems is the maximum OSB moisture content attained during the 3rd year of the simulation period. In order to be on the safe side, it should not exceed 20 M. -%. That means if rainwater penetration through imperfections is assumed, enhancing the drying potential towards the interior is no solution for Hannover. However it may help to enhance the drying potential towards the exterior by replacing the EPS insulation of the EIFS with high-density mineral wool slabs (MW). This kind of insulation material, largely unknown in North America, is widely used for EIFS in

Europe. Its thermal conductivity is very similar to that of EPS but its vapour permeability is very high. When such a system is applied to a stud wall in Hannover, the OSB moisture content remains well below 20 M.-%, even if the predefined rain water penetration occurs. The simulation results of all European locations are summarized in Figure 4 by comparing the maximum moisture content in the OSB sheathing during the third year. The best solution with the lowest OSB moisture content at all locations provides the choice of mineral wool (MW) as EIFS insulation material. However, all variants seem to work in Locarno and Vienna where the annual wind driven rain load is less than 140 l/m²a. In Lisbon the situation is comparable to Wilmington, i.e. enhancing the drying potential towards the interior by employing a humidity controlled vapour retarder appears to be sufficient.

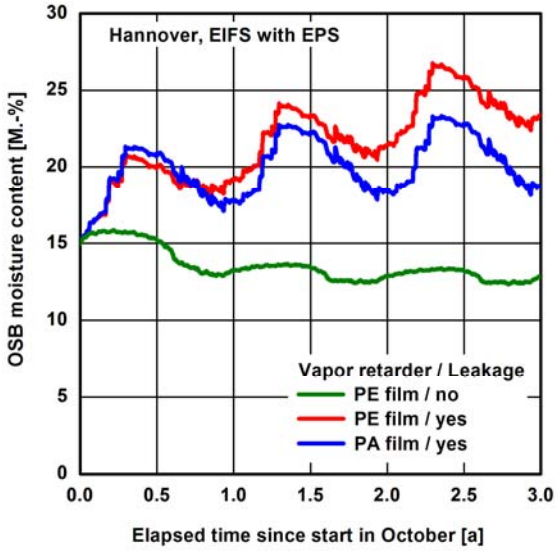

Figure 3. Temporal changes in simulated moisture content of the OSB sheathing beneath the EIFS in Hannover for the standard case with and without rainwater leakage and with a PA-film replacing the PE-film as vapour retarder of the stud wall.

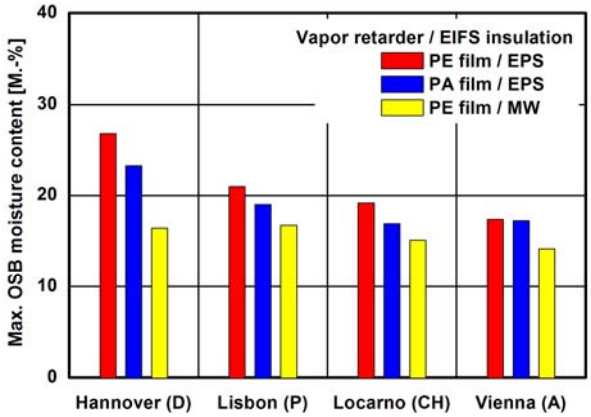

Figure 4. Maximum moisture content of the OSB sheathing during the simulated 3-year period at different European locations depending on the vapour retarder of the stud wall and the insulation material of the EIFS.

4 SUMMARY AND CONCLUSIONS

The results show that EIFS on lightweight structures pose no moisture problem when the detailing of joints and openings is well done, i.e. there is no rainwater leakage. This holds for all locations investigated. However, if water leakage cannot be completely excluded and therefore the North-American Standard assumptions - penetration of 1% of the driving rain load - are applied this picture

changes. Now, the drying potential of such wall assemblies becomes an essential feature to consider in the design process of the wall. Normal EIFS composed of vapour retarding EPS insulation slabs cannot provide much drying towards the exterior and may therefore be responsible in part for increasing the risk to moisture damage for the underlying substrate.

The application of a humidity controlled vapour retarder (PA-film) instead of a conventional polyethylene film at the interior side of the building assembly enhances the overall drying potential of the construction by allowing some vapour diffusion towards the interior spaces. However the use of such a vapour retarder should only be considered as a solution for warmer locations, such as Wilmington, North Carolina, or Lisbon where the enhancement of the drying potential may be sufficient to compensate the water leakage. Colder climates require additional measures or other solutions. The best, but also most expensive, solution for reducing the risk to moisture related problems in EIFS wall assemblies would be to replace the expanded polystyrene (EPS) by high-density mineral wool insulation slabs.

Alternative ways of solving the rainwater penetration problem are currently being developed and tested in North America. Some systems provide a drainage plane between the substrate and the EIFS as well as special devices to force out the water at the bottom. Initial tests of these drainable EIFS have shown encouraging results [Onysko & Thivierge 2007]. Other systems keep the face seal approach and rely on sophisticated detailing with improved sloping and flashing of openings and joints. In both cases the long-term performance is still unknown. In order to avoid a repetition of the North American problems with EIFS applied to wood frame structures, it is important to communicate this issue and possible solutions to the European construction trades. Hygrothermal simulations may help to raise the awareness to the risks of damage and the importance of qualified workmanship involved in the application of EIFS especially for locations with high wind driven rain loads.

Daily Hygroscopic Inertia Classes: Application in a Design Method for the Prevention of Mould Growth in Buildings

Nuno M. M. Ramos [1]
Vasco P. de Freitas [2]

T 33

ABSTRACT

The persistence of high relative humidity values inside buildings favours mould growth on material surfaces, causing their degradation and bringing about social and economical problems for the users. Heating and ventilating are fundamental actions for the control of humidity in the indoor environment, but the hygroscopic inertia provided by the materials that contact the inside air can be a complement for that control.
As the hygroscopic inertia concept can be very difficult to approach for building designers, a definition of daily hygroscopic inertia classes is presented, based on numerical and laboratory work on this subject.
An outline of a simple method, using those classes, that allows for the evaluation of the reduction of mould growth potential associated to a configuration of inside finishes is proposed.
The method is then used in several hygrothermal scenarios to illustrate how different values of hygroscopic inertia can contribute to the prevention of mould growth in buildings. The analysed scenarios also contribute to a sensitivity analysis of the influence in relative humidity of several parameters such as outside climate, ventilation, vapour production, heating, solar gains and envelope quality combined with hygroscopic inertia.

1 INTRODUCTION

Relative humidity (RH) inside buildings can influence thermal comfort, the perceived air quality (PAQ), users' health, building materials durability and energy consumption. This dependency has been established by science but the common user will not always recognize it. Mould growth on building element's surfaces, on the other hand, is easily associated with the persistence of high RH levels even by users and can be tied not only to durability but also to PAQ and health. The relevance of this pathology is one of the motivations for the heat and mass transfer research reported in this article.

The prevention of mould growth in building elements will greatly depend on the control of RH conditions. These are a function of exterior vapour pressure, ventilation, vapour production, hygroscopic inertia and inside temperature. Most of these factors can be easily combined and analysed to predict RH variation in time. Hygroscopic inertia, on the contrary, is a poorly defined concept and, as a consequence, usually ignored by building designers. The recent IEA Annex 41 research project (http://www.kuleuven.ac.be/bwf/projects/annex41/), which included the authors' participation, tried to enhance the knowledge on this subject.

This text defines daily hygroscopic inertia classes and proposes their implementation as an easy way of including the building materials moisture storage capacity influence on RH variation and mould growth risk analysis. A proper selection of interior finishes can obviously benefit from that inclusion. In the next sections a description of daily hygroscopic inertia classes can be found, followed by the selected method of mould growth risk assessment. A set of numerical simulations of a room's hygrothermal behaviour is developed in order to illustrate an evaluation method of the influence of inside finishes configuration in mould growth risk.

2 HYGROSCOPIC INERTIA CLASSES

2.1 Principle

A method of bringing the hygroscopic inertia concept closer to practitioners has been developed and experimentally evaluated by Ramos [2007]. The basic idea, illustrated in Fig. 1, is to have a prediction tool that can establish a relation between the moderation of the RH variation in a room and its hygroscopicity level, which is mainly dependant on the surface finishing materials.

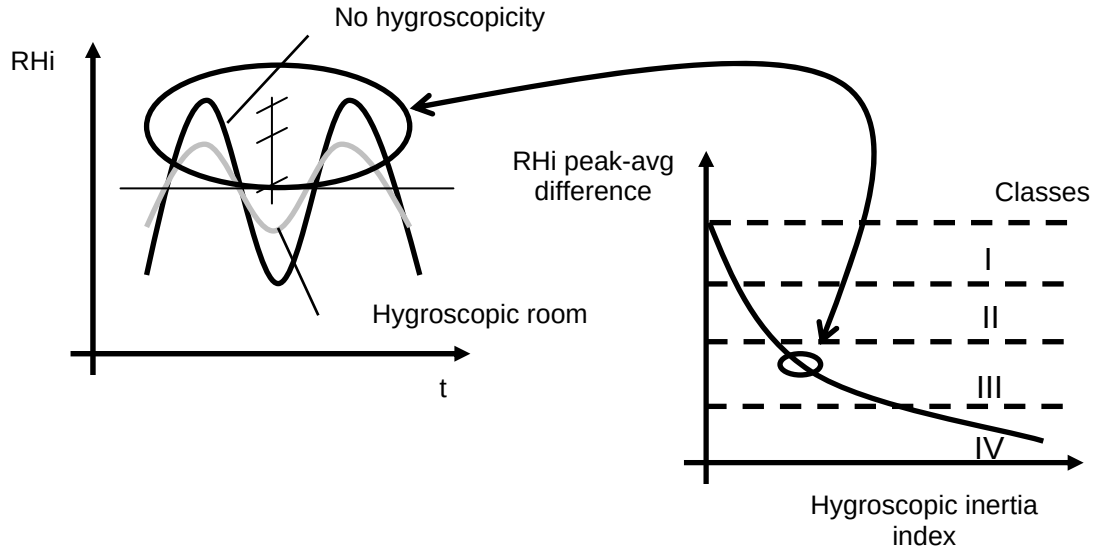

Figure 1. Hygroscopic inertia class's definition principle

2.2 Daily Hygroscopic Inertia Index

According to the principle established in the last section, a hygroscopic inertia index was defined as a single number, representing the hygroscopic inertia of a room and that can correlate to the expected reduction of the RH fluctuation. It was decided that this index should concentrate only on daily cycles and it should be derived from room configuration and known material properties.

The MBV – Moisture Buffer Value was the selected material/element property thus acting as a base for that index definition. MBV is a recently developed property [Rode et al, 2005] and it represents the amount of moisture buffered by a specimen with only one open surface exposed to a square RH variation. Cyclic climatic exposures should consist of 8h of high relative humidity, followed by 16h of low relative humidity. This test tries to replicate the cycle seen in bedrooms. The low relative humidity can be 33% and the high relative humidity 75%, for a constant temperature of 23ºC. The cycles are repeated until the specimen weight over the cycle varies less than 5% from day to day. A numerical example of MBV assessment, mocking the experimental procedure, is presented in the section 3.2 of this paper.

MBV can be obtained as a material or element property. For the purpose of this paper, it's always considered as an element property. This means that, for example, a 2 cm thick gypsum render, painted with a primer and an acrylic coating can be characterized with its MBV.

The proposed daily hygroscopic inertia index, $I_{h,d}$, is defined by Ramos [2007] as a function of MBV, according to expression (1), where MBV_i = Moisture buffer value of element i (g/(m^2.%RH)); S_i = surface of element i; MBV_{obj} = Moisture buffer value of complex element j (g/%RH); C_r = Imperfect mixing reduction coefficient (-); N = air exchange rate (h^{-1}); V = room volume (m^3); TG = Vapour production period (h). The $I_{h,d}$ can be understood as the room MBV, homogenized to air renovation conditions and vapour production period variations.

$$I_{h,d} = \frac{\sum_{i}^{n} C_{r,i} \cdot MBV_i \cdot S_i + \sum_{j}^{m} C_{r,j} \cdot MBV_{obj,j}}{N \cdot V \cdot TG} \rightarrow \left[\frac{g}{m^3 \cdot \%HR}\right] \quad (1)$$

2.2 RH Variation Evaluation

The evaluation of a RH variation curve in time should be based on a single number, keeping in mind the principle described in section 2.1.

The AMDR parameter was defined according to expression (2), where HR_m is the average relative humidity variation and $\overline{HR_{90}}$ stands for the daily average of the 90th percentile of the relative humidity variation. The index *ref* refers to the base scenario of a room without hygroscopicity and *sim* identifies a scenario under study for that same room. The AMDR parameter can therefore be interpreted as relative daily average amplitude of a RH variation of a room hygroscopic configuration. This parameter is interesting since the average RH variation in long-term analysis will not be affected by daily hygroscopic inertia.

$$AMDR = \frac{\left(\overline{HR_{90}} - HR_m\right)_{sim}}{\left(\overline{HR_{90}} - HR_m\right)_{ref}} \quad (2)$$

2.3 Classes Definition

The selected parameters were proven by Ramos [2007] to be connected by expression (3). The resulting curve supports the definition of daily hygroscopic inertia classes, according to Fig. 2, and the limits defined in Table 1.

$$AMDR = \frac{1}{0{,}00998 + 0{,}0793 \cdot I_{h,d}^{1{,}16}} \% \tag{3}$$

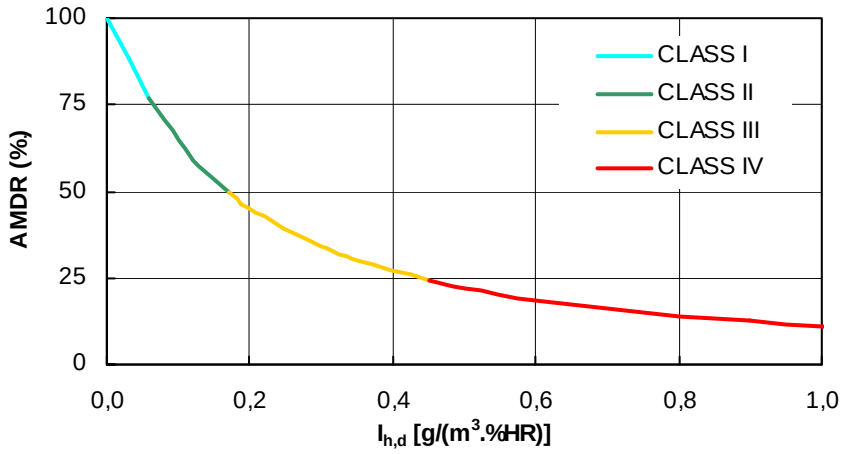

Figure 2. Graphic relation between AMDR and $I_{h,d}$

Table 1. Daily hygroscopic inertia classes limits

CLASS I	$0 \leq I_{h,d} < 0.06$	$100\% \geq AMDR > \sim 75\%$
CLASS II	$0.06 \leq I_{h,d} < 0.17$	$\sim 75\% \geq AMDR > \sim 50\%$
CLASS III	$0.17 \leq I_{h,d} < 0.45$	$\sim 50\% \geq AMDR > \sim 25\%$
CLASS IV	$0.45 \leq I_{h,d}$	$\sim 25\% \geq AMDR$

3 NUMERICAL SIMULATION

3.1 Purpose

A decision was made to numerically simulate the behaviour of a room and the moisture buffer capacity of the materials used in the room simulation. This provided data that can illustrate the desired relation between hygroscopic inertia and room configuration.

3.2 Numerical Model

The authors chose to use for these simulations the software program HAM-Tools [Kalagasidis 2004]. The International Building Physics Toolbox, is a software library specially constructed for HAM system analysis in building physics.
As part of IBPT, HAM-Tools is open source and publicly available on the Internet. The library contains blocks for 1-D calculation of Heat, Air and Moisture transfer through building materials. The toolbox is constructed as a modular structure of the standard building elements using the graphical programming language Simulink. All models are made as block diagrams and are easily assembled in a complex system through the well-defined communication signals and ports.

3.2 MBV Simulations

An assembly of HAM-Tools modules was used for simulating the MBV experiment. The simulations were performed using the virtual specimens listed in Table 2. The data for the chosen materials used in the simulations was retrieved from Kumaran [1996]. The different β (convective water vapour transfer coefficient) values used represent the possibility of coatings with different additional vapour resistances applied in the gypsum board specimens.

Table 2. Virtual specimen's characteristics

Specimen	Material	β (s/m)	Thickness (m)
1	Gypsum board	2e-8	0.01
2	Gypsum board	2e-9	0.01
3	Gypsum board	2e-10	0.01
4	Spruce	2e-8	0.01

In Figure 3, the mass variation of all the specimens in the steady cycle is presented. The MBV for each specimen is also presented in Table 3. As we can see, this number, when associated to the tested elements, provides the means to compare them. But as it was said before, this number is used ahead for hygroscopic inertia analysis.

Table 3. MBV for the four specimens tested

Specimen	1	2	3	4
MBV(kg/m^2)	0.0971	0.0366	0.0045	0.0832

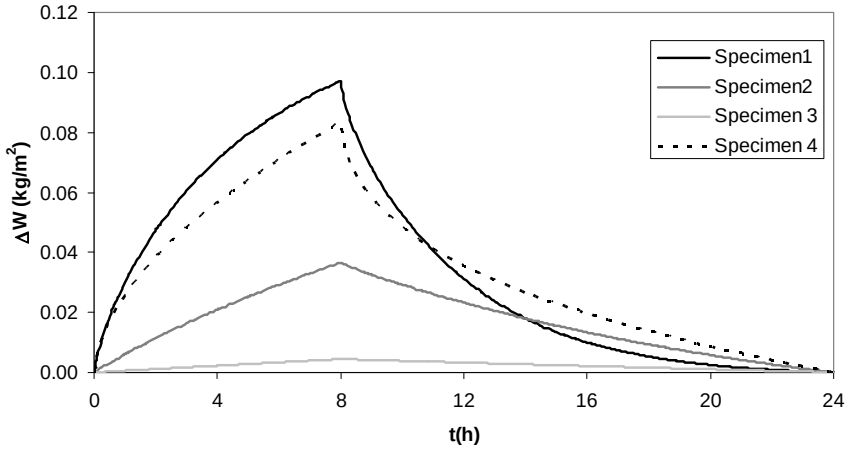

Figure 3. Moisture content variation of all the specimens in a stable cycle

3.3 Room Simulations

A different HAM-Tools modules association allowed for the simulation of a room's hygrothermal behaviour in yearly cycles. The virtual room is 3.5x3.5x2.5 m^3, with one exterior wall, containing a 1 m^2 window, facing south. The surrounding rooms are assumed to have similar conditions of temperature and relative humidity as the simulated room. The climate conditions were defined for Lisbon, using Meteonorm software. The inside temperature was allowed to float between Tmin and 28 ºC, and RH was allowed to float below 90%. The ventilation rate is constant and the vapour production takes place between 0h and 8h, with a constant value. On walls and ceiling the admitted material was gypsum board and on the floor spruce. Tables 4 and 5 describe the conditions that were changed for each simulation. It can be easily inferred that the room configuration in the first line of Table 5 stands for the room with no hygroscopic inertia, the reference room.

Table 4. Hygrothermal parameters adopted in simulations

Simulations	Tmin (ºC)	G (g/h)	N (h^{-1})
SG1-SG2	18	100	1.0
SG11-SG12	18	150	1.0
SG15-SG16	15	100	1.0
SG19-SG20	21	100	1.0
SG23-SG24	18	100	0.67
SG27-SG28	18	100	0.33

Table 5. Room configurations

Partial results from simulations SG1 and SG2 are presented in Fig. 4, illustrating the tested scenarios.

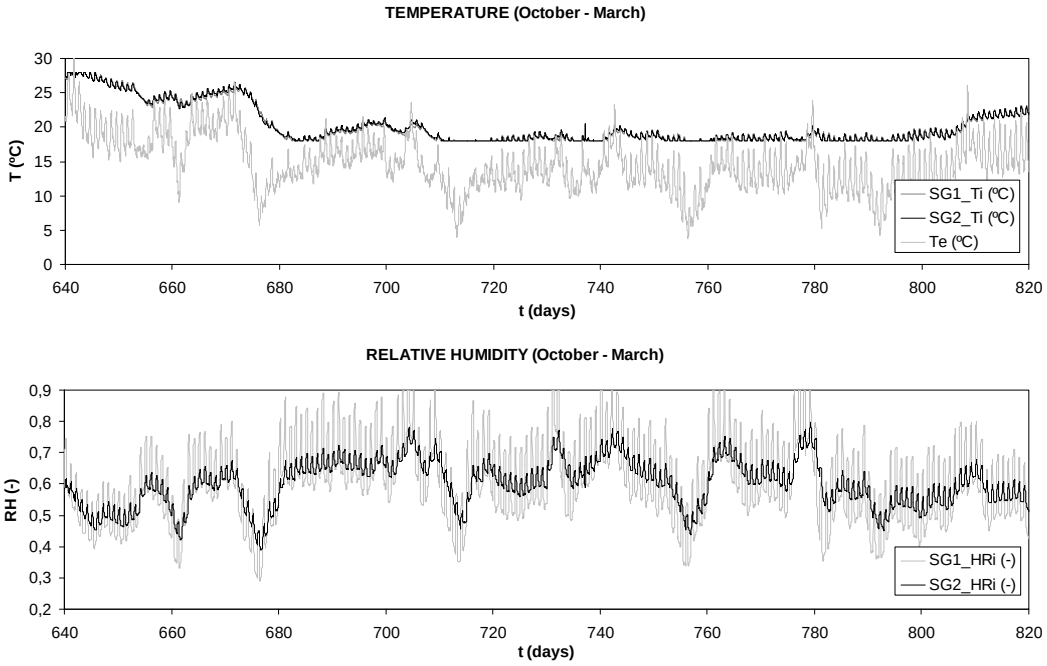

Figure 4. Results from simulations SG1 and SG2

3.3 Hygroscopic Inertia Analysis

The application of the method from section 2 allows for the definition of parameters AMDR and $I_{h,d}$ corresponding to the simulation scenarios. The values obtained are presented in Table 6, and reveal that the scenarios hygroscopicaly active would be placed in class III-IV

Table 6. Parameters for hygroscopic inertia analysis

4 MOULD GROWTH RISK ASSESSMENT

Several authors have studied the relationship between water activity in a substrate and the development of mould on its surface [e.g. Adan [1994], Sedlbauer [2001]]. The mould development under transient conditions of temperature and humidity is highly complex. Adan [1994] proposed a model based on the TOW (time of wetness) concept to solve this problem. TOW is the quotient between the time period where the surface RH is above 80% and the total duration of the period under analysis. Using that model in several laboratory tests, there was evidence that for TOW<0,5 the risk for mould growth is very low. Using the TOW concept when simulating a room's hygrothermal behaviour it is possible to define the number of days with TOW>0,5, $nd_{tow>0,5}$, as a simplistic indicator of the mould growth risk. This approach loses accuracy if the simulations indicate actual surface condensation and the analysis tool is unable to treat that process with high precision.

Additionally, the authors use another parameter, nd_{cond}, representing the number of days when surface condensation was detected. The objective of these indicators is not to accurately estimate mould growth risk, but rather to compare hygrothermal scenarios. Using these parameters in the above simulated scenarios and imposing an additional condition of the existence of a rather extreme thermal bridge, defined by $f_{Rsi} = \frac{T_{surf,i} - T_e}{T_i - Te} = 0.5$, the results for each scenario are as presented in Fig. 4.

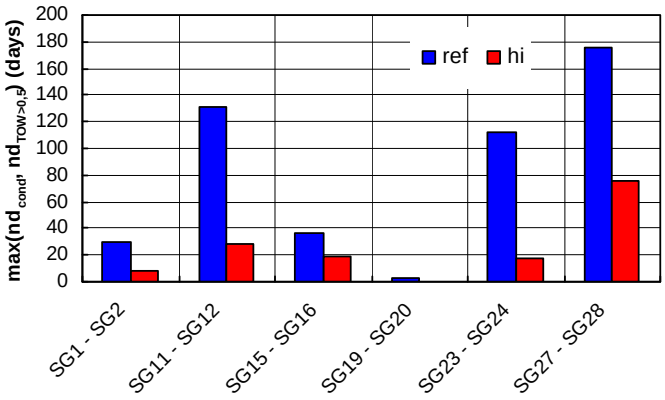

Figure 4. Mould growth risk analysis

This result shows the importance of hygroscopic inertia and the benefits that can derive from a stable RH variation with important peak reduction. A design method for the prevention of mould growth can be derived from this analysis. The method itself can have different levels of complexity. The basic idea is:

- define the risk associated with the room's RH variation for the four classes of hygroscopic inertia;
- select the adequate $I_{h,d}$ value and define the room's renderings to provide that value.

5 CONCLUSIONS

This paper presents research that allows for the following conclusions:

- The definition of daily hygroscopic inertia classes based on a room's index allows for the prediction of the RH variation amplitude;
- The MBV property can be used as an indicator of an element's contribution to the room's hygroscopic inertia;
- Mould growth risk is lower for higher values of hygroscopic inertia, admitting the same composition of the surface's final rendering;
- The design and selection of interior finishes in practice can benefit from the proposed approach to the hygroscopic inertia concept.

T 33

ABSTRACT

In this study, a durability assessment model for building envelopes design based on hygrothermal and wood rot decay analysis is presented. The durability assessment model can quantitatively predict hygrothermal conditions within the building envelopes, and progress of wood rot decay of timber frame under variable conditions. The followings are characteristics of the durability assessment models in this study. One is that development of wood rot decay is represented by a differential equation with a variable of mass loss; the other is that moisture production by wood rot decay is added into moisture balance equations. Hence, the model can assess long term performance regarding both durability and drying potential for building envelopes. Rate constants of the wood rot decay and a coefficient of the moisture production for the model are determined by the mass loss data of small wood samples in decay tests with a brown rot fungus *Fomitopsis palustris*. Additionally, progress of the wood rot decay within an external wooden wall is demonstrated.

1 INTRODUCTION

Moisture accumulation within building envelops of wood frame constructions significantly affects problems related to durability, such as wood decay, mould and termite. To avoid these moisture-related damages, various building components and wood preservatives have been developed and applied to actual constructions until recently. However, health issue for occupants, e.g. the indoor air quality, has potential to remove the chemical wood preservatives from the lumber in the building components, and energy issue such as the Kyoto Protocol has made the wood frame constructions airtight. The drying capability related to the durability of the building envelopes has consequently decreased. Therefore proper design for moisture control within the building envelopes is necessary to achieve both durable structure and healthy environment.

On the other hands, advanced hygrothermal analysis models can accurately predict temperature and moisture behavior within building assemblies under various climate conditions. The calculation results by these models [e.g. Hens 1996] are useful in design and assessment for the moisture control. Mostafa and Kumran [1999] presented an approach to develop durability assessment system that links the hygrothermal analysis model with the moisture related damages. As well Krus [2001] tried similar approach regarding the mould growth, and implemented damage analysis that integrates the hygrothermal model with the biological damage predictions. In these models, the calculated temperature and moisture profiles are applied to prediction for progression of the biological damages. However these challenges did not completely simulate decay process regarding degradation of wood substance in terms of moisture balance. Wood rot fungi that can degrade cellulose, e.g. *Sepula lacrymans* and *Coniophora puteana*, produce non-negligible moisture through the decay process. Consequently, this mechanism makes the decay process continue even though relative humidity of the surrounding air is below saturation point [e.g.Viitanen 1997]. Impacts of the moisture production on the biological prediction need to be verified in terms of safety evaluation for the wood constructions.

With these points as background, this study proposes a wood decay model to which the moisture production due to the decay process is introduced. Coefficients for the proposed model are determined by experimental data of decay tests with small wood samples. Furthermore progress of the wood rot decay in exterior wall assemblies is demonstrated to better understand the impact of the moisture production.

2 MODELING FOR WOOD DECAY CONSIDERING MOISTURE BALANCE

2.1 Hypothesis of Proposed Model

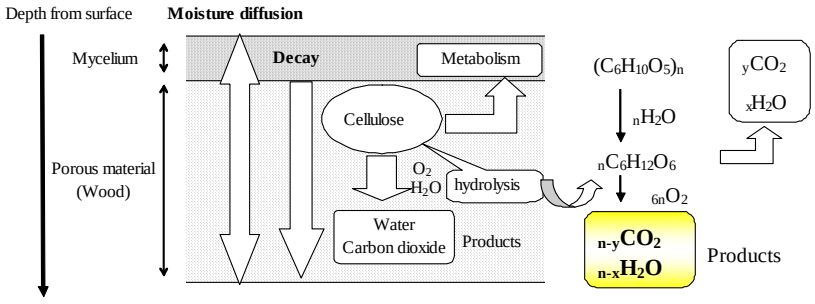

Figure 1. Scheme for wood decay and moisture transfer within the wood substance

Wood rot fungi degrade mainly cellulose within the wood substance by enzymatic reactions, and consequently produce both H_2O and CO_2 through this degradation. This wood brake down mechanism consists of two step biochemical reactions, which are hydrolysis and aerobic degradation. Both the biochemical reactions and moisture transfer occur simultaneously within the decayed wood, shown in

Figure 1. In this study, these phenomena are expressed as a numerical simulation model regarding the mass loss and the moisture content. Additionally, we define a rate constant that is determined by experiments to predict the mass loss, on the basis of deterministic un-structural model. The followings are hypothesis for the simulation model.

(1) Material properties for hygrothermal analysis are stable before and after the wood decay.
(2) Quantity of the mass loss has a single correlation with that of the moisture production by the biochemical reactions.
(3) Impacts of both O_2 and CO_2 concentrations to the wood decay can be neglected.
(4) Impacts of diversity of wood and fungus species are presented by experimental coefficients.

2.2 Progression of Wood Decay

The proposed wood decay model supposed that the progression of the mass loss is determined by hygrothermal conditions, such as temperature and relative humidity, at a control volume for finite difference analysis. The mass loss by the wood decay is defined as:

$$L = \frac{m_n - m_d}{m_n} \tag{1}$$

where L is the mass loss by the wood decay (-), m_n is the mass of the wood material before the decay, and m_d is the mass of the wood material after the decay respectively.
The wood rot fungi need liquid water to progress the mass loss based on the biochemical reactions. Thus the mass loss on the surface node of wood material progresses when the relative humidity within micro-pore is above the critical relative humidity φ_c (%RH) in Equation (2). As well, Equation (3) is applied to the progression of the mass loss at the inner node, because grown hypha of the wood rot fungi needs to reach this node for the decay progression.

$$\left.\frac{dL}{dt}\right|_{x=0} = k_m(\theta) \qquad (\varphi_i \geq \varphi_c) \tag{2}$$

$$\left.\frac{dL}{dt}\right|_{x>0} = k_m(\theta) \qquad (L_{i-1} or L_{i+1} > 0, \varphi_i \geq \varphi_c) \tag{3}$$

where t is the time (s), φ_i is the relative humidity (%RH) at the node i, φ_c is the critical relative humidity for the beginning of the wood decay (%RH), $k_m(\theta)$ is the rate constant that corresponds to a time factor for decay development by the wood rot fungus, as a function of temperature θ (^{o}C). The rate constant needs to be determined experimentally, because various conditions (e.g. wood species and hygrothermal conditions) affect development of the wood decay.
Concentration of the hypha in the each node may affect the rate constant. Gooding [1966] pointed out that growth rate of the hypha within the wood material is several millimeter per day. Thus this model assumes that the hypha concentration has already been uniformed within the node i, at the stage of beginning of the mass loss of the node $i+1$ or $i-1$.

2.3 Heat and Moisture Balance in Decayed Wood Material

Heat and moisture balance coupling the moisture production by the biochemical reactions is presented by Equation (4) and (5). The reaction fever with the biochemical reactions is neglected in Equation (4), and the third term of right side of Equation (5) corresponds to the moisture product.

$$\rho_m c \frac{\partial T}{\partial t} = \nabla\left\{\left(\lambda + r\lambda'_{Tg}\right)\nabla T + r\lambda_{\mu g}\nabla\mu\right\} \tag{4}$$

$$\rho_w \frac{\partial \phi}{\partial \mu}\frac{\partial \mu}{\partial t} = \nabla\left(\lambda'_\mu \nabla\mu + \lambda'_T \nabla T\right) + W_L \tag{5}$$

where ρ_m is the material density (kg/m^3), T is the Kelvin temperature (K), c is the material specific heat (J/kg), λ is the thermal conductivity (W/mK), r is the latent heat of moisture (J/kg), λ_{Tg} is the moisture conductivity in gaseous phase related to temperature gradient (kg/msK), $\lambda_{\mu g}$ is the moisture conductivity in gaseous phase related to water chemical potential gradient (kg/ms[J/kg]), ρ_w is the density of liquid water (kg/m^3), ϕ is the moisture content per volume of material (m^3/ m^3), μ is the water chemical potential (J/kg), and W_L is the the moisture product quantity (kg/sm^3).
Since this model assumes that quantity of the mass loss has a single correlation with the moisture product, moisture product ratio h (-) that corresponds to relation between them in a closed moisture system regarding moisture balance can be defined as:

$$h = \frac{d\phi}{dL} \tag{6}$$

The moisture product ratio h can not be determined from reaction formulae regarding the biochemical reactions for the decay process, because quantitative details of the metabolism regarding wood rot fungi within the wood substance is uncertain. However the moisture product quantity is expressed as Equation (7), where the moisture product ratio can be determined experimentally.

$$W_L = h\rho_w \frac{dL}{dt} \tag{7}$$

3 DETERMINATION OF COEFFICIENTS FOR THE MODEL

Wood decay tests under sterile condition in a laboratory were conducted to determine the rate constants and the moisture product ratio. Test samples of general standardized wood decay tests such as EN113 [1991] and JIS K 1571 [2004] are exposed on the surface of active agar colony of a fungus. Estimation of the moisture balance in the test samples is however difficult employing these standardized test methods, because the mycelium of the fungus keeps supplying moisture and nutrition to them through the agar medium. Therefore, the decay tests in this study were conducted in plastic dish without agar medium. Also the relative humidity levels in the plastic dish were adjusted by saturated salt solutions.

3.1 Outline of Experiments

The test samples for the decay tests (dimensions 40x20x5mm) were cut from the outer part of the sapwood of *Pinus densiflora* (wood species: Japanese red pine), which is classified as a un-durable species against fungus attack. A brown rot fungus *Fomitopsis palustris* was used as a test fungus, because this fungus showed less dispersion in the decay tests and is also employed as a test fungus in JIS K 1571 [2004]. Before the start of the decay tests, dry weights of the test samples were measured (at 105^{o}C). After the test fungus was grown on the agar medium for 2 weeks, inoculations of the test fungus were made through resin mesh on the mycelium (Figure 2). The resin mesh was employed to not contact directly between the test samples and the agar medium. The inoculated test samples were transferred to the plastic dish after the mycelium on the surface of the samples was observed by a microscope. Furthermore the plastic dish with the test samples were incubated at temperature between 5 and 40^{o}C.

In the incubation, the relative humidity in the plastic dish was controlled by the saturated salt solutions without the agar medium (Figure 3). These inoculation processes were performed under sterile condition.Exposure conditions for the decay tests are shown in Table 1. The mass loss and the moisture contents of the test samples were determined by weighting and drying after the exposure time in Table 1.

Table 1. The exposure conditions and details regarding the decay tests

Temperature (^oC)	5、10、20、30、40
Humidity (%RH)	93[KNO_3], 97[K_2SO_4], 100[distilled water]
Exposure time (months)	1, 2, 3, 6, 9, 12month (12month is only 100%RH)
Number of replications	5 (Summation of samples:475)
Initial moisture contents(kg/kg)	0.25 (Average of 10 replications after inoculation)

*[ ] means employed saturated salt solutions

3.2 Time-dependent Change of Mass Loss and Moisture Content

According to the results of the decay tests at 100%RH in Figure 4, the mass loss approximately reached to 0.4 by 12 months at 20 and 30 ^oC. Although progress of the mass loss at 5 and 15 ^oC were lower than 20^oC, the activity of the fungus and the mass loss could be clearly detected after 6 months. On the other hands, no decay was detected below 97%RH at any temperature conditions. Initial moisture contents of the test samples after the inoculation were approximately 0.25kg/kg. These results consequently indicate that the wood decay never progress without liquid water within micro-pore (i.e. under fiber saturation point).

Figure 5 shows the comparison of temperature dependence of the mass loss after 2 months' exposure. Although the temperature dependence in this experiment is similar to references at 28 ^oC [Fukuda 1980, Suzuki 1994], Suzuki's results that test samples were exposed on agar medium are approximately threefold compared to our values. It is conceivable that these impacts were caused by the agar medium supplying nutrition to the test samples. However the mycelium on building components is difficult to get such sufficient nutrition, if it can't reach soil around the foundation. Hence our results without the agar medium can be postulated as suitable for the time-dependent wood decay model on the actual exposure conditions within the building envelopes.

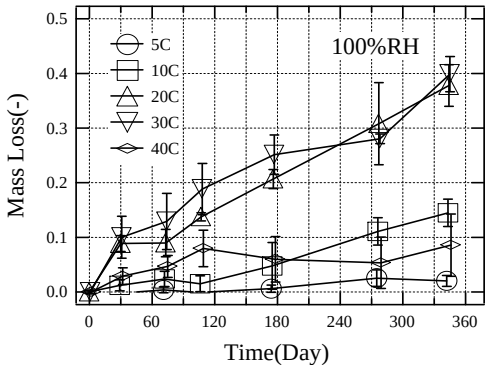

Figure 4 Time-dependent change of mass loss of test samples in 100%RH (Average and Standard deviation)

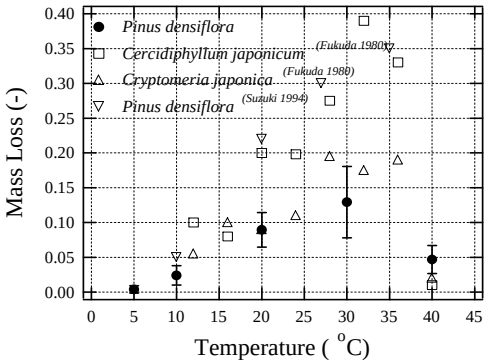

Figure 5 Comparison of temperature dependence of the mass loss after 2 months exposure in 100%RH (White dots are the quoted

3.3 Determination of Moisture Product Ratio

The moisture product ratio was determined by relation between the mass loss and the moisture contents of the test samples. Figure 6 shows the time dependent change of moisture contents at 100%RH. The gradients of the moisture contents in Figure 6 are similar to those of the mass loss in Figure 4. The differences of the gradients can be regarded as the impact of the reaction product related to the wood decay, where the moisture evaporation from the test samples is neglected in 100%RH. Consequently, the moisture product ratio h (-) could be determined as 0.319 by the relationship between the mass loss and the moisture content by volume in Figure 7. The coefficient of determination of regression analysis (R^2) was larger than 0.7.

3.4 Determination of Rate Constant

The rate constant was determined by linear regression analysis for the time dependent change of the mass loss in each temperature conditions shown in Figure 4. A regression curve in Figure 8 presents relation between the determined rate constants and temperature. The empirical formula regarding the rate constants is given by Equation (8). The mass loss were predicted using this equation and experimental conditions. Figure 9 shows good correlation between the predicted value and the measured values of the mass loss against all the test samples. The coefficient of determination of the regression analysis (R^2) was larger than 0.85.

$$k_m(\theta) = 2.77 - 3.23\theta + 0.865\theta^2 - 0.0189\theta^3 \quad (8)$$

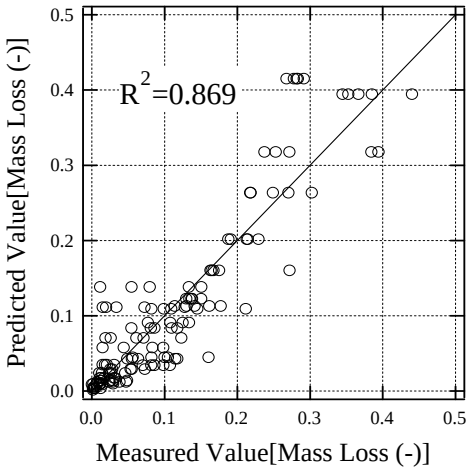

Figure 9 Relation between measured and predicted value in 100%RH

4 APPLICATION FOR BUILDING ENVELOPES

4.1 Outline for the Analysis

To better understand progress of the wood decay in building envelopes, the wood decay model was applied to an exterior wall using the determined coefficients. The numerical simulations for the wood decay that employed Equation (2) – (7) assumed one-dimensional heat and moisture flow in finite differential approximations. The critical relative humidity φ_c (%RH) for the beginning of the wood rot was set on 98%RH, on the basis of the experimental results in this study. Initial response time that is period to start the wood decay after reaching the critical relative humidity proposed by Mostafa and Kumaran [1999] was neglected.
Figure 10 shows the wall assembly for the analyses. Vapor retarder for the wall was removed intentionally, because the wood rot never progresses less than the critical relative humidity in this simulation. For the similar reason, the initial moisture content of the structural wood board (*Pinus densiflora*) was set 0.66 kg/kg. While the calculations regarding heat and moisture transfer were performed against all the layer of the building components, the wood decay analyses were implemented against only the structural wood board on the outside of the glass wool. The moisture properties of the building components are shown in Figure 11, and Table 2 shows calculation conditions.

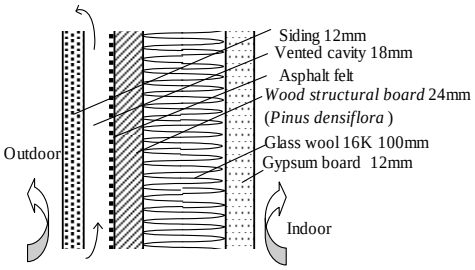

Figure 10 Wall assembly for analysis

Table 2. Calculation conditions

Indoor conditions	Temperature: $\theta_r = 25.0 + 5.0\cos[2\pi(DAY^* - 212)/365]$(°C)
	Relative humidity: 60(%RH)
Outdoor conditions	Climate data in Osaka (Mild climate region in Japan)
Calculation period	One year (From October 1st to September 30th)
Initial moisture content	0.66 (kg/kg) [Equivalent to 99%RH]

**DAY* means the number of days from January 1st.

4.2 Results and Discussion

In order to understand long-term progress of the wood decay, annual variation of the mass loss and the moisture contents are presented in Figure 12 and Figure 13 respectively. The mass loss at the surface node of the structural wood board (i.e. 0mm) increased mainly in the spring rather than the mid winter because of the temperature dependence regarding the rate constant. As well the moisture product that is attribute to increase of the mass loss was observed in this period in Figure 13. Monthly increase of the mass loss on the January and February was smaller than the value of spring according to Figure 12 (approximately 0.01). Hence, significant point in terms of the prevention of the moisture damage is that the moisture contents of wood products should be controlled below the critical relative humidity by the early spring in this climate region.

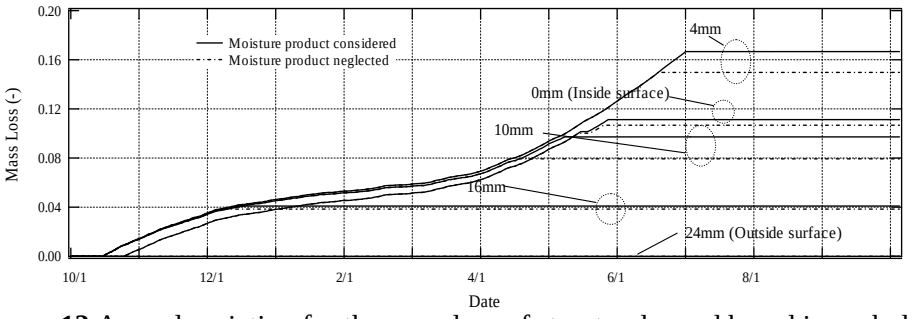

Figure 12 Annual variation for the mass loss of structural wood board in each depth

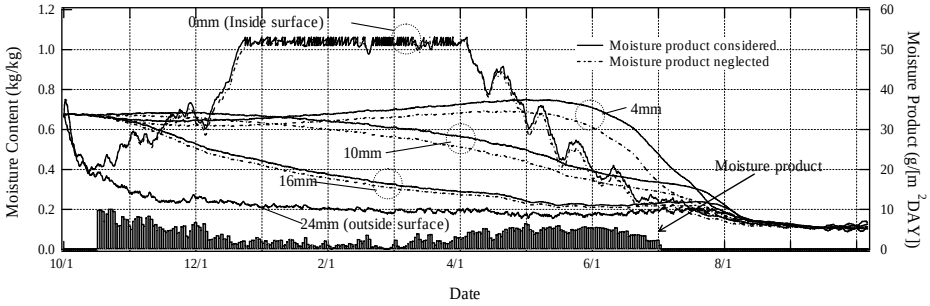

Figure 13 Annual variation of the moisture contents of structural wood board in each depth (lines) and daily summation of moisture product (Bar)

As for impact of the moisture production to the mass loss and the moisture contents, the differences in the calculation condition against the moisture product appeared at the internal node of the structural wood board (e.g. 4mm or 10mm) rather than the surface node in Figure 12 and Figure 13. This result suggests that quantity of the moisture product at the internal layer is larger than that removed by the moisture diffusion. Therefore, addition of the moisture product term to the moisture balance equations is significant in terms of assessment of the wood decay, where the moisture content at the internal layer is kept above the critical relative humidity.

5 CONCLUSION

The wood decay model considering the moisture balance due to the decay process has been presented. The decay tests using small wood samples were conducted under sterile conditions. Results of the decay tests were used to determine the coefficients for the wood decay model. Furthermore the wood decay analysis due to the moisture accumulation within a building assembly was implemented to better understand the impact of the moisture product on the decay progression. The analysis results suggested that the moisture product significantly affects the increase of the mass loss and the moisture contents at the internal layer of the wood substance. These consequences should be verified under various conditions experimentally to enhance reliability of this model. However, significance of this study from viewpoint of the building simulation is that the integration of biochemical reactions into hygrothermal analysis was presented as an advanced model.

ABSTRACT

This paper presents the results of a study conducted to investigate the causes of microorganism growth on several buildings' facades, in São Paulo, Brazil. Those buildings presented several rounded stains distributed along the facades. In order to investigate the occurrence of condensation mainly over the stains, measurements of surface temperatures in different areas of the facade and of temperature and relative humidity of the air next to these areas were made. Based on the values of dry bulb temperatures and relative humidity of the air, the dew point temperatures were calculated. The external surface temperatures of the wall were compared to the dew point temperatures. The comparison showed that the temperatures over the rounded stains, during long periods of the night, were lower than the dew point temperatures and condensation took place during those periods. At the same time, surface temperatures of other areas of the facades were higher than the dew point temperatures and on those areas condensation did not take place. The differences in surface temperatures along the facade were due to the fact that the wall material behind stained areas had higher thermal resistance than the materials behind unstained parts of the facades. In facade zones with higher thermal resistance the effect of night cooling of the surface is more pronounced leading to the occurrence of condensation problems and microorganism growth.

1 INTRODUCTION

The environmental conditions in hot and humid climates - such as those that occur in many areas of Brazil - can promote the growth of a great variety of micro-organisms. In São Paulo, Brazil, the largest metropolitan area in South America, disfigurement of paint by microbial growth on wall surface is a common scene in many buildings. Building design, thermal properties of the construction materials, climatic conditions and location are decisive factors in this process.

The object of investigation of this work are the causes of occurrence of patterned staining on facades of rendered walls, as a consequence of selective growth of microorganisms on their surfaces. It was verified that fouling patterns that were found were associated to the time of wetness of parts of the facade. Frequent repainting was therefore necessary to hide the affected areas and short repainting cycles meant high maintenance cost.

2 DEVELOPMENTS OF MICROORGANISMS

Fungi are heterotrophic organisms, in other words, they need pre-elaborated organic matter as nutrient source. These compounds can be found in several materials used as building coatings. Some coating systems can serve as a source of nutrients for fungi or just as a substratum allowing its development. Phototrophic organisms such as algae and cyanobacteria need light as energy source and CO_2 as carbon source. Both groups of microorganisms are found on external walls of buildings [Allsopp *et al.* 2004], [Gaylarde & Gaylarde 2005], [Shirakawa *et al.* 2002].

For the fungal growth to happen, relative humidity on the surface area should be above a critical value and the surface temperature should also be favorable to the growth of these microorganisms [Pasanen et al. 2000]. The longer the period in which the relative humidity stays above the critical value, the higher is the proliferation level and therefore more visible is the problem. The higher the relative humidity or the temperature, the shorter is the necessary period of time for the establishment of the colonies. The relative humidity of the surface depends on the humidity content of the material, on its properties and on the humidity conditions and temperature of the atmosphere [ASHRAE 1997], [BRE 1972]. The dependence of the relative humidity on the surface on these several factors makes it difficult to establish the relationship between this parameter and the proliferation of the microorganisms.

Beside the humidity and the nutrients in the coating, temperature, pH and the amount of oxygen are other factors that interfere in the occurrence of this pathology [GILLAT 1991].

Models to predict theoretically the germination and growth potentials or rates of microorganisms in buildings were developed [Sedlbauer 2002], [Moon & Augenbroue 2005], [Krus *at al.* 2001] considering the complexity of the biological or mycological mechanisms involved and the hygrothermal conditions of the surface. The results of the models may be used to indicate potentials or for comparisons but more data are still needed for the variety of building materials and available microorganisms.

3 PATTERNED STAINING OF FACADES

The patterned staining of rendered facades as a consequence of selective growth of microorganisms can be explained by differences in moisture content at various locations with different substrates. The more infected areas present larger moisture contents [Becker 2002].

Temperature and moisture content on external surfaces of walls can be predicted through simulation of heat and mass transfer through facades. With simulations Becker [2002] and Johansson at al.

[2005] found that the external surface temperature for an outgoing heat flux will always decrease with the increase in wall insulation and when radiation to sky is included, surface temperatures of insulated walls drop even further. Becker [2005] investigated areas of facades with different substrates including concrete column and lightweight aerated concrete block. He concluded that, due to the dynamic nature of the simultaneous heat and mass transfer phenomena and the phase lags associated with them, the lowest temperature of the external surface of the walls was above ambient dew point temperature and condensation did not take place. The results of simulation showed that the combination of surface temperature, ambient relative humidity and moisture transport phenomena leads to substrate-dependent evolutions of moisture contents in the rendering layer, observing that the moisture content of the rendering over thermal insulation was higher than over concrete.

Johansson *at al.* [2005] simulated the temperature over a rendered building facade with regularly spaced dots with less microbial growth on the facade otherwise covered with microorganisms. They found that a fastener of steel was placed behind every dot. The computer simulations showed that the fasteners are heat bridges that lead to 1-2 K higher temperature of rendering over the fastener than the rest of the facade. They concluded that this difference can promote a high enough difference in relative humidity to almost prevent the development of microorganisms.

This paper aims to evaluate the influence of facade details on condensation and microorganism growth on a residential condominium in São Paulo.

4 STUDIED BUILDINGS

The problem of microorganisms development in facades was investigated in a residential condominium located in the city of São Paulo (Figure1). The building is supported by a reticulated cast-in-place reinforced concrete structure. The external walls were composed of precast sandwich panels, constituted of expanded polystyrene boards with both faces covered with reinforced micro-concrete. Each polystyrene board has cylindrical holes filled with micro-concrete and a concrete border which constitutes thermal bridges and facade areas with higher thermal capacity (Fig. 2). All panels had been painted with a water-based paint. As it can be seen on Fig.1 the panels were covered with microorganisms, except on areas located just above the insulation holes and reinforced borders of the precast panels. In other areas – such as the reinforced concrete structures – of the facade, microorganism growth was less intense.

Figure 1. Building facade with microorganism development

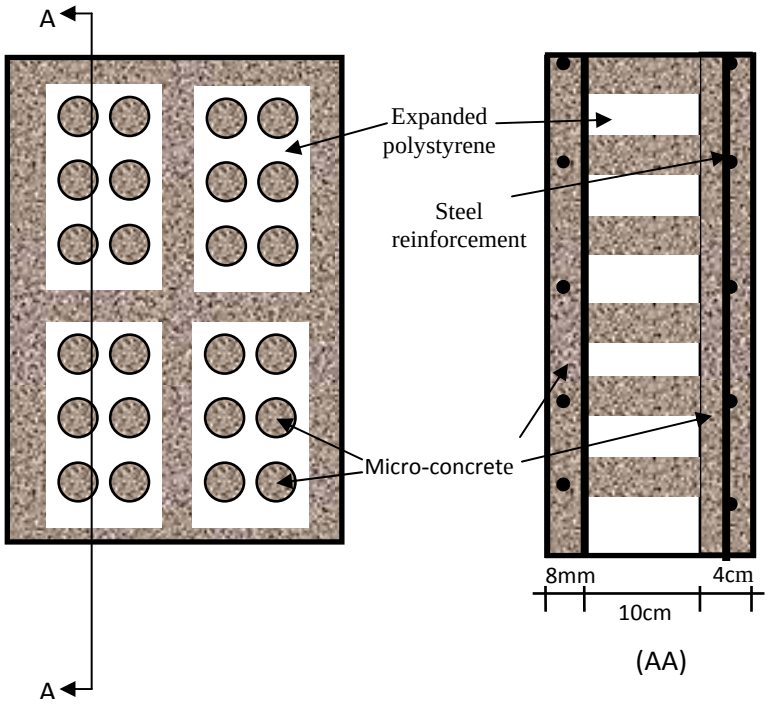

Figure 2. Schematic details of the precast panel facade.

5 MATERIALS AND METHODS

In order to indentify microorganisms that appeared in the darkened areas, microbiological evaluations of material collected from the surface were made. Samples were collected with sterilized carpet for the assesment of surface fungal colonization [Shirakawa et. al. 2002]. The culture was carried out in Agar Sabouraud Dextrose at 25 ^{o}C for 72 hours and identification was defined according Lacaz et. al. [2002]. Adhesive tape was used to collect samples for analysis of phototrophic organisms [Gaylarde 2005].

An investigation was conducted in order to see if there was humidity on the facade. A hypothesis was made that the humidity was due to water condensation. To determine the occurrence of condensation over the facade, measurements of dry bulb temperature and of wet bulb temperature of the air and surface temperature of the facade were made. From the values of dry bulb temperatures and wet bulb temperatures of the air, the dew point temperatures were calculated. The surface temperatures were compared with the dew point temperature of the air to see if condensation occurred.

The temperatures were measured with copper-constantan thermocouples connected to a Datataker Acquisition System every 5 minutes for several days.

6 RESULTS

6.1 Kinds of Microorganisms Present in the Darkened Areas of the Facade

Predominant genera of fungi found on the dark discoloration of facades were *Cladosporium*, followed by *Aureobasidium*. Other genera were also found in minor concentrations: *Alternaria*, *Arthrinium*, *Epicoccum*, *Monascus*, *Nigrospora*, *Penicillium* and *Pestalotia/Pestalopis*. *Mycelia sterilia*, a non sporulating group was found as well. Among the phototrophic microrganisms the predominant genus found was *Gloecapsa* (cyanobacteria). These results are in agreement with studies carried out by Shirakawa et al [2004] in others building in the same city.

6.2 Condensation

The results of the measurements are presented on the following figures. The caption for the following figures is:

- External air: dry bulb temperature of the external air;
- Concrete: temperature of the external surface of the facade in the area that had concrete as substratum;
- Thermal insulation: temperature of the surface of the facade in the area that had the expanded polystyrene as substratum;
- Dew point: dew point temperature.

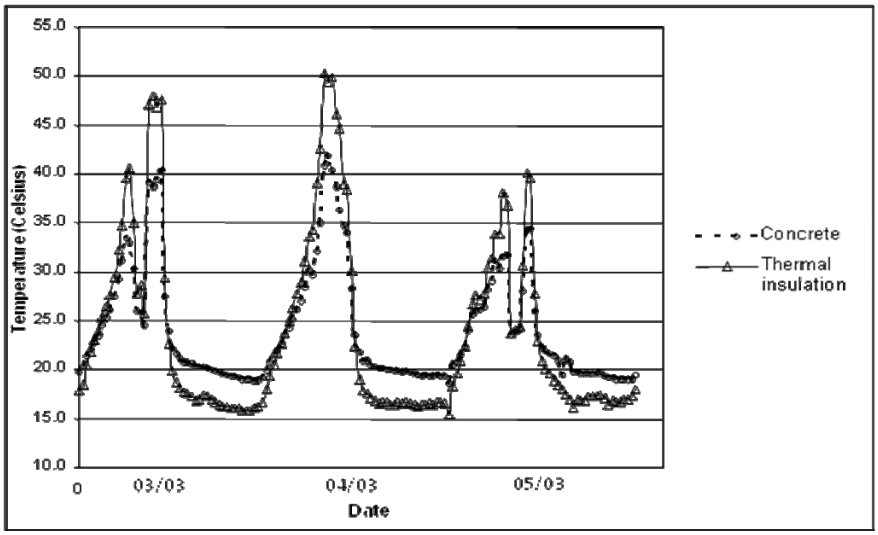

Figure 3. Surface temperatures of the facade during three consecutive days

Figure 3 shows that during the measurement period, the amplitude of oscillation of the surface-temperature in the area with thermal insulation as substratum is always higher than the one over the area with micro-concrete that fills the insulation holes. The amplitude of the temperature at the insulated area was about 35ºC whereas the temperature on surfaces that lied above concrete had amplitude of about 23ºC.

Assuming that the heat transfer is one-dimensional, during the day the incident solar radiation on the facade is absorbed by the external covering and transferred to the internal surface of the wall. Due to the lower thermal conductivity of the thermal insulation, the absorbed solar energy is transferred to the internal surface at a lower rate than in the area with concrete only, resulting in a higher temperature over the insulation during this period. At night the temperature on facade in the area over thermal insulation is lower than in the area over concrete only because the amount of heat accumulated internally during the day in this part of the wall is lower than in the area with concrete. This means that the relative humidity on the surface over thermal insulation will be higher and increase the risk of microorganism growth.

At dawn the temperature in the area of the facade over the thermal insulation becomes lower than the dew point temperature. During this period condensation takes place on the surface. This phenomenon occur in facades of buildings because, even if the atmospheric air is not saturated, the temperature of external surfaces of the buildings during the night is lower than the temperature of the external air, due to the loss of thermal energy by radiation of long waves to the sky.

Depending on the material of the facade, night cooling can be more or less intense. In facade areas with low thermal resistance and of large thermal capacity, night cooling is weaker than in façade areas

with high thermal resistance and lower thermal capacity, because the heat accumulated during the day in the material and in the internal environment of the building is transmitted on a larger scale to the outdoor, reducing the effect of the external night cooling.

The condensed water stays on the surface for a period of time that can be longer or shorter depending on – among other factors – the solar orientation of the facade, air temperature and humidity and on the speed and direction of the wind. In the southern hemisphere the time of wetness in facades with south orientation is longer than ones with north orientation. Due to the fact that they receive a smaller amount of solar radiation, the rate of evaporation of the condensed water is lower, favoring the development of microorganisms.

During visits to the site early in the morning (around 6:00 a.m.) it was observed that the amount of condensed water was enough to be clearly visible on the surface of the facade.

As condensation occurred only during the night, measurements made overnight are presented on figures 4, 5 and 6. In the area of the facade with only concrete as substratum, the surface temperature was always higher than the dew point temperature and therefore over this part of the facade the water did not condense. However, in insulated areas of the panels, even on a summer night, the temperature can be close to or even bellow dew point temperature, making condensation possible.

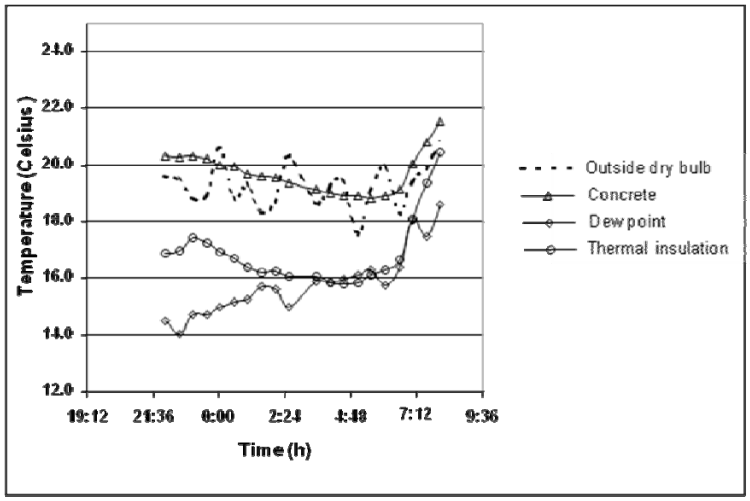

Figure 4. Condensation on facade over thermal insulation substratum from approximately 3:00 to 6:00 a.m.

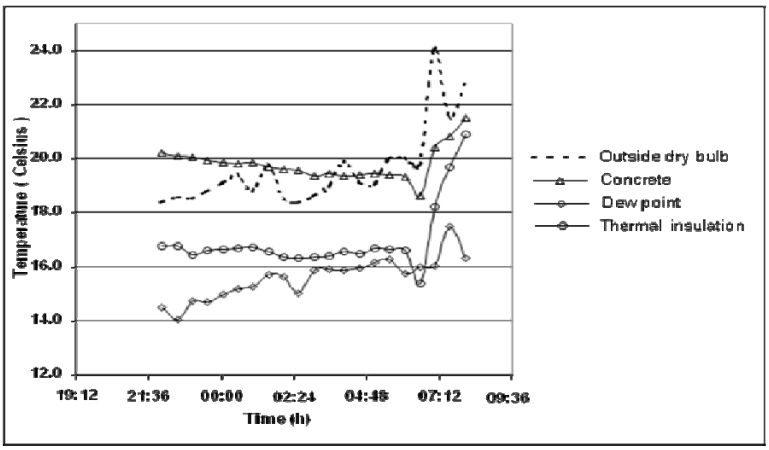

Figure 5. Condensation on facade over thermal insulation substratum from approximately 5:00 to 6:00 a.m.

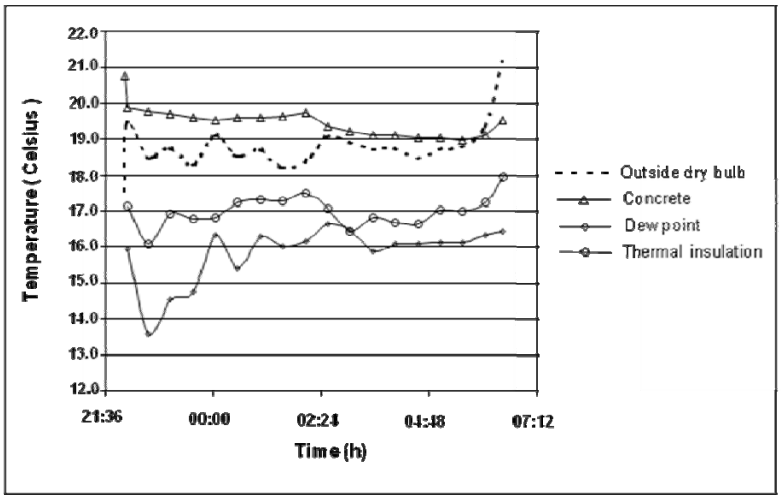

Figure 6. Condensation on facade over thermal insulation substratum at certain moments

7 CONCLUSIONS

The fouling pattern of the facades is a result of selective growth of microorganisms on the facade mainly on the rendered area over thermal insulation. No significant difference was observed among the humidity content inside of the concrete or of inside of expanded polystyrene substrate, indicating that the humidity was essentially on the surface and that the painting system protected the facade against water penetration.

Unlike the other study by Becker [2002], from the measured data it was possible to conclude that the necessary water for the development of microorganisms originated mainly from the condensation of the humidity of the air.

Development and Benchmarking of a New Hygrothermal Model

Fitsum Tariku [1]
Kumar Kumaran [1]
Paul Fazio [2]

T 33

ABSTRACT

Building enclosures are subjected to a random climatic loading on the exterior surface and a relatively stable indoor condition on the interior. These loadings result in a transport of Heat, Air and Moisture (HAM) across the structure. Depending on the boundary conditions, a building envelope component may experience wetting or drying as it is exposed to real weather conditions that change by hours and seasons. In addition to the time varying external loading, the thermal and moisture storage characteristics of the layers, which constitute the enclosure component, make the HAM transport a complex non-linear process. HAM models, which take these complex interactions, have a significant benefit for evaluation of building envelope performance as they can provide detailed spatial and temporal conditions of the component.

In this paper, the development and benchmarking of a new hygrothermal model (HAMFit) are presented. First, a set of partial differential equations (PDEs) that govern the heat, air, and moisture transfer across building envelopes are formulated based on building physics. Then, these nonlinear and coupled PDEs are solved simultaneously for air velocity, temperature, and moisture distributions in the computational domain for a given outside environmental condition (weather data) and prescribed indoor conditions. The PDEs are solved using finite-element based commercial software called COMSOL Multiphysics and MatLab. The model is benchmarked using internationally published numerical model test cases. The good agreements obtained with the respective test cases suggest that the model can be used for products development and evaluations as well as hygrothermal performance assessment of different building envelope components.

1 INTRODUCTION

Building enclosures are subjected to a random climatic loading on the exterior surface and a relatively stable indoor condition on the interior. These loadings result in a transport of Heat, Air and Moisture (HAM) across the structure. The direction of flow of these entities depends on the gradient of the driving potential of the respective entity. In addition to the time varying external loading due to time varying weather conditions, the thermal and moisture storage characteristics of the layers, which constitute the enclosure component, make the heat and moisture transport in the building envelope a transient and complex process. The complex phenomena including the dynamic wetting and drying processes of the building envelope component can be captured using computer models. In various research projects, hygrothermal models are used to assess the performance of a wall system as it is exposed to climatic conditions of different geographical locations, or to select an appropriate building envelope system for a given geographic locations (Tariku et al. 2007; Tariku and Kumaran, 2006, 1999). The model presented here (HAMFit) is part of the recently emerging class of HAM models that use commercial software to solve building physics problems (Kalagasidis, 2004; van Schijndel, 2007). These models are more transparent and flexible for futures upgrades (for example to 2D or 3D), addition of new features and integration with other models.

2 MATHEMATICAL MODELS IMPLEMENTED IN HAMFit MODEL

2.1 Moisture transfer

The general equation for moisture transfer through a porous media is given by Equation [1]. This governing equation is based on conservation of mass, and accounts for moisture transfer by vapor diffusion, convection and liquid water conduction. The vapor diffusion and liquid conduction fluxes are given by Fick's and Darcy's law, respectively.

$$\frac{\partial w}{\partial t} + div\left(\rho_a V \omega\right) + div\left(-\delta_v \frac{\partial P_v}{\partial x_i}\right) + div\left(D_l\left(\frac{\partial P_s}{\partial x_i} + \rho_w g\right)\right) = 0 \qquad (1)$$

Where w is moisture content (kg/m^3), ρ_a is air density (kg/m^3), V is air velocity (m/s) and ω absolute humidity (kg/kg-air), P_v and P_s are vapor and suction pressures (Pa), respectively, ρ_w is density of water (kg/m^3), g is the acceleration due to gravity (m/s^2), δ_v and D_l are the vapor permeability and liquid conductivity of the material (s). The moisture balance equation, Equation [1], comprises of various moisture driving potentials, P_v, P_s, w and ω. In the numerical method adapted here it is important to express the driving forces and flow variables with a single flow potential. The chosen flow potential in this work is relative humidity (ϕ) since it is continuous at interface of two layers of materials with different moisture storage properties (sorption and moisture retention), in the contrary to moisture content, which is discontinuous. Thus, the mathematical model implemented in HAMFit for moisture transfer through building envelope component is presented as shown in Equation [2], The full mathematical derivation of the moisture and heat transfer equations are given in Tariku's Ph.D. thesis (to be published in early 2008). In Equation [2] Θ is sorption capacity (kg/m^3), T is temperature (^{o}C), $C_c = \frac{0.622}{P_{atm}}$, $\hat{P}$ and P_{atm} are saturated vapor and atmospheric pressure (Pa), respectively, R and M are the universal gas constant (8.314 J.mol^{-1}) and molecular weight of water molecule (0.01806 kg.mol^{-1}), respectively

$$\Theta\frac{\partial\phi}{\partial t}=\frac{\partial}{\partial x_i}\left(D_\phi\frac{\partial\phi}{\partial x_i}+D_T\frac{\partial T}{\partial x_i}\right)-\frac{\partial}{\partial x_i}\left(D_l\rho_w\vec{g}+\rho V_i C_c\hat{P}\cdot\phi\right) \tag{2}$$

where: $D_\phi=\left(\delta_v\hat{P}+D_l\frac{\rho_w R}{M}\frac{T}{\phi}\right)$ $D_T=\left(\delta_v\phi\frac{\partial\hat{P}}{\partial T}+D_l\frac{\rho_w R}{M}\ln(\phi)\right)$

2.2 Heat transfer

After some mathematical manipulations, the conservation equation for the total energy (sum of internal, kinetic and potential energy) can be expressed in terms of enthalpy, *h*, Equation [3] (Kuo, 1986).

$$\frac{\partial(\rho h)}{\partial t}+div(\rho Vh)=-div(j_q)+\dot{Q}_s \tag{3}$$

Where j_q is a diffusion term, which comprises heat transfer by conduction and enthalpy transport due to moisture transfer. Q_s is a heat source (or sink) term. The mathematical model that is implemented in the HAMFit model for heat transfer through building envelope component is obtained (Equation [4]) after substituting the transient, convection and diffusion terms with the corresponding mixture enthalpy (moisture, air and solid matrix), and carried out some mathematical manipulations.

$$\rho_m Cp_{eff}\frac{\partial T}{\partial t}+\rho_a(Cp_a+\omega Cp_v)div(VT)+div(-\lambda_{eff}grad(T))=\dot{m}_c h_{fg}+\dot{m}_c T(Cp_v-Cp_l)+\dot{Q}_s \tag{4}$$

Where ρ_m is density of material (kg/m^3), ρ_a is density of air (kg/m^3), Cp_a, Cp_v and Cp_l are the specific heat capacity of air, vapor and liquid water (J/(K.kg)), respectively. Cp_{eff} and λ_{eff} are the effective specific heat capacity and thermal conductivity (which take moisture effect into account), respectively. h_{fg} is the latent heat of condensation/evaporation (J/kg). $\dot{m}_c=div\left(\delta_v\frac{\partial P_v}{\partial x_i}\right)-\rho_a div(V\omega)$ is the amount of moisture condensation/evaporation (kg/s)

2.3 Airflow through porous media

Airflow through a porous media can be expressed by using Poiseuille's law of proportionality (Hens, 2007), which relates pressure gradient and flow velocity (Equation [5]).

$$V=-\frac{k_a}{\mu}div(P) \tag{5}$$

Where k_a and μ are the airflow coefficient and dynamic viscosity, respectively. Combing the mass conservation equation for incompressible flow (in building physics applications, the air is considered as incompressible due to very low airflow speed, and low pressure and temperature changes) with Equation [5], gives the governing equation for airflow through porous media.

$$div\left(\delta_a div\left(P\right)\right)=0 \tag{6}$$

Where $\delta_a = \rho_a \frac{k_a}{\mu}$ is the air permeability of the porous media.

3 DEVELOPMENT OF A NUMERICAL TOOL FOR HAM ANALYSIS (HAMFit)

3.1 Numerical tool

The governing equations implemented in the building envelope model (HAMFit) are Equation [2], [4], and [6] for moisture, heat and air transport, respectively. To obtain the airflow velocity, temperature and relative humidity fields across the computational domain (building envelop component), the coupled and nonlinear partial differential equations (PDEs) need to be solved simultaneously. Here, a finite-element based computational tool called COMSOL Multiphysics and MatLab (Mathworks) are used to solve these three equations. COMSOL Multiphysics has a library of predefined models to solve familiar engineering problems such as convection diffusion problems, fluid dynamics, heat transfer and other similar problems. Also it has a provision to create and solve user-developed models, which may not be solved by the standard modules. In fact, HAMFit model is developed using this equation based modeling technique "PDE Modes", where the formulated HAM governing PDEs are directly implement it in the COMSOL Multiphysics working environment. The solver is based on an explicit scheme with variable time stepping. The user can predefine the maximum time step so that it will match with the boundary condition change period. It is possible to solve any one of the three or all equations simultaneously. In addition to its efficient solver it has a graphical user interface (GUI) to create computational domain geometry, automatic and user controlled mesh generator, and also has an integrated post processing capability for plotting, interpolating and integrating simulation results.

3.2 HAMFit model

The newly developed building envelope model, HAMFit, has two versions, HAMFit-1D and HAMFit-2D. HAMFit-1D is used for one-dimensional heat, air and moisture analysis of building envelope components. And HAMFit-2D is used to solve two-dimensional HAM problems that are caused by the geometry of the region of interest such as wall-floor junction, two-dimensional corner section, and also in cases where the physical process itself has three-dimensional nature but can be approximated in two-dimension (for example airflow and gravitational moisture flow in the structure). The models take advantage of the smooth interfaces of COMSOL Multiphysics, MatLab and SimuLink computational tools, which all are from the same development environment. In fact COMSOL Multiphysics is one of the blocks in the SimuLink model library, and it is also possible to call MatLab functions from COMSOL Multiphysics working environment. Making use of these flexible simulation environments, HAMFit model is developed in such a way that a number of functions are created in MatLab; and these functions are called by COMSOL MultiPhysics multiple times during solving the HAM equations, which are caste in COMSOL MultiPhysics "PDE Modes". The "PDE Modes" data structure of the problem including the geometry, mesh, PDEs and boundary conditions are embedded in the SimuLink S-function. Finally, the hygrothermal simulation (S-function) is run in the SimuLink simulation environment where the overall simulation parameters including outputs of the simulation results are controlled. S-function is a user-developed SimuLink block written in MatLab or C programming language, and where the developer sets the block's tasks, inputs and outputs. One of the advantages of this modeling technique is that it allows simulation of HAM transfer in any building envelope detail with no geometric (shape) restriction.

4 BENCHMARKING OF HAMFit

In this section, the newly developed building envelope model, HAMFit, is benchmarked against published test cases. The complete benchmarking exercises that are undertaken to test the model are presented in Tariku Ph.D. Thesis (to be published in early 2008). Here, two of the five benchmarking exercises that are designed in the European HAMSTAD (Hat, Air and Moisture Standards Development) project are used for assessing the accuracy of the model through inter model comparison. The objective of the HAMSTAD project was to develop test cases by which the accuracy of the existing and newly developed hygrothermal models will be evaluated (Hagentoft, 2002).

4.1 Comparative Analysis 1—HAMSTAD Benchmark Exercise #3

In benchmark #3, the effect of airflow (exfiltration and infiltration) on the wetting (accumulation of moisture) and drying of a lightweight structure of 200 mm thickness is analyzed. Although the main moisture transfer mechanism in this exercise is by airflow, moisture transports due to temperature and moisture gradient across the monolithic wall layer. The pressure gradients across the wall, which causes heat and moisture transfer by convection, in both infiltration and exfiltration periods are 30 Pa, Figure 1. The exterior surface of the structure is vapor tight (painted), where as the interior surface is open. Accordingly the mass transfer coefficients of the exterior and interior surfaces are 7.38E-12 and 2E-7 s/m, respectively. The heat transfer coefficients for both surfaces are 10 W/(m^2K).

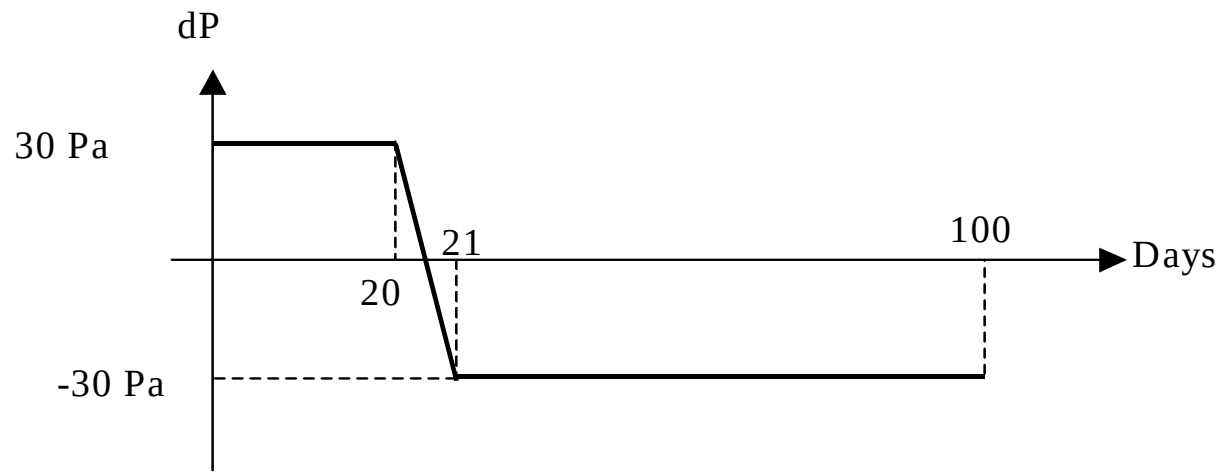

Figure 1. Pressure gradient across the wall.

The initial hygrothermal conditions of the structure are 20^{o}C and 95% temperature and relative humidity, respectively. In the first 20 days the airflow is from inside to outside (exfiltration) and the airflow is reversed in the next 80 days (infiltration). The interior temperature and relative humidity conditions are 20^{o}C and 70%, respectively. Where as the exterior temperature and relative humidity conditions are 2^{o}C and 80%, respectively. These boundary conditions are maintained constant for the 100 days of simulation period. The density and specific heat capacity of the monolithic layer are 212 kg/m^3 and 1000 J/(kg.K), respectively. The full description of this benchmark exercise is given in Hagentoft (2002). Here, the temperature and moisture content time history of the left and right section of the wall, 0.05 and 0.19 m respectively, are presented in Figure 2 below. For comparison purpose, the HAMFit simulation results are superimposed on the solutions provided by the HAMSTAD participants. The top two figures are the temperature and the bottom two figures are the moisture content profiles of the left and right sections of the walls. As can be seen in these figures, the HAMFit simulation results agree very well with the other models solutions (labeled 1 to 4).

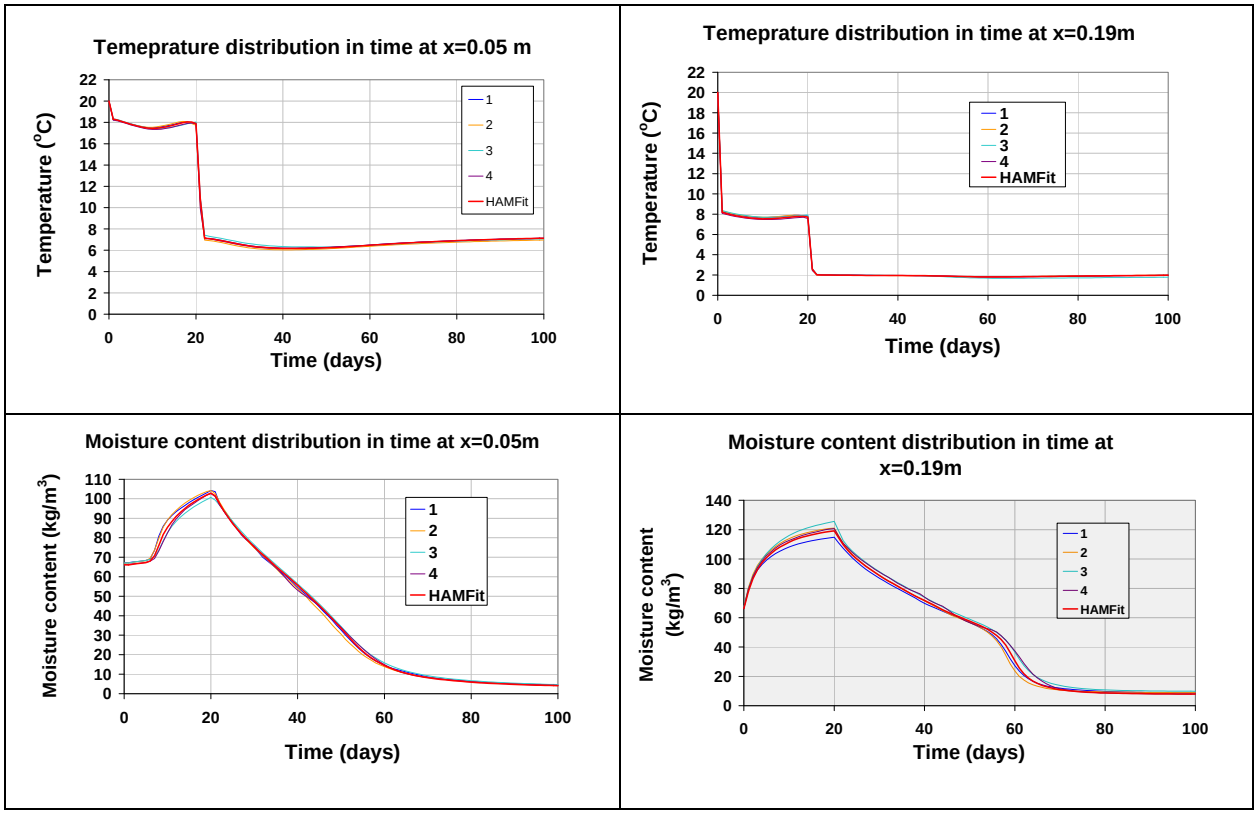

Figure 2. Temperature and moisture content time history of the wall at 0.05 and 0.19 m depth.

4.2 Comparative analysis 3—HAMSTAD Benchmark Exercise #4

The second comparative analysis deals with heat and moisture transfer in a two-layer wall system exposed to realistic internal and external boundary conditions. The wall system is composed of a load-bearing layer on the exterior and finishing layer on the interior. The load-bearing is 100 mm thick and has a density of 2050 kg/m^3, and specific heat capacity of 840 J/(K.kg), where as the finishing layer has a thickness of 20 mm, density 790 kg/m^3 and specific heat capacity of 870 J/(K.kg). The full description of this benchmark exercise is given in Hagentoft (2002). The test case is more challenging (Hagentoft et al., 2004) as it involves severe climatic load that causes surface condensation on the exterior surface due to nighttime cooling (low equivalent temperature), and frequent occurrences of wetting and drying of the wall due to the alternating rain and solar radiation loads. Moreover, the problem involves rapid rainwater absorption at the interfaces and fast moisture movement within the layers due to the extremely high liquid water absorption property of the load-bearing layer. For comparison purpose, the simulation results of HAMFit are superimposed on the corresponding HAMSTAD project participants' solutions. In Figure 3 the surface moisture content and temperature, as well as the moisture and temperature profiles across the wall sections at 96 hours are presented. As can be seen in these typical results presented here, the simulation results of HAMFit agree very well with the other six models solutions (labeled 1 to 6).

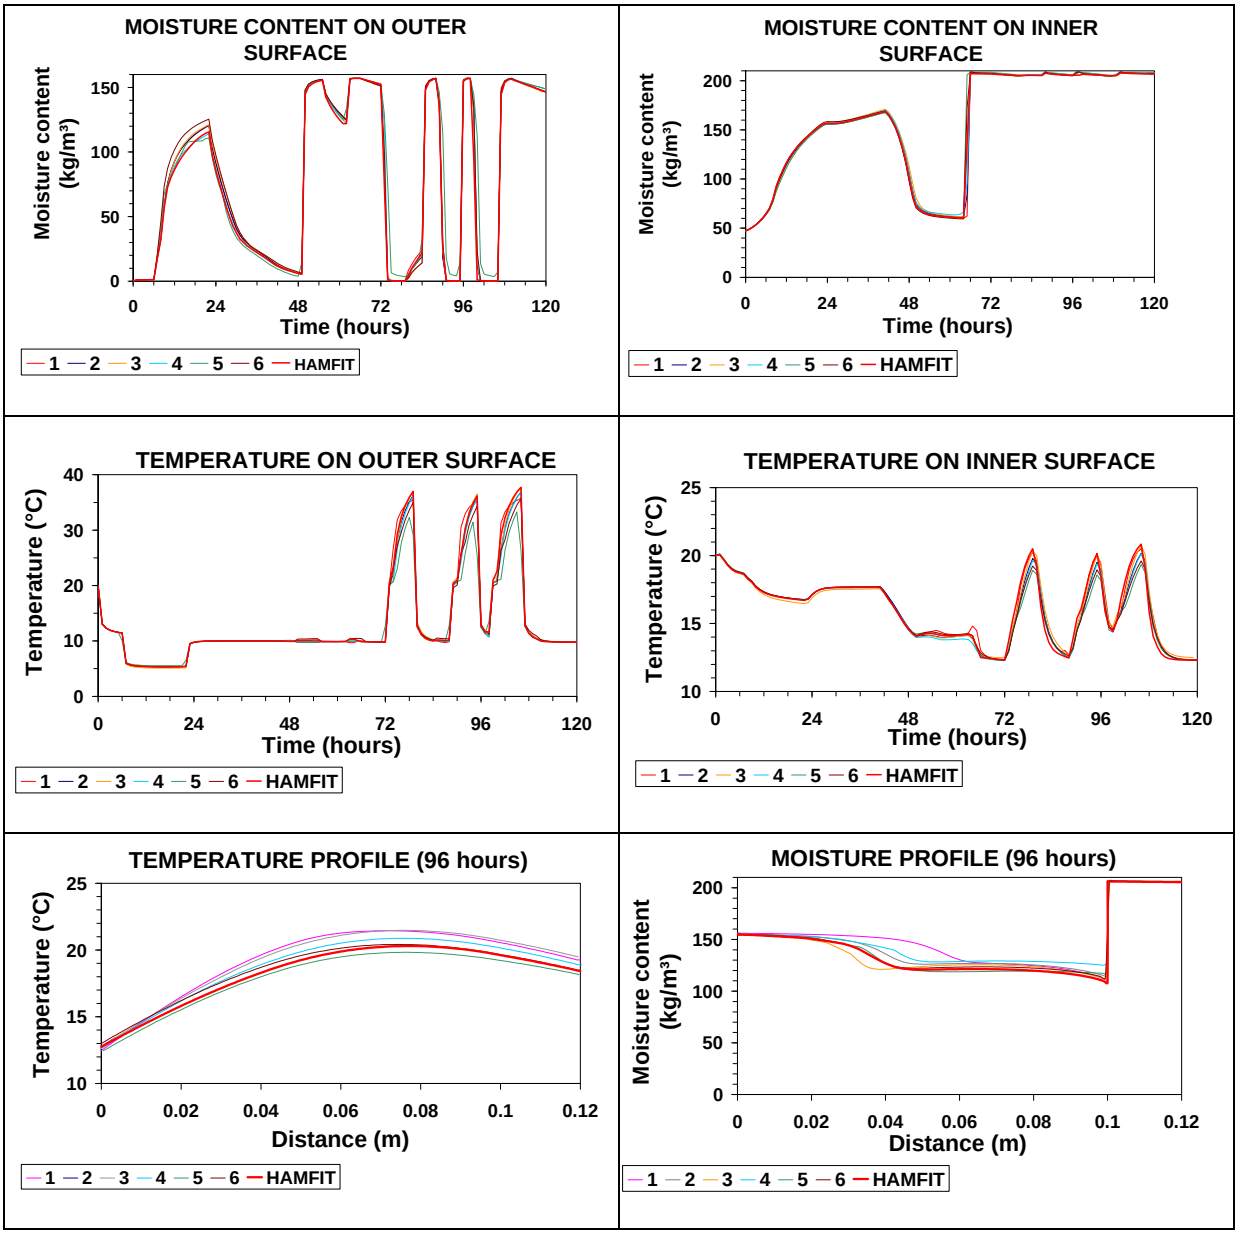

Figure 3 The moisture and temperature conditions of the surfaces and the wall at 96 hours

5 CONCLUSION

Heat, Air and Moisture (HAM) models are useful for hygrothermal performance assessment of building envelope components, new building materials and systems. In this paper, a new hygrothermal model, which utilizes equation based modeling technique, is developed. The model takes advantage of the smooth interfaces of commercial software of the same family, namely COMSOL Multiphysics, MatLab and SimuLink. The equation based modeling technique provides high transparency and flexibility of modeling HAM problems. Moreover, with this modeling technique addition of new feature and maintaining the software are relatively easy and less time consuming. The accuracy of HAMFit model is tested by carrying out two internationally accepted test cases. In both benchmarking exercises, the HAMFit

simulation results are in very good agreement with other models' respective solutions, and consequently the model can be used with great confidence. In general, the model can solve airflow through a building component and the associated heat and moisture transfer, and accounts for simultaneous vapor and liquid capillary flow, and also has a capability of solving multi-dimensional HAM problems.

ABSTRACT

In civil engineering there is an increasing demand for calculation methods to assess the moisture behaviour of building components. Intensive work has been done over the past few years on the development of mathematical approaches and procedures to evaluate real thermal and moisture transfer processes. The boundary conditions have, beside the correct material properties, a very significant influence on the simulated hygrothermal performance.

In this paper the moisture behaviour of the different construction assemblies of a house are simulated with a well validated one dimensional model using the internal boundary conditions according to the European standard EN 13788 and EN 15026. But it is well known, that the hygrothermal behavior of the building envelope affects the overall performance of a building as well. Therefore in this paper such a combined model, that takes into account moisture sources and sinks inside a room, input from the envelope due to capillary action, diffusion and vapor ab- and desorption as a response to the exterior and interior climate conditions as well as the well-known thermal parameters will be applied. In influence of different scenarios (usage of the building, loads, ventilation strategies,…) will be compared to the simplified approaches described in the standards.

1 INTRODUCTION

The hygrothermal behaviour of building components is very important, due to the effects of weathering and ground moisture as well as increased airtight construction and higher indoor relative humidity. Thus, it is significant to assess this behaviour as concerns the construction of new buildings or in case of renovation measures. The indoor air temperature and relative humidity must be known parameters besides outdoor climate boundary conditions to carry out hygrothermal computation of building components. The indoor climate is determined by the behaviour of the users in contrast to the outdoor climate. The thermal capacity and water vapour sorption capacity of the internal components and furniture, however, provide a slightly dampened progress of air temperature and relative humidity. Hourly measurement values are therefore only necessary, if special problems occur. More exact values for the real conditions of indoor environments, especially for relative humidity, have not always been measured. Indoor boundary conditions according to DIN 4108-3 [1] for the dew period (20 °C and 50 % r. h.) and the evaporation period (12 °C and 70 % r. h.) can only be „generally“ applied for simple steady-state methods, e.g. the method of Glaser, and comprise security aspects. But it is impossible to calculate the real behaviour of building components in this way. This shortcoming became obvious in the past few years and resulted in extensive data acquisition of occupied and unoccupied rooms, aimed at determining the representative annual progressions of indoor air conditions [see 2, 3, 4, 5, 6, 7, 8, ,9].

More exact predictions on the indoor environment, occurring in interiors, especially relative humidity, can be achieved by means of hygrothermal indoor climate simulations under the condition that all non-stationary influencing factors are taken into consideration [10, 11]. Numerous models were developed in the past few years to compute the thermal behaviour of buildings, which have become a routine application in building design in the meantime. Besides the energetic assessment of the indoor environment, the combination with humidity processes in the enclosure surfaces is required. But so far, previous computation models offer only relatively simple approaches on humidity behaviour [12, 13]. The combined effects of non-stationary sorption, diffusion and capillary duct processes in the enclosure surfaces are not at all or only insufficiently considered. Yet the latter play an important role [14, 15].

The objective is to investigate the impact of standard boundary conditions or hourly measured indoor climate simulation values on the behaviour of the building components of a wall or roof construction. For this purpose, hourly measured weather data of a typical year for the Holzkirchen location served as climate outdoor boundary conditions.

Indoor boundary conditions for hygrothermal building component simulations are differently handled at present. The standard EN-ISO 13788 [16] has been especially developed for steady computations according to Glaser, and the standard EN-ISO 15026 [17] for non-stationary building component simulations. In addition, a data sheet for hygrothermal building component simulations was established by the International Association for Science and Technology of Building Maintenance and Monument Preservation (WTA) [18], which is valid especially for Central European countries.

2 STANDARD AND BOUNDARY CONDITIONS

The results of these investigations show that there is a correlation of outdoor air temperature, indoor relative humidity and moisture load in buildings with natural ventilation. Various standard boundary conditions for hygrothermal simulations are described in the following text and differences are discussed.

2.1 EN-ISO 13788

Indoor air humidity in buildings with natural ventilation is calculated from the monthly average value of outdoor air temperature, indoor air humidity and moisture load according to the European standard

EN-ISO 13788. The correlation of outdoor air temperature and indoor moisture load, as well as the resulting relative humidities are indicated in Figure 1 for a building in Holzkirchen with varying utilisation. Humidities are defined in 5 different classes according to utilisation.

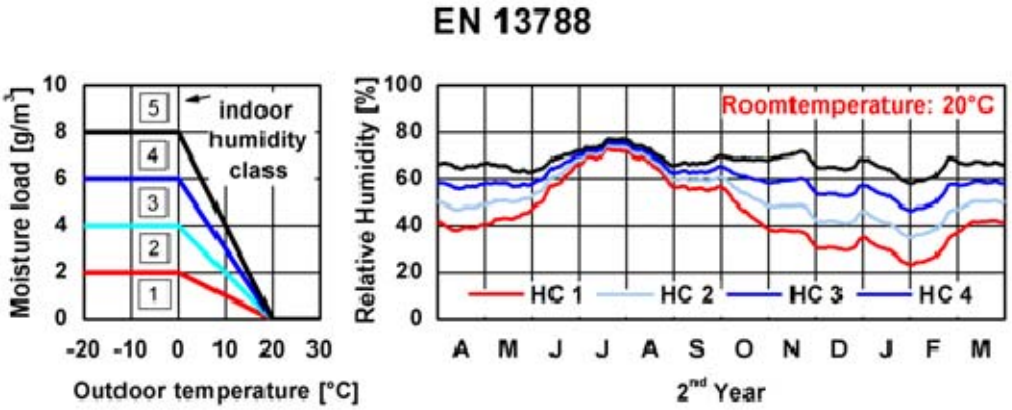

Figure 1. left: moisture load ranges in heated rooms without air-conditioning in dependence of the monthly average outdoor air temperature. Utilisation is defined as a class:
1: storehouse
2: offices, shops
3: apartments with low occupation
4: apartments with high occupation, sports halls, kitchens, staff canteens, buildings with gas thermes
5: specific buildings, i.e. breweries, indoor swimming pools, etc.
right: progression of calculated relative indoor air humidity for the Holzkirchen location according to 5 moisture classes.

Relative indoor humidity is determined by the absolute humidity of indoor air at the constant annual indoor air temperature of 20° C. The result for the absolute humidity ci is ci= ce + □c, with ce as outdoor absolute humidity and □c as moisture load, resulting from the monthly outdoor air temperature and the respective classification in 1 to 5.

The approach to compute indoor environment conditions described in this standard is based primarily on Scandinavian findings. The transformation of this approach to non-stationary conditions is highly dependent on the type of building and ventilation conditions. Another question is, whether this approach can be transformed to other European climate regions, especially southern European countries. The progression of moisture generation at temperatures below 0° C and classification in moisture classes is still problematic.

2.2 EN-ISO 15026

The method described in EN-ISO 15026 is based on measurements, carried out in different buildings in Germany. The progression of indoor temperature and relative humidity can be determined by means of transfer functions from outdoor air temperature. In this case and in contrast to EN-ISO 13788 a 24-hour variable average value is used for outdoor temperature with the intention to simulate daily variations. The transfer functions for indoor air temperature and relative humidity in dependence of the 24-hour variable average value of outdoor air temperature as well as the respective indoor environment conditions for the Holzkirchen location are indicated in Fig. 2.

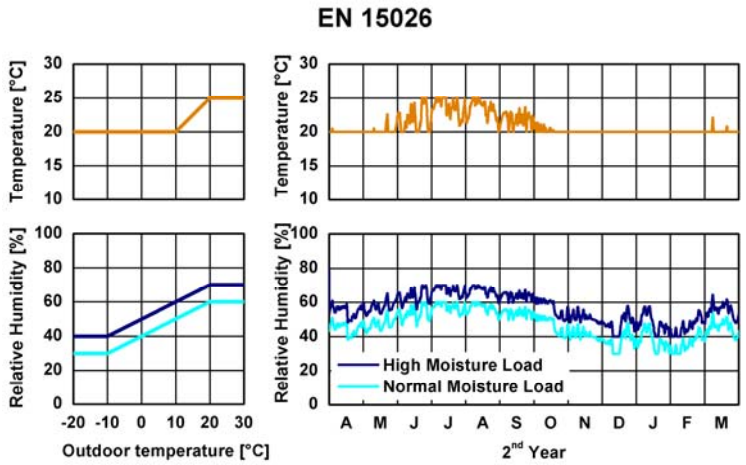

Figure 2. left: Transfer functions for indoor air temperature and relative humidity in dependence of the 24-hour variable average value of outdoor air temperature
right: progression of the computed relative indoor air humidity for the Holzkirchen location according to 2 moisture classes.

The progression of temperature seems to be more realistic in this standard in comparison to EN-ISO 13788, especially as concerns the fact that indoor temperatures in summer rise to values between 20° C and 25° C. There is generally a differentiation between only two moisture classes, a high and a low moisture load.

International Association for Science and Technology of Building Maintenance and Monument Preservation – Directive 6-2-01

Indoor environment conditions are reproduced in a simplified way by a sinusoidal smoothed annual progression in the German WTA-Directive 6-2-01. This approach is exclusively suited for Central European climate conditions. In contrast to EN-ISO 13788, however, there are only three moisture classes. If we compute the respective moisture load for a room, we learn that the limits of the respective classes intensely diverge in both standards. For example, the maximum moisture load for a living room with usual occupation at a monthly average outdoor air temperature of 10 °C results in 2 g/m3, and according to DIN EN ISO 13788 in 3 g/m3 (corresponds to a high moisture load in the WTA Directive). A possible explanation for this fact may be the differences in construction and climate-related ventilation behaviour, and could be justified as future approach on the basis of a secure interpretation of the moisture computation (higher indoor air humidity generally means higher humidity in the construction).

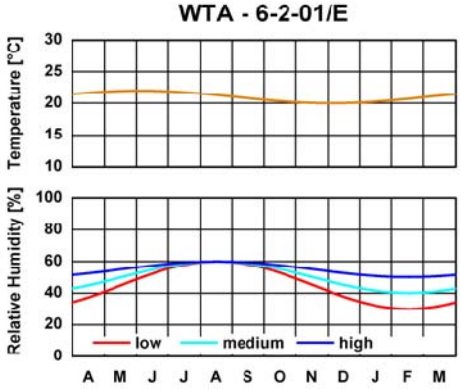

Figure 3. top: Transfer functions for indoor air temperature and relative humidity in dependence of the 24-hour variable average value of outdoor air temperature
bottom: progression of the computed relative indoor air humidity for the Holzkirchen location of 2 moisture classes.

Figure 3 clearly shows that the days with maximum values for relative humidity and temperature diverge. The maximum value is already reached in June in contrast to the observed progression of indoor air humidity.

3 HYGROTHERMAL BEHAVIOUR OF THE ENTIRE BUILING

The hygrothermal behaviour of the surfaces influences the behaviour of the entire building. The programme WUFI-Plus offers the possibility to simulate indoor climate conditions in buildings. The new hygrothermal computation tool can compute the temperature and humidity conditions of the ambient surfaces and of indoor air as well as the energy requirements or energy consumption.

3.1 Description of the Building

The hygrothermal behaviour of a 1½-storey building with a total living space of 160 m2 and a net spatial volume of 422 m3 was investigated for the study. The building is ideally constructed without basement. The roof has an inclination of 50 degrees and an orientation to the north and south. In case of the investigated roof, the 160 mm high clearance between the rafters is filled with cellulose fibres (assumed bulk density of 60 kg/m3). The wooden formwork is covered with a vapour-tight bitumen sheet. The insulation material has a thermal conductivity of 0.04 W/mK and a µ-value of 1.5. In contrast to mineral fibre materials, cellulose fibres have certain humidity storage capacities, which may have an influence on the hygrothermal behaviour. The vapour barrier is taken into account by a 1 mm thick layer with adequate µ-values. The limiting gypsum plasterboard, which is installed inside, has a respective sd-value of 0.15 m. The total u-value of the construction is 0.226 W/m2K. All façade elements have the following structure from the outside to the inside: 1cm mineral plaster (short-wave absorption 0.4), 5 cm wood wool lightweight construction sheet, OSB boards, 20 cm hydrophobic mineral wool. A wooden panel construction serves as internal shell. Two-pane windows are installed in each façade. All material data come from the WUFI database.

The hygrothermal computations started in April with an initial water content equivalent to 80 % relative humidity. The computations were carried out over a period of 2 years. Hourly climate boundary conditions for the Holzkirchen location are applied. Impacts of driving rain are only considered for façades and according to orientation. The external heat transmission resistance is 0.0526 for the roof and 0.0588 m2K/W for the façades. The heat transmission resistance for all internal surfaces is 0.0125m2K/W. The minimum indoor temperature of 20° C should be maintained by means of a heating system of 15 KW.

3.2 Description of the Investigated Variations

Fig. 4 gives a survey of the different simulated scenarios. The daily profile of ventilation and internal thermal and moisture loads is varied in the process. First of all, the pure hygrothermal behaviour of an empty building is simulated in the cases 1 and 2. The building is only ventilated by infiltration air exchange in case 1. Due to the airtight windows, the hourly air exchange rate amounts to 0.2 h-1. In the following cases, air exchange is varied in a way that the daily average air exchange is 0.5 h-1. In the cases 3 and 5, the building is occupied by 4 persons over a period of 24 hours a day. Two short-term ventilation strategies are investigated to simulate the impact of user behaviour. In case 4, the window is left ajar over a period of 1 hour, at 8 a.m. and 6 p.m. (n = 4 h-1). In the cases 5 to 7 ventilation is shorter (30 minutes), but more intensive (n = 8 h-1). To simulate the impact of irregular user behaviour, the building is occupied by 4 persons only between 6 p.m. and 8 a.m. in the cases 6 and 7. Thermal and moisture loads vary hourly during the day. In the process, special attention was paid to the fact that the moisture load was kept constant at 12 kg/day in all cases.

3.3 Simulated Indoor Climatic Conditions

The results for indoor air temperature and relative humidity computed for the cases 1 to 7 by means of WUFI-Plus are indicated in Fig. 5. These clearly demonstrate the impact of the internal thermal and moisture load as well as the non-stationary ventilation behaviour. If there are no additional thermal and moisture loads in the building, relative humidity varies between 15 % in winter and 70 % in summer. The difference of an air exchange of 0.2 and 0.5 is almost negligible. In an occupied building with a constant air exchange rate of 0.5 relative humidity varies between 40 % and 70 %. The minimum temperature of 20° C can be maintained. The temperature in summer rises to maximum values of almost 30° C. The reason is that no additional ventilation was assumed in summer and no additional measures for solar control were adopted. Most obvious is the impact of ventilation behaviour. In contrast to continuously constant ventilation short-term ventilation by opening the window modifies daily variations of relative humidity by almost -10 %. Moreover, it is impossible to maintain the indoor air temperature of 20° C in winter because of the insufficient heating systems during the ventilation phase. This corresponds to the measurements.

The resulting indoor air temperatures and humidities must be statistically analysed. The direct comparison of standard boundary conditions and progressions computed by WUFI-Plus shows clear-cut differences. This may be demonstrated by the example of an apartment with low and normal occupation. In this case and in accordance to EN 13788 the humidity class HC 3 is to be applied. The average value of relative humidity is approx. 60 % with fluctuations of approx. ± 10 %. The usual moisture load can be applied for such a building according to EN 15026. In this case, the average value of the relative humidity is approx. 45 % with fluctuations of approx. ± 10 %. A similar progression of the relative humidity is achieved by applying the standard boundary conditions according to the WTA Directive with an average value of approx. 50 % with fluctuations of approx. ± 10 %. If we compute the progression of relative humidity by means of WUFI-Plus, the result for the two first cases without any additional thermal and moisture sources is a relative humidity of a value slightly below 40 % with fluctuations of slightly below 20 % to 60 %. The impact of the users (cases 3 to 7) is clear-cut. The average relative humidity is increased by 45 % to 50 % for the respective case only by the real utilisation of the building simulated by thermal and moisture load. Indoor relative humidity is increased by a further 5 % by short-term ventilation by opening the window despite the same amount of thermal and moisture load.

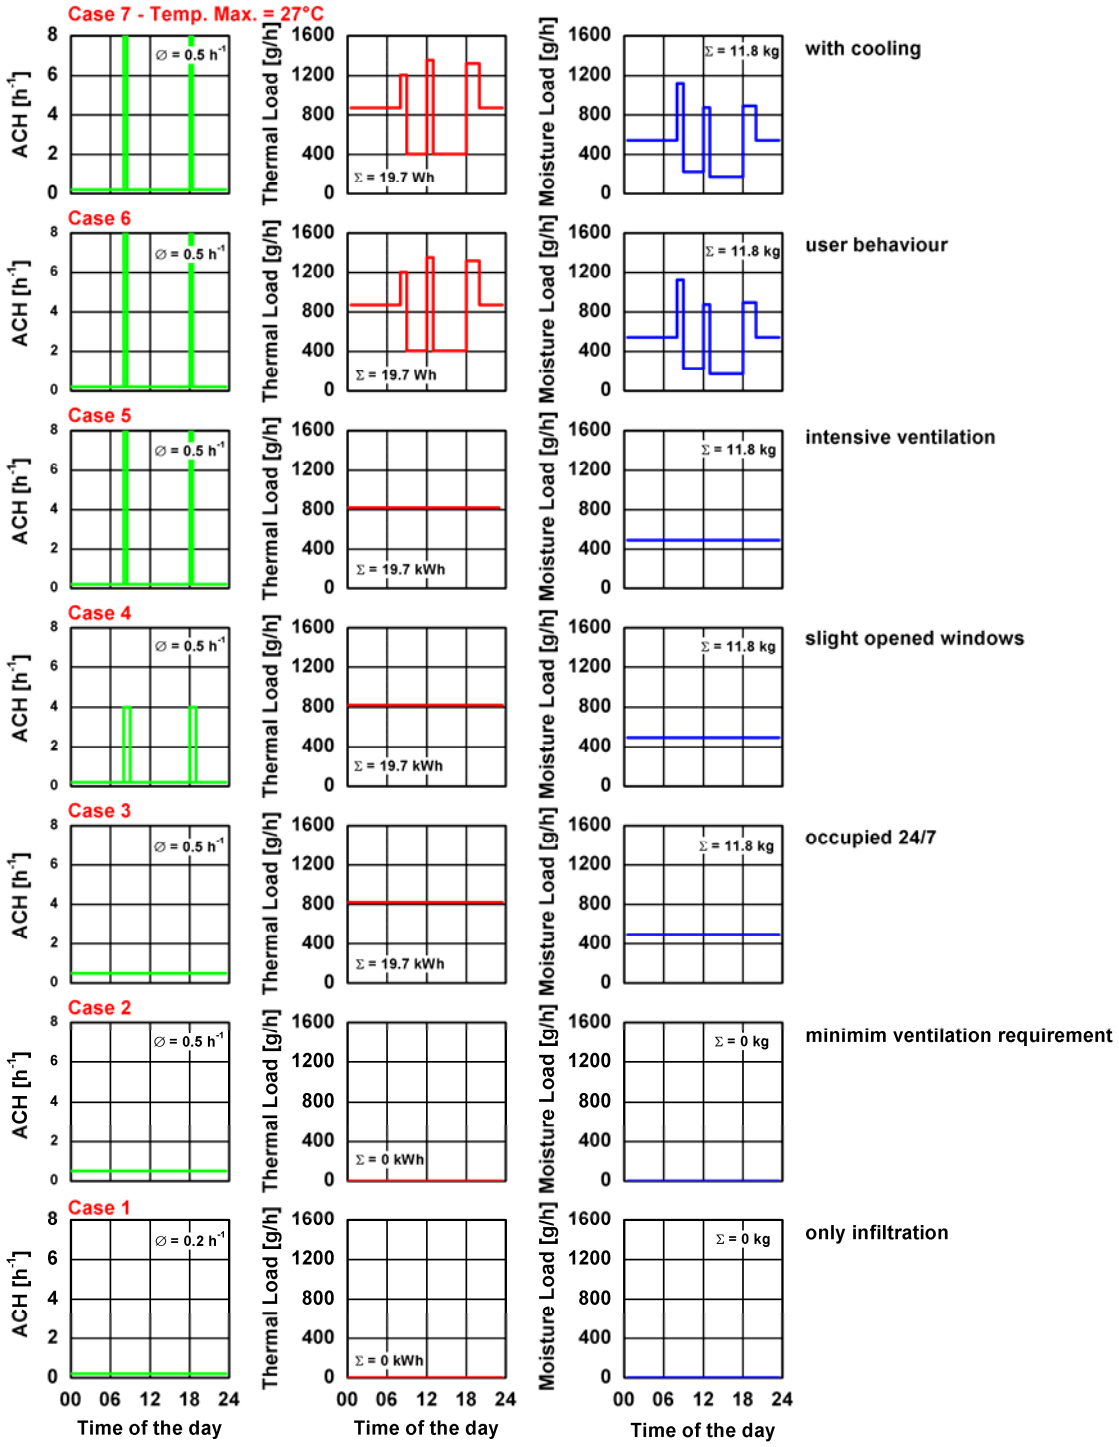

Figure 4. Daily profile for the estimated air exchange as well as internal thermal and moisture loads in seven cases.

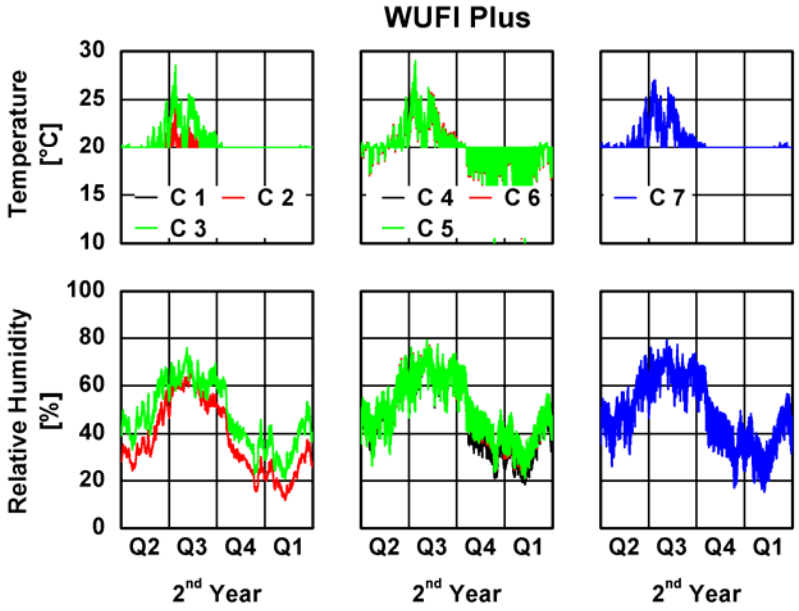

Figure 5. Resulting relative humidity and temperature of seven variations.

4 IMPACT ON THE HYGROTHERMAL BEHAVIOUR OF BUILDING COMPONENTS

It is investigated in the following, how the various standard boundary conditions according to the 3 standards and different user behaviour computed by means of WUFI-Plus influence the hygrothermal behaviour of a roof orientated to the north, or of a façade orientated to the west. For comparison, the water contents in the timber shell of a roof with a 50-degree inclination to the north was investigated as well as the total water contents in the construction.

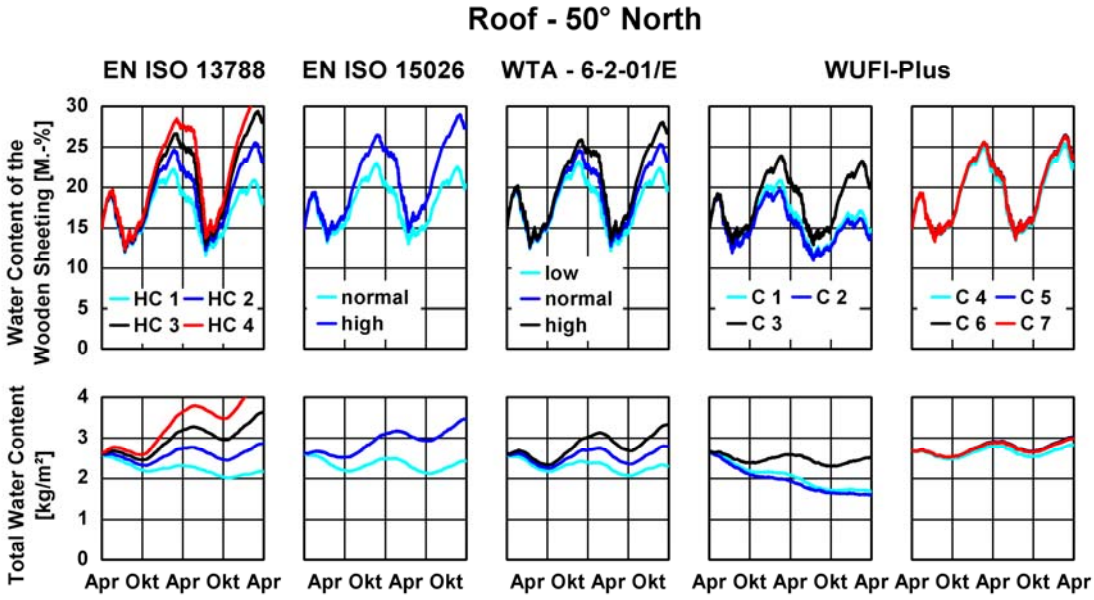

Figure 6. Computed progression of the water content in the timber shell (above) and of the total water content (below) based on various indoor climate data.

Figure 6 shows the results for the investigated roof in a diagram. Computations by means of WUFI of the hygrothermal behaviour according to the boundary conditions of EN 13788 show that this roof is no longer hygrothermally "secure" from moisture class 2. The assessment of this construction

according to EN 15026, however, rates it as hygrothermally harmless according to the respective usual boundary conditions. According to WTA, a slight increase in the total water content occurs in the course of the year at a standard moisture load. Computations by means of WUFI-Plus also provide clear-cut differences in the hygrothermal behaviour. Whereas the construction is rated to be hygrothermally harmless for the cases C1 and C2, it is assessed to be just hygrothermally harmless for case C3 (continuous occupation, constant ventilation). In case of non-stationary ventilation or non-stationary user behaviour with the same thermal and moisture load, however, the total water content as well as the water content in the timber shell clearly increase. If the results are compared to the respective standard boundary conditions, it is obvious that the moisture class is modified by one category by non-stationary behaviour alone. This means that the computations according to EN 15026 in case of non-stationary behaviour provide more realistic values for the moisture class. Similar results are achieved for the west façade (Fig. 7). If we compare the computed results by means of WUFI-Plus with those of the standard boundary conditions, we see that the standard boundary conditions have various effects on the hygrothermal behaviour, and that there is a clear impact of the user behaviour.

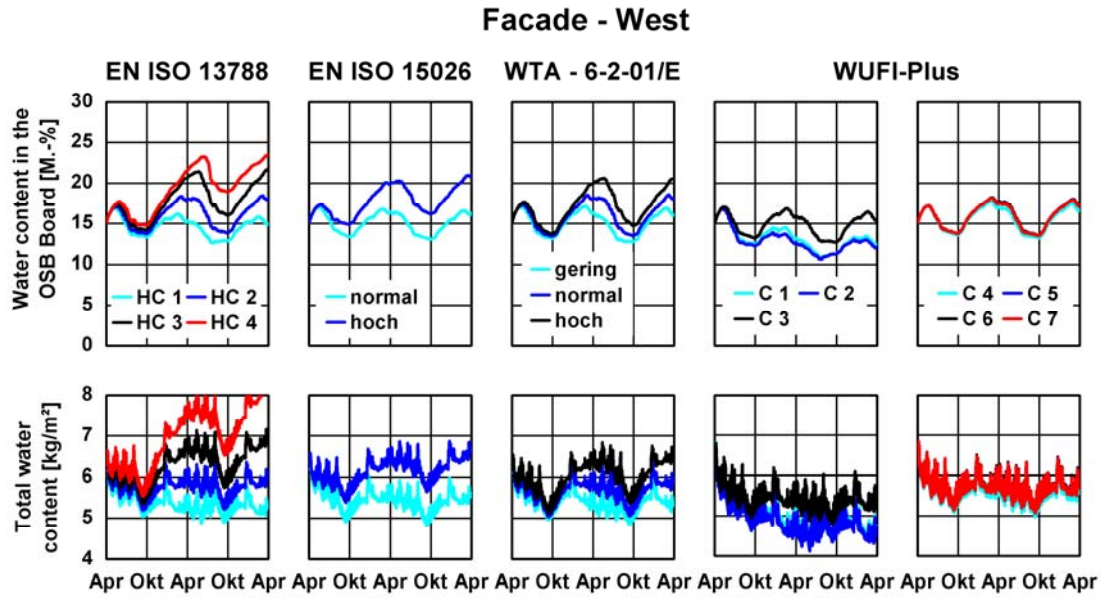

Figure 7. Computed progression of the water content in the timber shell (above) and the total water content (below) based on various indoor climate data.

5 SUMMARY

Average relative humidity in residential buildings is characterised by the seasons in Central European climate conditions. At outdoor air temperatures around the freezing point it is usually around 30 % r. h., during in-between seasons it is between 40 % and 50 % r. h., and in mid-summer it may rise to 60 % r. h. Since the hygrothermal measurement or assessment of building components strive for a result "on the safe side", excessive boundary conditions are applied for the most part instead of average indoor climate conditions.

As the effects of boundary conditions in case of simulation computations are manifold (e. g. impacts on the humidity- and temperature-dependent material parameters), it is recommended to apply climate conditions as realistic as possible. Supported by new standards and directives, the hygrothermal building component simulation continuously replaces the stationary calculation of Glaser as hygrothermal assessment method for building structures. Adequate boundary conditions must be selected accordingly, whereby indoor relative humidity is especially important.

The comparisons of the results from indoor climate simulation show that WTA boundary conditions for a standard moisture load should be usually applied for residential buildings or the respective

boundary conditions according to EN ISO 15026. Applying these boundary conditions means the choice for the safe side. It seems to be reasonable to apply high moisture loads in buildings, where particularly unfavourable indoor humidity conditions must be expected.
The moisture classes according to EN ISO 13788 provide too high values in any case, and must thus be selected with caution.

T 33

ABSTRACT

Current models to predict heat, air and moisture (HAM) conditions in building components assume uniform boundary conditions, both for the temperature and relative humidity of the air in an indoor space as well as for the surface transfer coefficients. Such models cannot accurately predict the HAM conditions in the component and on the surface of the component with non-uniform air temperature or relative humidity distributions in an indoor space. Moreover, the heat and moisture surface transfer coefficients strongly depend on the local air velocity, local temperature, water-material interactions and water content at the material surface and surface texture of the material. The objective of the present paper is to analyze the influence of the non-uniform local air velocity near the surface of a building component on the HAM conditions in the component. A case study and sensitivity study have been used to investigate this influence. The research showed that the indoor environmental conditions and local airflow velocity have a relatively large influence on the predicted HAM conditions in a building component. The influence of the convective surface heat transfer coefficient on the HAM performance of the component is relatively large compared to the influence of the convective surface mass transfer coefficient. With respect to the analyzed building component, the investigations showed that assuming an average value for the surface mass transfer coefficient is acceptable, while assuming an average value is not acceptable for the convective surface heat transfer coefficient. The study showed that the influence on the surface relative humidity is limited.

1 INTRODUCTION

The durability of building components is strongly dependent of the heat, air and moisture (HAM) conditions in the component. Current models to predict heat, air and moisture conditions in building components commonly assume uniform indoor boundary conditions, both for the temperature and relative humidity of the neighbouring interior air as well as for the interior surface heat and mass transfer coefficients. Due to local heat and moisture sources, imperfect mixing and microclimatic effects, temperature and relative humidity in the neighbouring air are seldom uniform. Similarly, the convective surface heat and moisture transfer coefficients strongly depend on the local air velocity, local temperature, water-material interactions and water content at the material surface and surface texture of the material. The HAM conditions on or in building components resulting from such non-uniform boundary conditions cannot be accurately predicted by current HAM models. This article investigates how the variability of the surface heat and mass transfer coefficients may affect the HAM performance of building components.

Currently, researchers assume average, uniform and constant values for the convective surface heat and mass transfer coefficients when performing a HAM component analysis. The convective surface transfer coefficients are obtained from fundamental theory or experimental work, in [Hens, 2007] for example, values of 3.5 W/m^2K and $3 \cdot 10^{-8}$ s/m for the interior convective heat and mass transfer coefficients respectively are recommended.

Previous research [Worch 2004] [Novoselac 2005] have shown that different relationships for the surface heat transfer coefficient for mixed convection near a building component have been reported. Similar experimental investigations of the relationship between the surface mass transfer coefficient and the local airflow velocity have been described in [Bednar & Dreyer 2003], [Mortensen *et al*. 2006] and [Iskra & Simonson 2007]. Other researchers, for example [Steeman *et al*. 2007], tried to determine the surface heat and mass transfer coefficients by using Computational Fluid Dynamics (CFD).

The literature study showed that a considerable number of relationships between the indoor environmental conditions and the surface heat transfer coefficients have been developed, all having their specific limitations and applications. When performing a HAM building component analysis, often, researchers arbitrarily use these relationships for a HAM component simulation, without considering these limitations. The use of these correlations may introduce errors in the predicted HAM conditions. The objective of the present paper is to analyze the influence of the non-uniform distribution of the transfer coefficients caused by variations in the air velocity near the surface of a building component on the HAM conditions on and in the component. A parameter study has been used to investigate this influence.

2 CASE STUDY

A building detail has been selected for the analysis. Two rooms (on top of each other) are connected by a lightweight concrete floor. Both rooms are connected to the outdoor climate by a wall, consisting of a layer of brick, interior mineral wool insulation and a gypsum board finishing layer. Air circulates in the room from the ceiling along the wall to the floor. The construction is presented in Fig. 1. Due to inertia effects, the air velocity near the corners (indicated by 1 and 2, Fig. 1) is relatively low compared to the average air velocity in the room. Lower air velocities result in relatively low convective surface heat and mass transfer coefficients near the corner compared to the surface transfer coefficients in the centre of the components.

First of all, lower and upper limits for the surface transfer coefficients have been determined based on the literature study. Second, the HAM performance of the component Fig. 1 has been investigated using several indoor environmental conditions and different values for the convective surface heat and

mass transfer coefficients. The specific conditions which have been analyzed are described in Section 2.1. Section 2.2 presents the climatic conditions, which have been applied.

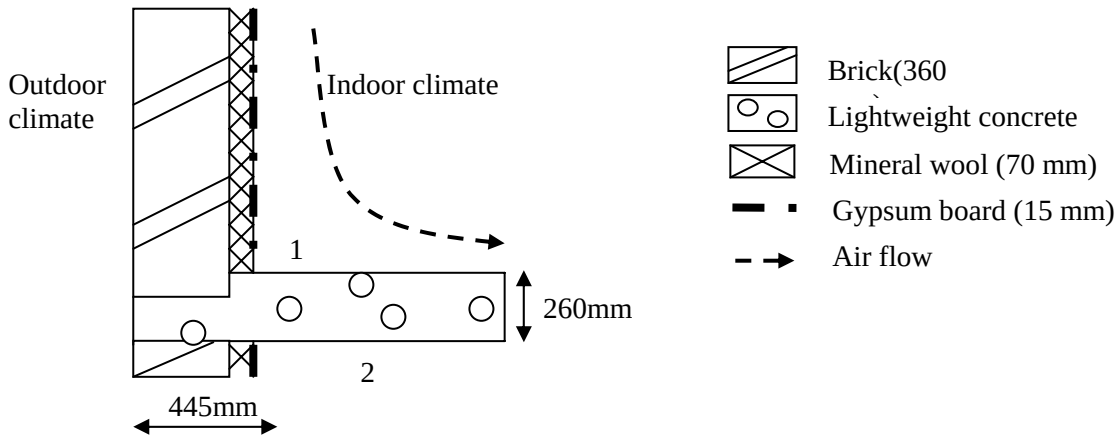

Figure 1. Building detail that has been selected for analysis. Two rooms, connected to the outdoor climate by a wall, consisting of a layer of brick, interior mineral wool insulation and a gypsum board finishing layer. Air circulates in the room from the ceiling along the wall to the floor. The surface heat and mass transfer coefficients near the corners are relatively low compared to the surface transfer coefficients in the centre of the components.

2.1 Parameter Analysis

Based on the literature study, lower and upper limits for the surface heat and mass transfer coefficients have been determined. For 'still' air conditions, where the local air velocity near the component is relatively low, the surface heat and mass transfer coefficient are assumed to be respectively 1 W/m^{2}K and $1 \cdot 10^{-8}$ s/m. For 'moving' air conditions, where the local velocity near the component is relatively high, values of 8 W/m^{2}K and $1 \cdot 10^{-7}$ s/m for the convective surface heat transfer coefficient ($_c$) and the convective surface mass transfer coefficient ($_c$) respectively.

Several indoor environmental conditions have been investigated:
Lower limits: A HAM component analysis assuming lower limits for the convective surface transfer coefficients has been performed.
Upper limits: A HAM component investigation applying upper limits for the convective surface transfer coefficients has been carried out.
Lower limits and average heat transfer coefficients: A HAM component analysis assuming lower limits for the surface moisture transfer coefficients and an average value for the convective surface heat transfer coefficient ($_c$) has been applied.
Upper limits and average heat transfer coefficients: An average value for the convective surface heat transfer coefficient ($_c$) has been applied, while the higher limit for the convective moisture transfer coefficient is applied.
Lower limit region: A (more realistic) situation was analyzed using a combination of a lower limit for the surface transfer coefficients in the region near the corner and upper limits outside of this layer. The size of the region has been varied between a distance of 30 cm (5a) and 10 cm (5b) from the corner of the building component

Typical values for the convective heat and moisture transfer coefficients, which have been applied for the different indoor environmental conditions, are presented in Table 1. The objective of the investigations (1 and 2) is to determine minimum and maximum HAM conditions, which are likely to

occur in the building component. The objective of studying the conditions using an average value for the convective surface heat transfer coefficient (conditions 3 and 4) is to compare the influences of the convective heat transfer coefficient and the moisture transfer coefficient separately. With respect to the lower limit region, this investigation intends to determine the influence of the size of the still air region on the predicted HAM conditions.

Table 1. Convective heat and moisture transfer coefficients, which have been applied for the different indoor environmental conditions.

Conditions	$_c$ [W/m^{2}K]	$_c$ [10^{-7} s/m]
1 Lower limits	1	10
2 Upper limits	8	1
3 Lower limit $_c$ and average $_c$	3.5	10
4 Higher limit $_c$ and average $_c$	3.5	1
5a 30 cm region	1 and 8	10 and 1
5b 10 cm region	1 and 8	10 and 1

2.2 Boundary conditions

The parameter analysis has been performed using the Test Reference Year (TRY) for Danish (Copenhagen) outdoor climatic conditions. With respect to the indoor environment, hourly values for the indoor air temperature and relative humidity have been obtained using a whole building performance simulation of the building from the IEA & ECBCS programme, Annex 41, Subtask 1 [Rode & Woloszyn 2006]. The document [Rode & Woloszyn 2006] presents Common Exercise 1 which expands on Common Exercise 0 by adding an analysis of the indoor and building envelope moisture conditions for the BESTEST building used in Common Exercise 0 (from IEA SHC Task 21 & ECBCS Annex 21). The building has been simulated in HAMBASE [Wit, de 2006] using set points of 20^{o}C (during office hours) and 12^{o}C (outside office hours) for heating and 27^{o}C for cooling (during office hours). With respect to the moisture production in the building, an average vapour production of 10 litres per day is spread out over the day. The indoor environmental conditions resulting from the simulation are applied as boundary conditions on the surfaces at the internal sides.

3 RESULTS

The HAM performance of the building component (Fig. 1) has been simulated using the CHAMPS-BES Program for Coupled Heat, Air, Moisture and Pollutant Simulations in Building Envelope Systems [Nicolai & Grunewald 2006]. Outdoor and indoor climate conditions (Section 2.2) have been applied at the boundaries. With respect to the initial conditions, an initial temperature and relative humidity of 20^{o}C and 50 % RH respectively have been applied throughout the entire component. The simulation time is one year. The simulation results for 70 days are presented in Fig. 2.

Figure 2 shows that a relatively large difference is present between the lower limit (1) and the higher limit (2). Considering the average difference between both limits over the entire year, an average temperature difference of 2.5^{o}C and an average difference in relative humidity of 16.8 %RH have been observed. A difference in partial vapour pressure of approximately 77 Pa between the lower limit and higher limit condition has been observed. For temperatures around 15-20 °C and saturation pressures around 1500-2000 Pa, this is less than 4 % RH difference and may be negligible. Moreover, the partial vapour pressure resulting from both conditions (1) and (2) follow a similar trend. The influence of the convective surface heat transfer coefficient on the HAM performance is thus relatively large compared to the influence of the convective surface mass transfer coefficient. Figure 3 presents the heat and

moisture fluxes to the indoor environment. Comparing conditions with lower (1) and higher limits (2), a significant difference between the size and the direction of the heat fluxes has been observed.

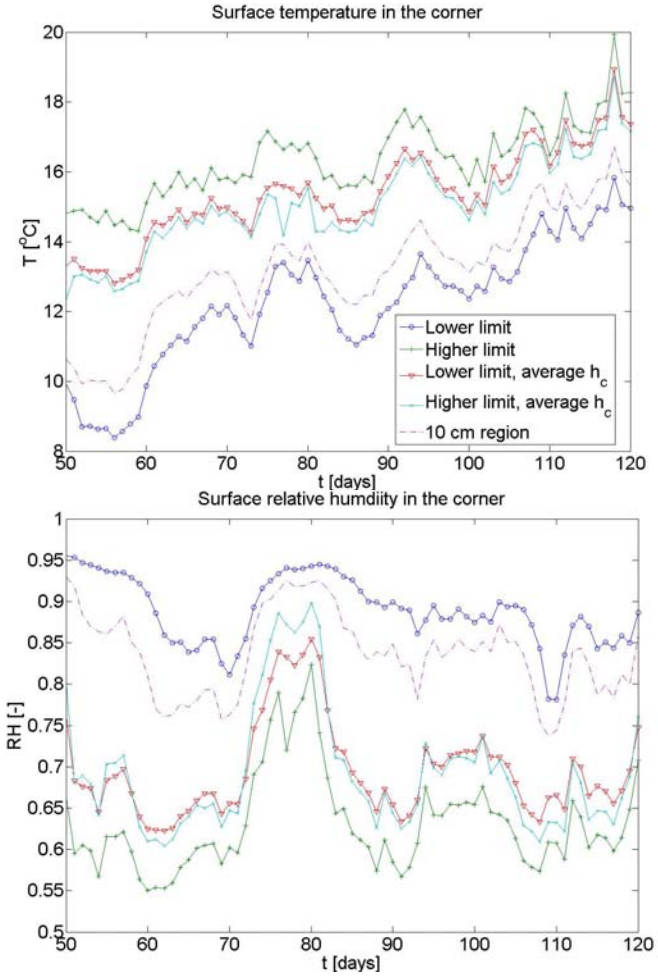

Figure 2. Surface temperature (left) and relative humidity (right) in the corner of the building component. The different conditions (Section 2.1), i.e. lower limits, higher limits and average values for the surface transfer coefficients corresponding.

Figure 2 shows that the predicted HAM conditions for the conditions with an average surface heat transfer coefficient (conditions 3 and 4) are comparable. The average temperature and relative humidity deviation over the year between conditions 3 and 4 is approximately 0.33°C and 0.26 % RH respectively. The simulation results show that the influence of the surface heat transfer coefficient on the predicted HAM conditions is relatively large compared to the influence of the surface moisture transfer coefficient. In addition, the moisture fluxes (Fig.3) for both conditions (3 and 4) are relatively comparable.

Regarding the size of the still air region (condition 5), the difference in average surface temperature and relative humidity in the corner is 0.5°C and 2.5 % RH respectively. Figure 2 presents relatively comparable HAM conditions even when the size of the still air region is varied by a factor 3. In summary, the investigations show that the local airflow conditions near the component (especially in the corner) should be taken into account. The size of the lower limit region, which is assumed, is less important for the conditions in the corner. However, the size of the low coefficient region will of course determine the size of the region with potential durability problems.

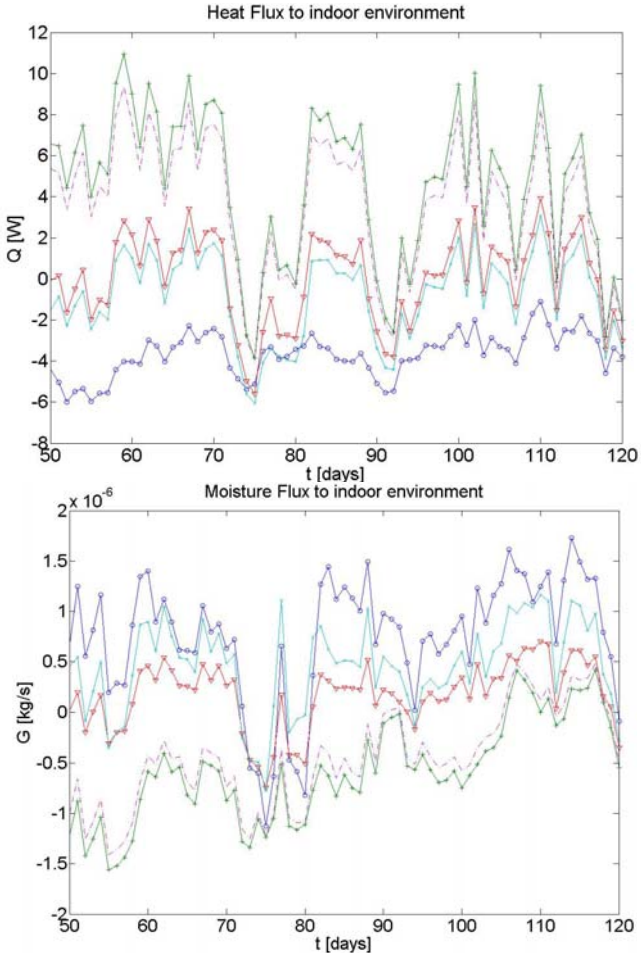

Figure 3. Heat fluxes (left) and Moisture (right) to the indoor environment. The different conditions (Section 2.1), i.e. lower limits, higher limits and average values for the surface transfer coefficients corresponding. The corresponding legend is presented in Fig. 2.

The simulation results show that a relatively large deviation is observed between the lower limit and higher limit conditions. Assuming 'moving' air conditions near the component, the average temperature and relative humidity in the corner are approximately 17.7°C and 70 %RH. These conditions may develop moisture problems, for example mould growth. However, the risk for moisture problems is relatively small compared to the predicted lower limit conditions, i.e. an average temperature of 15.2°C and a relative humidity of 87.8 %RH in the corner. Focussing on the (more realistic) case with a 'still' air region near the corner, these results also show that moisture problems are likely to occur. It is concluded that the application of the appropriate airflow conditions near the component has a relatively large influence on the predicted HAM performance of the component.

4 CONCLUSION and DISCUSSION

This section presents the conclusions from the parameter study and the consequences of the investigations for HAM component performance analysis. The influence of the non-uniform surface heat and mass transfer coefficients on the HAM conditions in the building component has been analyzed. A parameter study has been used to investigate this influence. Lower and upper limits for the convective surface transfer coefficients ($_c$ and $_c$), assuming respectively 'still' air and 'moving' air conditions, have been assigned. The simulated conditions resulted in minimum and maximum HAM conditions in the building component. Moreover, the combination of a 'still' air region near the building component has been investigated.

It is concluded that:

- The non-uniform distribution of the transfer coefficients caused by variations in the air velocity near the surface of a building component have a relatively large influence on the predicted HAM conditions in a building component. Different surface temperature, relative humidity and vapour pressures are predicted, when different airflow conditions near the component, resulting in different convective surface transfer coefficients, are applied. When performing a HAM performance analysis and simulation, it is important to take the local airflow velocity near the component into account.
- The influence of the convective surface heat transfer coefficient on the HAM performance is relatively large compared to the influence of the convective surface mass transfer coefficient. With respect to the analyzed building component, the investigations showed that assuming an average value for the surface mass transfer coefficient is acceptable, while assuming an average value is not acceptable for the convective surface heat transfer coefficient. The study showed that the influence on the surface relative humidity is limited. However, an influence on the fluxes is still present.
- Local indoor environmental conditions and deviations in local air velocities, for example due to corners, should be taken into account. A possible approach is to assume a still air region. The size of the still air region, which is assumed, showed to be less important for the quality of the predicted conditions in the corner, but will determine the possibly mould affected region's size.

Building researchers and designers should be aware that the appropriate indoor environmental conditions are applied, when performing a HAM component simulation and analysis. The local airflow conditions near the component have a relatively large influence on the predicted HAM performance of the component. It is recommended that, for example in a design stage, different local airflow conditions are investigated to predict the influence of these conditions on the HAM performance of the specific component.

Future research should focus on the analysis and determination of the relationship between the local air velocity near the component and the convective surface heat transfer coefficient. A more detailed description and prediction of the interaction between the indoor environment and the HAM conditions in the building component is desired. The quality of such an analysis could be improved by providing guidelines and relationships between the convective surface heat transfer coefficient and the local air velocity near the building component. With respect to the convective surface mass transfer coefficient, it is acceptable to assume an average coefficient.

Feedback System for Determination and Elimination the Effects of Durability Problems

Gamze Özkaptan Alptekin [1]

T 41

ABSTRACT

Depending on the innovation in material engineering and technology, a great many building materials and building components have been served to the construction market. Entering these newly developed materials and components to the building system, without finding sufficient opportunity for experimentation, may cause quality problems named as building failure. Selection of inappropriate materials/components and detailing errors in design phase (design failure), construction errors in construction phase, insufficient maintenance and misusage in occupation phase results in building failure, some of stemming from durability problems in life cycle of the building.

In order to improve building quality, multi-disciplinary and multi-phased building production process should be integrated by using the means of communication technology. Tracking of durability problems in occupation phase and feed-back of information to the design and construction organizations should prevent these organizations from repeating similar failures in further projects. Some models were developed in the context of Customer Relationship Management (CRM) in order to collect information from occupation phase, but a model which is focused especially on durability problems and their effects is needed. It is possible to use an information model in order to record building failure information systematically for eliminating losses and improve building quality. In this paper, conceptual structure of an information model developed for organizing building failure is presented.

1 INTRODUCTION

Building production process is a multi-disciplinary and multi-phased activity. Usually independent organizations collaborate in the scope of a project for a limited time and scattered when their contract finished. Each organization has its own characteristics with their organizational culture such as organizational structure, type of working, information system and procedures. These organizations join to the project team for a limited time, in whatever time needed and leave whenever they finish their work. This situation constitutes a fragmented structure that obstructs the continuity in the building production process and results with some quality problems.

Some vital information which can be used in programming, design and constuction phases can be obtained in occupation phase in life cycle of the building. Lack of information flow between these phases and especially lack of feed-back information to the design organization causes quality problems stemming from coordination problems in the process as well as integration problems in the product.

Construction is a project type production and quality of a construction project can be evaluated with its process (production phases) and product (building) as a whole. Quality problems in a construction project can be resulted as cost overruns, time overruns and performance problems. Building failures constitute the main reason in quality problems. Reasons of building failure may differ, but durability problems are the major factor of building failure that can be determined in occupation phase. Enabling integration among the the poject phases and disciplines, feed-back of information from occupation phase to the design phase may increase project quality by eliminating durability problems.

Design phase and design product is core of the quality problems because the most critical decisions, according to the scope of the project, construction system, technical subsystems, materials and components, that are determinant on building quality, are taken on this phase. As the volume of information flow in design phase is very large, an information system is needed for keeping and tracking of this information to secure the quality of design phase and design documents in project level. When we look from design organization's point of view, more than one complex projects may be undertaken which are in different phases simultaneously. Information in a design organization is constituted from the information produced in the design organization and information gathered from outer resources. Design organization uses and integrates the information that is gathered from outer resources in order to produce design products. Some of this information is related with the materials selected, codes, standards, specifications and information taken from material suppliers which is directly related with the scope of this paper. Information flow in a design organization is so complex and must be put in order by using a systematically structured information system. Such a system may have a sub-module for enabling feedback information according to performances of building materials and components determined in occupation phase.

2 RELATED WORKS

In a literature review, it can be seen that there are some resarch studies about integration of building production process. Conceptual models by Baldwin *et al.* [1999], Tan & Lu [1995], Matta *et al*. [1998] and Chan & Chan [1999], Erdener [2003] were proposed to serve as interfaces of information management, design management, facility management and quality management.

Some of the application models which were developed by Kanoglu [2001], to serve integration of design and construction management; by Mokhtar *et al.* [1998], Hegazy *et al.* [2001], Zaneldin *et al.* [2001], to serve design change management, can be found in literature.

Some studies realized by Marques *et al.* [2006], Ugwu *et al.* [2005], Richard [2007] according to durabilities of materails in particular can be found in literature.

There are some commercial softwares as SAP, InfoExchange, Barracuda, etc. Serving to FM (Facility Management) and CRM (Customer Relationship Managment) [http://solutions.iinet.org].

These models and studies bring out some partial solutions to the quality problems in building production. However, it has not been possible to locate a model to record and feedback building failures determined in occupation phase in order to increase building quality.

3 PROBLEM STATEMENT

Depending on the innovation in material engineering and technology, a grate many building materials and building components have been served to the construction market. By the enforcement of economical or technical requirements, or design preferences, these new materials take part in designs. Entering these newly developed materials and components to the building system, without finding sufficient opportunity for experimentation, may cause quality problems named as building failure. Selection of inappropriate materials/components and detailing errors in design phase (design failure), construction errors in construction phase, insufficient maintenance and misusage in occupation phase results in building failure, some of stemming from durability problems in life cycle of the building.

Information according to the materials and components supposed to be used in a design project is taking a significant place, in the large volume of information flow in design phase. Catalogues, codes and standards are some of the guiding documents that are to be used in preparing design documents and especially specifications. Nevertheless, many factors may have impact on the behaviour of the materials' or components' life cycle. Besides selecting the materials and components by the help of their testing results, appropriateness to the codes and standards, considering their warranty conditions, the risk caused by unexpected conditions may lead to problems on building quality. An information system is needed in order to record, organize and deliver project information in all the phases of building production process for tracking the performance of building components and materials in life cycle of the building.

Facility managers developed tools and guidelines to ensure occupants' comfort, building energy efficiency, environmental sustainability, building security, workplace flexibility, and other work environment requirements. The economic execution of the organizational, financial and operational processes as well as the continous fulfillment of the quality, security and environmental requirements, constitute the principal elements of facilities management [Ashuri, B. *et al.,* 2007]. There are some information models developed in the context of CRM, and FM, considering especially sales, service (operation and maintanence) and marketing, but there is a gap in feedback of information between design and FM organizations in order to determin and eleminate the effects of durability problems.

Feedback information is needed to be structured systematically as a part of the information system, because when it is not, relevant decisions often get lost or are ignored by busy specialists. Fisher [1995] emphasized some problems about feedback information in preconstruction phase as 'feedback loops are random, feedback is unmanaged, feedback is slow, significant feedback is very late, there are no inherent criteria for defining design versions, organizational control may lead to unstable designs, errors and omissions may occur in moving data from one discipline to another'. Potential benefits of successful integration include increased efficiency, reduced time, and improved quality for clients. Early, structured, precise, and rapid feedback will help specalists to recognise the effects of their choises on other specialties. Complete feedback from the viewpoint of all relevant disciplines is a major benefit of technical integration and will assist discipline experts in their understanding of the impact of their decisions and of the requirements of other disciplines [Fisher, 1995].

4 AIM OF THE STUDY

Building failures which constitute the main group in quality problems, may appear in construction and occupation phases. Building failures determined in construction phase generally may be solved preferably by a change order system or in situ. However, building failures determined in occupation phase are solved in the context of facility management, apart from the design or construction organization. Information according to technical details of building failures such as, reasons and effects of them are needed to be recorded and used by project participants, especially by design organizations. Reasons and effects of building failures determined in abovementioned phases differ, so separate information feedback models, as seen in 'Fig. 1' should be designed for each of them, as being the sub-modules of an integrated information system.

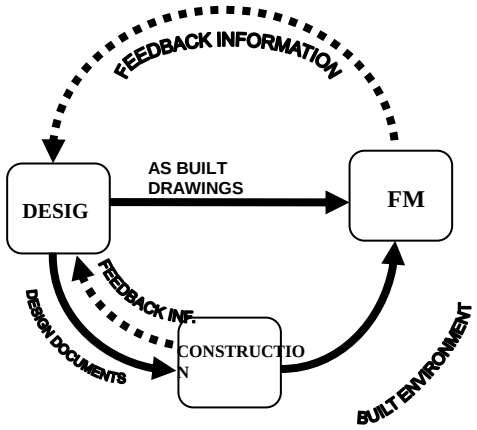

Figure 1. Information flow in Building Production Process

An information model in order to record and analyse the effects of building failure determined in construction phase 'IDEA' (Integrated Design Automation For Design/Build Organizations) was developed in an other research study made by the author [Alptekin 2006]. This model then integrated into MITOS-Multi Phased Integrated Automation System for Construction Industry, which has been developed for design/build organizations [Kanoğlu 1999]. A similar information model regarding building failures determined in occupation phase should be developed as a complementary module in order to be integrated into MITOS. By this way, it should be possible to determine the effects of building failure in general, and durability problems in particular serving to increase building quality.

A conceptual model, emphasizing the basic points that must be considered in the background of a practical model according to identify building failures determined in occupation phase will be put forward in this study.

5 A MODEL FOR DETERMINING AND ELEMINATING THE EFFECTS OF DURABILITY PROBLEMS

5.1 Reasons Of Durability Problems

Durability is defined as 'staying in good condition for a long time, even if used a lot' [Longman Dictionary of Contemporary English Online]. Peris Mora [2007] defined durability as 'the characteristic of those objects or materials that maintain their properties over time'. It can be understood that durability is directly related with the performances of materials or components in their lifecycle. Each material or component has a life span. Durability problem occurs when the material or component fails to accomplish its function before its intended life time. Because of this, durability problem is a type of building failure that can be detected in occupation phase. There are some factors

affecting the life span of the materials and components. Chew [2005] grouped these factors as design, material, construction and maintanence. Ugwu *et al.* [2005], added 'quality systems in use at the construction stages and environmental exposure of the building elements' as the factors affecting durability.

It can be seen from literature study that, mostly environmental factors are investigated as reasons of durability problems. Ransom [1987] defined the agencies causing deterioration as; solar radiation, moisture, biological agencies, gaseous constituents and pollutents of air, ground salts and waters, manufactured products and juxtaposition of materials and components. Addleson [1992] explained the causes of mechanisms of failure as; condensation,entrapped moisture, rain penetration, rising damp, movement, loss of adhesion, corrosion and timber decay. Although environmental factors are playing the main role on durability problems, design failure resulting from inadequate information about the materials or the interaction between the materials, and design defects in details have also a significant impact on them. Mitropoulos and Tatum [2000] emphasized the risk and liability involved in trying something new, difficulty in giving approval from third parties and resistance to change. Despite these barriers to innovation, nowadays designers are willing to take the risk and liability of using innovative materials, components and technologies in the competitive positions, for being different or for being cost-effective or for technical reasons. Neverthless, lack of information according to longterm behaviour of materials and lack of experince in applicaation on site may result with building failures.

Another problem may arise from the construction methods and workmanship on site. Construction is still a workman-based activity despite the efforts through industrialisation. Innovation in materials, components and procedures may require qualified site skills. Application of new materials and components by incompetent workmanship may affect durability of the materials and components.

Another reason of durability problems is related with the requirements of maintanance in occupation phase. Almost every building material or component has maintenance periods. Neglecting maintanance work or repair when needed, should have a negative impact on durability of building materials or components. Maintenance and repair activities are achieved in the context of facility management. An information model can be used in order to track maintenance periods and performances of building materials and components.

5.2 Effects Of Durability Problems

Durability problems cause the occupants feel unsatisfactory. If quality is explained as 'client satisaction', it is obvious that durability problems are one of the reasons of building quality problems. Durability problems have negative affect on performance of materials or components, as well as life cycle cost of the building. For a sustainable design, beginning from design stage to facility management, future maintenance, repair and replacement requirements are taken into account in life cycle cost planning. Durability problems causes revisions on cost plans because of unplanned repair or replacement costs. Durability problems may appear in a critical building element or component that is very difficult to reach, or may be in a close interaction with the other parts, so it may be a complex and costly work, to repair or replacement. Sometimes repair or replacement work may affect different subsystems or components. Under these sircumstances, durability problems may cause additional consequential costs including additional workmanship. Peris Mora [2007] suggested to use the advantage of certain building technologies as a solution for this problem. Modular construction would facilitate partial replacement of defective materials in engineering works enhancing the durability of the construction. But still durability problems can be considered as a risk for life cycle cost planning of the building.

5.3 Basic Elements Of Conceptual Model

There are some conseptual and practical models developed in literature and in practice according to both FM and CRM. These models are generally focused on sales, service (operation and maintanence)

and marketing. There are also some models serving to increase building quality by enabling integration between the phases of building production. There is a gap between facility management and design phase from the feedback of building failure information point of view. Information gathered in the context of facility management should be used in a structured feedback mechanism by the design organization in order to prevent repeating similar defects in further projects.

A model should be designed to function as a part of an integrated information system of Design/Build/FM organizations, in order to record building failure information determined in occupation phase. The model aims to maintain a feedback mechanism between facility management and design organizations. The proposed model should be built on the following dimensions:

- Integration in physical dimension: Organizations taking place in a project should be integrated by an appropriate organizational model as D/B/FM.
- Integration in conceptual dimension: New philosophical approaches should be considered such as Supply Chain, Just In Time, Lean Production, Total Quality Management should be used.
- Integration in virtual dimension: An information model should be designed by the existing possibilities and means of information technology.

A conceptual model should be developed considering the above dimensions. Such a model should be open to every organization taking part in the project. The reliability and functionality of the proposed model depends on mutual confidence. D/B/FM type project procurement system is the appropriate model for both the integration of project organizations and running of the proposed model. New philosophical approaches must be considered in order to supply integration in conseptual dimension. The conceptual model then should be converted to an information model as a further study.

Building failures determined in occupation phase should be collected, kept and fedback to the design organization in order to increase building quality. Durability problems as a type of building failure can be captured by using this proposed model. Design organizations may use this information to constitute an archieve of construction materials, components and details for tracking their long term performances. Building failures determined in occupation phase should be recorded and fedback with their technical details according to the type of failure, related dicipline, corrective actions, cost, duration and technics needed for corrective action and preventive actions. The model allows to filter the past projects and making analysis according to the types of failures, reasons of failures, cost losses etc. These analysis constitute a tool for eleminating the losses and prevents from further failures. Analysis of the data collected in occupation phase allows designers identifying the important risk factors affecting the level of maintainability and frequency of the occurrence of defects.

6 CONCLUSION

Integration of the project phases and project stakeholders may decrease quality problems in building production process. D/B/FM contracts combine Design, Build and Facility Management activities under a single company or by a joint venture structure. Organizational integration is a necessary, but not an enough attempt for enabling integration problems. Integration should be realised in philosophical and virtual dimensions as complementary tools.

Feedback of building failure information from both construction and occupation phases is vital for increasing building quality in general. Durability problems, which appear in occupation phase may be captured by such a feedback mechanism, in particular. Recording the building failure information in a systematically structured information system, with its technical details, will allow determination the reasons and effects of durability problems. Such an information system will also be a useful tool for eleminating durability problems and not repeating similar failures in future projects.

Riccardo Paolini [3]

T 41

ABSTRACT

Among Estimating Service Life methods, Factor method is considered one of the main international references within ISO for the evaluation of building components' Service Life in the specific conditions of use; it gives an easy contextualization of Reference Service Life values of building components outside the system and the specific design context: the biggest advantage in choosing this method is, in fact, its great simplicity, which becomes itself its highest limit because it doesn't avoid possible errors in assigning factors' values according to user's own experience and point of view.
In order to avoid, or at least limit as more as possible, such subjectivity, Durability of Building Components Group of Politecnico di Milano suggests for this method some criteria to make more objective and scientifically validated values attributed to each single factor: the report deals with the development of an Enhanced Factor method ruled with grids which drive users in correctly assigning values to each factor, keeping the simplicity of the method, but making it more objective.
The paper reports about the definition of such Factor Grids, focusing on the methodological approach followed to individualize the main degradation actions, characterizing each factor, which has to be expressed through the use of specific sub factors. Once found these sub factors, it's then necessary to determine in which way and, above all, how much they can influence Service Life.
Eventually, an example of factors' grid for ETICS is showed, built using the proposed procedural iter.
This enhanced Factor method represents an important tool, scientifically validated but contemporarly easy to use: as a consequence, it can contribute to a more diffused application of Service Life planning.

1 INTRODUCTION

The evaluation of Service Life, according to international ISO 15686 and national UNI 11156 standards, can be made following some different methods proposed: it can be individualized a sort of reliable hierarchy among the three main families to which these methods belong:

1. probabilistic methods;
2. engineering methods;
3. deterministic methods.

The Factor method described in cited standards is proposed with a deterministic approach, but keeping its simplicity it can be developed using an engineering way to proceed: Politecnico di Milano is enhancing Factor method in order to standardize ESL's calculation, limiting users' subjectivity, thanks on one side to Montecarlo semi-deterministic method and on the other side to the use of ad hoc grids which can drive the user in choosing each factor.

As underlined by Bourke and Davies [1997] a Service Life Prediction system should desirably include the following important features:

- easy to learn, to update and to communicate;
- easy and quick to use;
- accurate;
- adaptable;
- supported by data;
- links with existing design methods and tools;
- free of excessive bureaucracy;
- recognises the importance of innovation;
- relevant to diverse environments;
- acceptable to practitioners and clients alike;
- reflects current knowledge;
- a flexible level of sophistication for either outline or detailed planning.

The evolution of Factor method based on driving grids perfectly answer to these requests. Moreover the structure of French Italian Data Base for collecting Reference Service Lives is based on grids: the enhanced method proposed by Politecnico di Milano can be easily implemented in the data base itself, exploiting its easy accessibility by internet.

2 ENHANCING THE FACTOR METHOD USING FACTORS' GRIDS

The application of factors' grids can be used with two different approaches:

1. in a static way: they can give a sort of photograph of the referring conditions in order to easily individualize the configuration associated to the given value of Referenfe Service Life;
2. in a dynamic way: they can allow to calculate the ESL by driving the user in giving the correct value to each sub-factor and then to factors themselves just selecting the real conditions associated to the considered building component.

The creation of evaluating grids should be done by experts: preferably, manufacturers themselves should provide such evaluation grids within the product's technical documentation. Evaluation grids are just functions, receiving as input data the performance classes found in the standards and returning particular values [Re Cecconi & Iacono 2005]. As the Factor Method is based on the comparison between reference and in-use conditions, and as the evaluation grids are built starting from the reference conditions of the building component, user has just to put the performance specification

inside the grid: in such a way, the comparison between two components will be automatically obtained.

Once defined the "n" sub-factors, it is possible to evaluate the relative importance of each characteristic compared to the others. Attention should be paid to the fact that comparisons among performance, in this step, represent precise design choices; the predominance of a sub-factor on another one is determined every single time by the designer, after considerations about:

- the final destination of the environment in which the building component will work;
- the final user;
- environmental loads and in-use conditions;
- etc.

All the evaluation grids are characterized by the fact that the neutral value is associated to the performance class in reference conditions; adopting and combining increasing or decreasing values is then possible to obtain the Estimated Service Life by the use of Factor method.

Hovde [1998] stated that there is a strong need for further evaluation of this method. He underlined the necessity of input data both for the quantification of Reference Service Life (RSL) as well as for the different factors in the equation. He pointed out the need of a more comprehensive evaluation of Factor method, including possibilities of quantitative description of the RSL and the factors, according to the general requirements for Service Life prediction methods, such as the requirements given in the introduction of this report. Moreover he gave a brief discussion of the following items that ought to be further evaluated:

- Estimation of the reference Service Life (RSL);
- Important factors;
- Necessary number and type of factors;
- Use of the factors in an equation;
- Reasonable span of the values of the different factors;
- Relative importance of the factors;
- Uncertainty of the factors;
- Factor dependency on material or component to be evaluated;
- Important considerations for practical use.

2.1 A Methodological Procedure Proposal for Defining a Grid

The system of equations that rules the Service Life Estimation is both a second order mathematic problem (the result at time t depends on the result at time t-1) and a bad conditioned system (which means that for little variations in input data there could be relevant variations in output) and so reliability and accuracy cannot be both achieved with the same entity.

In designing a factor method is important, as stated above, to avoid subjectivity and get an acceptable reliability and precision needed in results for the specific application. This means that for maintenance programming or for LCA and LCC evaluations a precision of one or two months over a Working Life of 25 years is not necessary. The consequence of this need is the development line of the method: it should be strong and reliable, despite of an extreme precision.

Another important issue for designing a factor method is to keep it easy to use and free of excessive bureaucracy. In order to achieve this target, a factor method should be designed needing input data already available and used in the design process. This could be done thanks to a basic research programme which gets the RSL value of the building component in a defined context, studying the degradation causes and finding the relationship between degradation – performance decay and basic

aspects (concerning factors from A to F) already known (used by designers, contractors, public administration, maintenance planners, real estate, etc.).

In the paragraphs below, guidelines in finding factors, sub-factors and their values are proposed.

2.1.1 Factor A – Quality of Component

Factor A could be assessed with simple tests on properties of basic material or of the whole building component that portray the sensibility of the material or of the building component in relation to the agent or aspect, which has been found as the most influent for the studied component's Service Life thanks to a basic experimental research programme.
For instance, in case of reinforced concrete structures two simple parameters concerning the material are used to characterize and study their durability: water – cement rate and compression resistance.
Basic research focuses on finding the relationship between w/c and freeze – thaw resistance, CO_2 penetration resistance, Cl^- penetration resistance or other chemical agents that lead the degradation evolution in the specific context.

2.1.2 Factor B – Design Level

Design level could be assessed considering three main aspects:

- cross section's dimensioning and designing (that could be assessed with simple tests on single characteristics):
  - thickness of layers (e.g. cover's thickness in reinforced concrete structures or painting's thickness in steel structures or base coat's thickness in ETICS);
  - dimensioning of joints, number of fixings (e.g. in ETICS), etc.;
  - different configurations of constraints (in cross section);
- design of building details (some could be assessed with simple specific tests, some thanks to interviews of panels of experts, some others with reference to database collecting data from inspections on existing buildings and information from maintenance managers):
  - risk of non-continuous protection against agents in critical points (e.g. structural joints);
  - use of special components and elements (e.g. profiles, components for connections, etc.);
  - increase in ageing and agents intensity due to specific configuration;
  - different configurations of constraints (at boundaries);
- influence of design of building details of other components on the durability of the studied building component (again simple specific tests, interviews of panels of experts, reference to database):
  - modification of microclimate (e.g. modification of driving rain on the façade, modification of shadows, etc.);
  - modification of stresses due to un-designed constraints.

2.1.3 Factor C – Work Execution Level

Work execution level could be assessed considering the respect of the construction plan relative to four main aspects:

- storage of materials in construction site;
- curing time and conditions;
- laying method;
- environmental conditions during construction.

2.1.4 Factor D – Indoor Environment

Indoor environment conditions critic for durability usually concern:

- condensation aspects and so relative humidity (for all kind of buildings): in this case the factor D could be assessed with a small set of parameters got with simulation by use of HMT (heat and moisture transfer) calculation methods with input data (moisture storage functions, thermal conductivity water content dependent, liquid water absorption and diffusion coefficients, etc.) get by characterizing the different materials in the building component; mold growth risk too could be assessed with specific tests on the finishing materials;

- storage of chemical products in industrial buildings: this aspect could be assessed with specific tests considering resistance and reaction to the chemical agent in the context;

- stress due to strain or vibrations of the structure: this aspect could be evaluated with suited fatigue cycles for internal partition kits too (not only for load bearing walls).

2.1.5 Factor E – Outdoor Environment

The influence of an outdoor environment different from the one reproduced by the experimental exposure could be taken into account analyzing the environmental data (climatic, concerning chemical pollution, or other agents too) and their "distance" from the experimental conditions. First of all a climatic context completely different from the tested one cannot be assessed modifying the experimentally determined RSL with factor E, but another experimental exposure should be set. The climatic data analysis should so consider the ageing phases in context in comparison to the ageing cycles reproduced in accelerated tests and set a proportion (number of cycles in real context per year on number of cycles per year in reference context reproduced with accelerated tests) and so define a scale in ageing conditions.

The same comparison method could be used in analyzing components subjected to degradation due to chemical agents, but in this case accelerated cycles cannot be set: suited test useful for measuring the sensitivity to that chemical agent could be used to build up a scale.

2.1.6 Factor F – In-use Conditions

In-use conditions usually concern impacts, perforations, vibrations of the structure due to the users and vandalism; a direct assessment of in-use conditions so is not possible and Reference condition (see ISO 15686-8) is absence of impacts, perforation, etc.

In order to correct the value of RSL, the factor F could be so determined according to the following procedure: a suited number of specimens is subject to a number of hard body impacts sufficient for providing a performance decay (measured with other tests suited for surveying performances) which overcomes the performance limit (end of Service Life). Then the decrease in Service Life due to in-use conditions different from reference ones is taken into account assessing the risk of the critical event in a defined context thanks to a stochastic evaluation on frequency of that critical event in a set of buildings collected in a durability database. The database should divide the study cases into classes of risk of critical event – frequency of critical event and each class could be assessd by one factor.

2.1.7 Factor G – Maintenance Level

The extension of Service Life provided by maintenance could be determined by tests too, depending on maintenance strategy programmed for the building component. In determining the values of other factors, the reference conditions should be chosen "as medium as possible", in order to reduce the transport error in transforming the RSL into ESL. In case of Factor G instead, considering absence of maintenance work as reference condition could be useful due to the fact that:

- the typology of maintenance is not known and fixed for a defined kind or class of building component and so deciding the frequency of maintenance (for each strategy) to be considered as reference is hard;

- expressing maintenance in terms of extension of Service Life could be useful in assessing the maintenance costs and convenience;

- accelerated tests without maintenance have to be performed in order to gain the complete degradation and performance decay curve.

2.1.7.1 Maintenance after failure (components with very high reliability at life time - for not bistable components, that doesn't pass suddenly from a working to a not working situation): on the aged sample, when the limit performance has been overcome, a maintenance work is executed and the ageing cycles go on until end of Service Life (overcoming of limit performances) is reached again. The rate expressed by the value in years of the extended Service Life after maintenance (multiplied for the foreseen number of economical acceptable maintenance works) over the value of RSL without maintenance determines the value of Factor G for this maintenance strategy.

2.1.7.2 Threshold preventive maintenance typologies (for the substitution at a constant age or at constant time steps during Service Life period – can be used for components with high reliability at life time i.e. for bistable components, that pass suddenly from functioning to not functioning situation): this type of maintenance could be studied with accelerated tests only if the exact value of years for accelerated ageing cycle has been determined with a previous exposure. Then a maintenance work can be performed at a fixed number of cycles and so the Factor G can be determined through the proportion between the Service Life of component with maintenance and the Reference Service Life without maintenance. The influence on durability of this kind of maintenance could be assessed thanks to databases too (but if data concerning costs and type of maintenance works is available, data concerning performances levels is more difficult to be collected).

2.1.7.3 Maintenance under condition (reparation and substitution maintenance works after inspections, with planned frequency, with the partial or total failure observation for components with low reliability at life time i.e. for not bistable components): during accelerated tests a maintenance work is performed each time that the performance limit is overcome and the value of Factor G is determined as the rate between Service Life with maintenance (considering an economically acceptable and sustainable number of maintenance works) and Reference Service Life without maintenance.

2.2 An example of Creating a Factors' Grid: The Application on ETICS

In the table below an example of the structure of a factors' grid specific for a building component is presented. The studied case is ETICS in environmental context of Milan.

The presented grid is only a first step in defining sub-factors classes. Future work will concern assigning the exact value to each sub-factor and the weight, in each context, of each factor on the whole ESL. This means that for ETICS several contexts of use and solicitation (i.e. maximum four classes according to ISO 15686-7 and EOTA Guidance Document 003) will bet set and a collection of Reference Service Lives and suited grids will be provided.

Table 1. Grid for a Factor method suited for ETICS in Milan context (or similar climates)

A	CE marking of products	Yes				No			
	ETA	Yes				No			
	Water absorption over 24h [kg/m^2] [ETAG 004]	known				unknown			
		W< 0,5	0,5 ≤ W ≤ 1	W > 1					
	Kind of base coat	Resin added 95% ≤ PVC ≤ 98 %		Resin added PVC > 98 %		Only cement mortar			
	Insulator material	EPS 100	EPS 120	XPS		Min. Wool		Wood Fiber	Other
	Fixing accessories	Yes				No			
	Finishing kind	Acrylic paint PVC 45 2 cycles	Acrylic paint PVC 60 2 cycles	Acrylic paint PVC 45 1 cycle	Acrylic paint PVC 60 1 cycle	Vynilic paint PVC 45 2 cycles	Vynilic paint PVC 60 2 cycles	Finishing coat acrylic binder	Finishing coat vynilic binder
B	**Base coat thickness**	t < 3 mm		3 mm ≤ t ≤ 4 mm		t > 4 mm			
	Mechanical fixings	Dimensioned considering wind load				Not dimensioned (1 for insulator panel)			
	Dilatation joints	No				Max every 200 m^2			
	Insulator storage time in construction site	Limited				Long			
	T[°C] during laying	T < 5 C°		5 C° ≤ T ≤ 30 C°		T > 30 C°			
	Substrate kind	New one				Old one			
	RH of substrate	RH ≤ 80%				RH > 80%			
	Substrate planarity	Yes (Δ ≤ 7 mm)				No (Δ > 7 mm)			
	Mechanical fixing scheme	 Type A				 Type B			
	Laying team	Specialized				Not specialized			
	Laying according to construction plan	Yes				No			
D	**Indoor RH**	RH ≤ 65 %				RH > 65%			
E	**Climatic zone (Guidance Document 003 EOTA)**	A		B		C		Special conditions	
	Finishing color	Bright (α = 0,3)		Medium (α = 0,5)		Dark (α = 0,9)			
	Rain class	High		Medium		Low			
	Wind load zone	Zone 9	Zone 8	Zone 7	Zone 6	Zone 5	Zone 4	Zone 3	Zone 2	Zone 1
	Ground rugosity	Class A		Class B		Class C		Class D	
	Pollution	High		Medium		Low			
F	**Foreseen impacts**	Yes				No			
G	**Access for maintenance**	Yes				No			
	Maintenance level	High		Medium		Low			

3 CONCLUDING REMARKS

As reported in the general comments of ISO 15686 standards, Factor method brings together consideration of each of the variables that is likely to affect Service Life. It can be used to make a systematic assessment even when reference conditions do not fully match the anticipated conditions of use. Its use can bring together the experience of designers, observations, intentions of managers, and manufacturers' assurances as well as data from test houses.

Factor method does not provide an assurance of a Service Life: it merely gives an empirical esteem based on the available information. It is different from a fully developed prediction of Service Life, which will ideally provide the Reference Service Life for a factored estimate.

The activity undertaken by Durability of Building Component Group at Politecnico of Milano is finalized to improve Factor method proposed by ISO 15686, in order to control its great limit: the subjectivity. This can be done by the use of evaluating grids which can drive the user in obtaining the correct value of each factor.

The methodological procedure described has been applied to the experimental programme for defining Reference Service Life of External Thermal Insulation Composite Systems: thank to the analysis of

the state of the art, the experimental durability tests undertaken in the last two years and different simulation by using a specific software it was then possible to build the factors' grid presented (which has still to be implemented and eventually validated).
The report, starting from a general analysis approach, wants to give an idea of the work necessary to develop (making it more objective and reliable) the methodology proposed by ISO 15686, presenting a contribute to the work itself.

This evaluation grid, together with all the other ones built for other building components, will be inserted inside the Reference Service Life data base, so that the information about durability can be easily shared exploiting the use of internet.

Service Life Estimation using Reference Service Life Databases and Enhanced Factor Method

Bruno Daniotti [1]
Sonia Lupica Spagnolo [2]

T 41

ABSTRACT

Service Life Prediction to plan optimized maintenance involves the necessity for designers to handle with tools which can allow the definition of Estimated Service Lives of single buildings' components and moreover of buildings themselves: ICT tools to manage service life prediction need Reference Service Life Data Bases. The report deals with the development of tools for the application of enhanced Factor Method through grids to guide users in assigning the values to the factors, avoiding subjectivity. Application of Factorial Method needs the knowledge of Reference Service Lives of building components, starting point of the calculation. That's the reason why, it is fundamental to provide a data collection of reference Service Lives which can help and drive the designer in obtaining the value of Extimated Service Life in each context of application. In collaboration with the C.S.T.B., Research Group on Durability of Building Components of Politecnico di Milano is collecting data coming from researches at Politecnico's itself and from the Italian durability network. The work wants to provide an open database which can be constantly implemented through the auxilium of researchers, owners, designers, manifactures, insurance companies, property asset managers from all over Europe, leaking and driving the insertion thanks to grids of control purposely prepared. Service life management systems are, therefore, analysed from the point of view of the information due to allow designers to manage service life prediction and maintenance planning. Databases will supply the input datas to predict Service Life of each single building component and will be available on internet in order to be a valid tool for designers. The paper reports on methods and tools developed to produce data and information in an easy-to-use form, on the durability of building components about both the quality of the manufacturing processes and the service life of products.

1 INTRODUCTION

The Reference service life data is the information that includes the reference service life and any qualitative or quantitative data describing the validity of the reference service life.

As reported on the standard proposal ISO 15686-8, which provides guidance on the provision, selection and formatting of reference service life data and on the application of this data for the purposes of calculating estimated service life using the Factor method, a RSL and the appurtenant reference in-use conditions, together with additional required or useful information concerning the RSL, form a set of RSL data. A set of RSL data should be formatted into a RSL data record.

This International Standard provides guidance on RSL issues and a means of determining the ESL through application of the Factor method. The guidance for reference service life is structured into discussions regarding:
- provision of RSL data utilizing existing general data (see 4.2);
- selection of RSL data or general data (see 4.3);
- formatting of general data into RSL data records (see 4.4).

Manufacturers of building and construction products are usually in possession of considerable knowledge concerning the service life and durability of their products. However, such information is only occasionally made public, typically in product declarations, other documents, company websites and/or databases. Use of this International Standard is expected to motivate manufacturers to compile their knowledge and provide service life data following the guidelines and requirements stated in the proposal itself [ISO-DIS 15686-8: 2007].

The evaluation of service life, according to international ISO and national UNI standards, can be made following some different methods porposed. Politecnico di Milano is developing these methods, looking in particular an implementation of the Performance Based Approach in the construction industry, specifically in the design and management stages.

Analysing service life management systems form the point of view of the information due to allow designers to manage service life prediction and maintenance planning, Politecnico di Milano is structuring a Reference Service Life Data Bases thanks also to the Italian research durability network; that's the input needed by ICT tools to manage service life prediction in order to plan a sustainable building maintenance.

2 THE COLLABORATION WITH CSTB: THE FRENCH-ITALIAN DATABASE FOR RSL

In collaboration with the CSTB – Scientific and Technical Centre for the Building Industry, Durability of Building Components Group of Politecnico di Milano is going to collect data coming from all researches untertaken in the last 10 years in order to create a French-Italian database of reference Service Lives of building components. in order.

The aim is to to make available to designers, real estate and manifactures all data collected, giving them the possibility to apply methods described in ISO 15686 standards, and in particular the Factor one, for calculating Estimated Service Life.

To minimize the subjectivity of Factor method, ad hoc grids will be created which will drive users in choosing the right values of each factor according to the context conditions in which building components are placed.

These grids, obviously, can't avoid the subjectivity in calculating Service Life, but they move it in the moment of grid creation: that' why grids should be built by building sector experienced people, such as manufacturers themselves.

2.1 The French database

Currently, CSTB has already predisposed a Reference Service Life database, which is available on the web (see www.duree-de-vie-batiment.fr) and which becomes a very important tool to:
- exchage and collect data deriving from different providers of data, such as manufacturers of building and construction products, researchers, national assessment bodies and technical approval organizations, database holders;
- elaboration of evaluating and driving grids to determine each the seven factors needed by the Factor method (see table below).

Table 1. Factors used applying the Factor method.

AGENTS	REMARKABLE FACTORS		
Agent related to the inherent quality characteristics	A	Quality of components	Manufacture, storage, transport, materials, protective coatings (factory-applied)
	B	Design level	Incorporation, sheltering by rest of structure
	C	Work execution level	Site management, level of workmanship, climatic conditions during execution of the work
Environment	D	Indoor environment	Aggressiveness of environment, ventilation, condensation
	E	Outdoor environment	Elevation of the building, microenvironment conditions, traffic emissions, weathering factors
Operation conditions	F	In-use conditions	Mechanical impact, category of users, wear and tear
	G	Maintenance level	Quality and frequency of maintenance, accessibility for maintenance

An example of the layout provided by French database is given below and it shows how with a user-friendly grid it is possible to select the context conditions of designing for determining Estimated Service Life.

2.2 The Italian contribution

Thanks to the cooperation among six Italian research units, Service Life prediction tools will take the input data from a set of the national regionalized information sources, a Reference Service Life Database, contemplating also a performance evaluation for feedback of Service Life data from practice, with an agreed European international structure (in conformity with ISO 15686).

The six research units of as many Italian university centres involved are Politecnico di Milano, Politecnico di Torino, University of Naples, University of Palermo, University of Brescia and University of Catania.

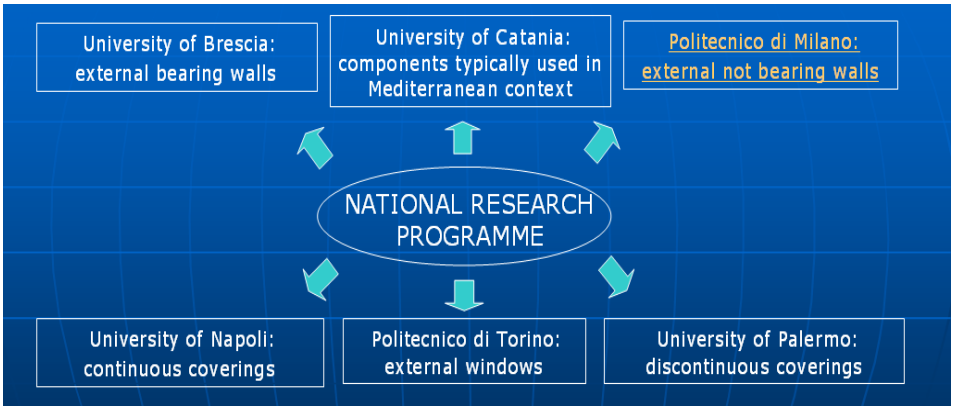

Figure 3. Italian research network for durability.

Using Factor method Politecnico di Milano is structuring a service life data collection of opaque vertical and horizontal enclosures taking into consideration different climatic contests; it is a collection of Reference Service Life values for different technical solutions among opaque vertical and horizontal enclosures, such as:

- traditional walls (double boarding of hollow and semi-hollow bricks with heat insulation interposed);
- externally thermal insulated walls;
- ceilings;
- enclosures typical of the Mediterranean contest.

Initially, the problem to solve is to defined the range of the study established, including identification or specification of essential data, depending on the aim and ambition of the SLP and on the level of existing knowledge of the component.

Two extreme ranges are as follows:
a) specific study: this is intended to focus on a rather specific application of the component tested in terms of service environment and usage with a specified set of performance requirements;
b) general study: this is intended to cover a broad application of the component tested in terms of service environment and usage with an unspecified or a loosely specified set of performance requirements. The aim is to establish performance-over-time functions for the performance characteristics chosen in the whole range of applications.

2.3 Ways of providing and selecting Reference Service Life data

The standard proposal ISO 15686-8 provides also a guidance to the providers of data on how to structure and format general data into RSL data, which have to be selected in order to be correctly applied for the evaluation of Estimated Service Life using Factor method.

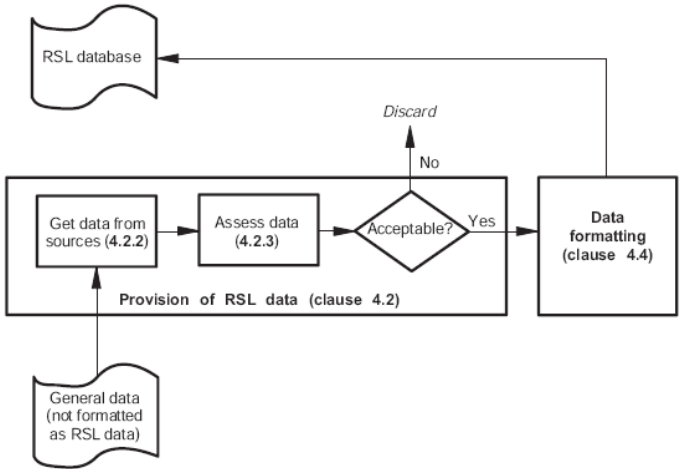

Figure 4. The process of providing RSL data.

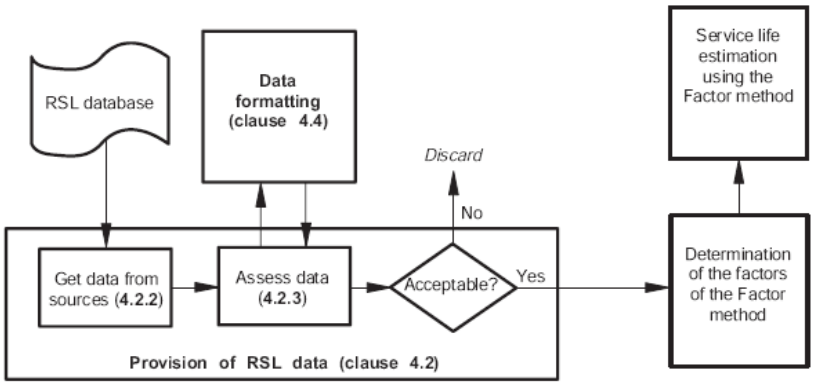

Figure 5. The process of selecting RSL data.

2.4 Enhanced Factor method

Durabity of Building Components Group has also developed the Factor method defining some criteria in order to make as more objective and scientifically validated as possible values given to each single factor. In fact, the Factor method provided by ISO 15686 is a very simple method for evaluating service life: thanks to seven deterministic factors, this method tries to model aleatory phenomena, such as climatic agents. That's the reason why the scientific community has showed the necessity to improve the method, through two ways to proceed.
As a consequence, DBCG suggests a probabilistic approach and uses the same equation proposed by ISO standard, but treating factors as aleatory variables. The proposal is based on the use of triangular distributions of ISO factors, adopting Montecarlo method for solving the equation. Aleatory variables' use describes better the complexity of decay and provides both the Service Life and an estreem of data's reliability: it is possible to obtain a evaluation of duration with precise probabilistic guarantees.

ABSTRACT

At the beginning of the 20th century, about 90% of the cost of a building was attributable to the structure and the enveloppe. According to the good durability of the component contributing to the structure, it is understandable that we were designing building for 70 or 100 years without the same need of knowing the service life of the components as knowing its mechanical resistance.
New performances are today measured and taken into account during the design to fullfill among others, acoustic, fire safety or thermal insulation requirement.
But new requirements have to be thinked ahead. Today, up to 75% of the cost of a building is allocated to equipments and indoor fittings. Most of the time these components have to be replaced during the service life of the building, and the economical impact on the life cycle cost are significant: for 1 euros spent in the construction phase of an office building, 5 can be spend to maintain and manage it during 30 years! [Tupamaki, 2005]
The Environmental assessment of a building using Environmental Product Declaration is also required to estimate the service life of the components.
Thus, service life is on the point to become a very usefull data for building design and facility management according to the sustainable development principles [ISO SC17, 2007]. The aim of this paper is to present a platform for service life planning. www.durée-de-vie-batiement.fr . It's a french tool for the moment, but we intend to propose it at an international level to optimize its interest.
A collaboration between contracting authorities, architects, research offices, manufacturers and entrepreneurs has been established to develop this collaborative tool, a plateform to collect Reference Service Life (compatible with the ISO series of standard 15686). It proposes an organization of knowledge in grids in which are stored and indexed the essential informations, to estimate the service life of construction components and to evaluate the factors impacting building durability (quality of materials, quality of the implementation, environment, users, maintenance…).

1 INTRODUCTION

Buildings have always been built to last "for a long time". Houses have a patrimonial value, while office buildingsmay acquire, sometimes, an historic value. Since actors have diversified, the building action has become the result of a relatively prompt transaction: an owner orders a work to a contractor in order to obtain function more or less precisely defined. The building's owner is interested in its exploitation and therefore in the future stages of its history. The need addresses the perenity of the performances, materialized through the setting up of legal guarantees (decennial in France). A way to match the requirements related to these guarantees, can be to produce results of accelerated ageing tests applied to building materials and components. Moreover, the European Construction Product Directive underlines that the essential requirements which products must confer to the work must be satisfied "for an economically reasonable Working Life".

In the last few years, the need to respect the principles of this development, as well as the new economic models (life cycle cost, **Private Finance Initiative** (PFI) "Public-Private Partnerships" (PPP)) have changed the expectation related to the "durability" of construction works, and introduces the "service life planning" process. The whole life cycle of the building becomes a trading object, while protocols and consensual assessment ans decision aid tools (references, methodologies, databases, technical and economic guarantees) become essential.

Some more focused demands for service life data appear in different practical procedures.: typical service life are required in the environmental product declarations (EPD). The service life data of the components can be asked for in the contract in the frame of a private public partnership (PPP), which generally goes beyond legal decennial guarantee. Service life data should be attached to a performance in the energy diagnosis that will soon become compulsory for real estate transactions. In the energy saving certificates as well such data are needed These certificates allow validation of energy savings due to additional actions, such as reinforcement of insulation, change of energy supply product, …The energy unit used in the certificates is the kWh of final energy needed summed up and updated on the entire product's service life.

2 PRESENTATION

This plateform allows to organize and to share in a dynamic manner the knowledge concerning building components' Service Life.

The web address is: http://www.duree-de-vie.batiment.fr

First of all, the aim of the platform is to established a bridge between durability specialist and final users of service life data. For this reason, it first gives the possibility to create specific grids for each family of building components:

The specific grids for every family of building components will be established in accordance with the ISO 15686-8 [ISO SC14, 2007], to associate a "script" of ageing to every defined service life data for each component.. The following factors will be taken into consideration :

- A- Quality of materials and components
- B- Design level
- C- Work execution level
- D- Indoor environment
- E- Outdoor environment
- F- in-user conditions
- G- Maintenance level

For every grid created, reference service life data can be stored, by using the range of parameters which is provided by the corresponding grid.
Of course all the gathered data can the be read by all the user of the platform.

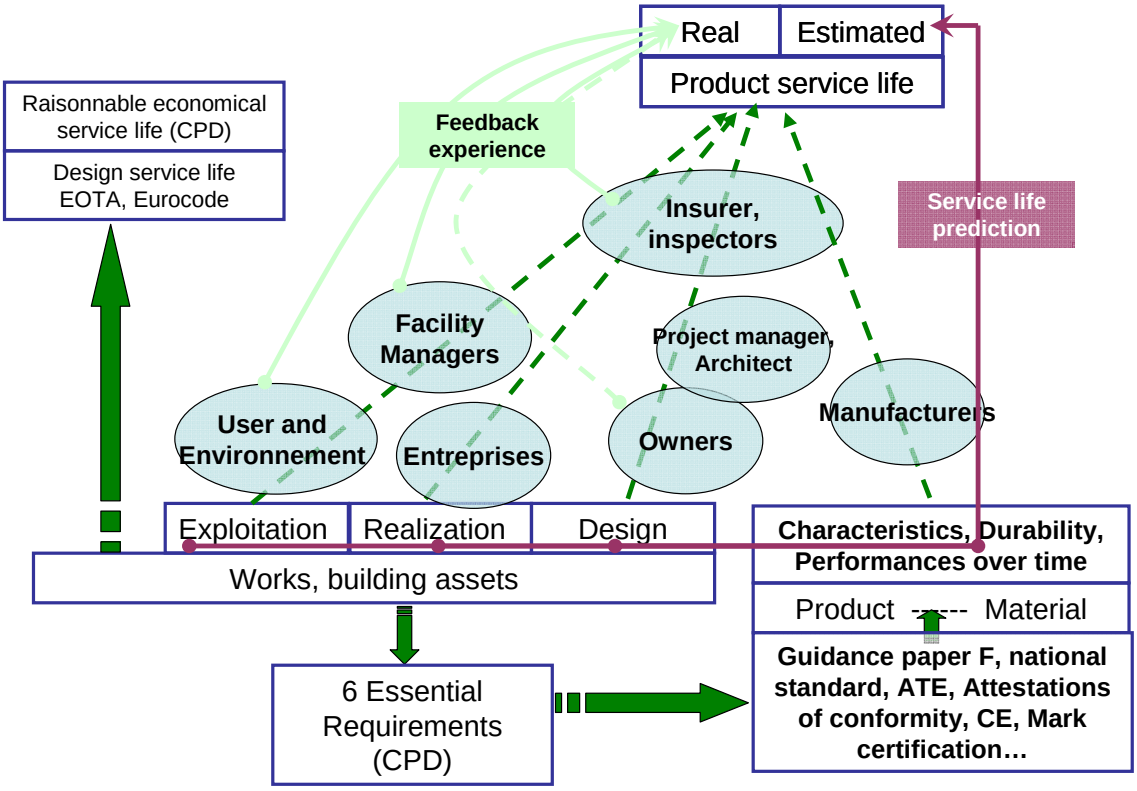

Figure 1. Impact of stakeholders on service life of building products, ability of each stakeholders to capitalize Reference service life. [HANS, 2006]

2.1 Creation of grids for factors conditioning Service Life

The first database's function is to allow the creation of grid for any building components, In these grids it is possible to take into consideration all factors impacting on building components' Service Life (materials, design level, inside and outside environment, in use condition, mechanical, thermal loading, etc.). The ISO 15686 part 8 standard developped within the ISO TC 59-SC14"Building and constructed assets – Service life planning" [ISO SC17, 2007] suggests to use seven factors (from A to G), as listed in [Table 1].

The creation of grids takes place in the following way:

- The first step consists in defining the component to study and the materials it is made of (generic window, or more specifically window wood, PVC window, window Aluminium);
- The second stage consists in identifying the possible damaging scenarios for this kind of component which the grid must permit to characterize. That's why it is necessary to lead a functional analysis and/or an analysis of the failure scenario of the component;
- The third stage has for object to define the grid of building component's service life and to create the different influencing factors and the level of this influence.

Table 1. Conditions to take into consideration for evaluating Service Life.

AGENTS	REMARKABLE FACTORS		
Agent related to the inherent quality characteristics	A	Quality of components	Manufacture, storage, transport, materials, protective coatings (factory-applied)
	B	Design level	Incorporation, sheltering by rest of structure
	C	Work execution level	Site management, level of workmanship, climatic conditions during execution of the work
Environment	D	Indoor environment	Aggressiveness of environment, ventilation, condensation
	E	Outdoor environment	Elevation of the building, microenvironment conditions, traffic emissions, weathering factors
Operation conditions	F	In-use conditions	Mechanical impact, category of users, wear and tear
	G	Maintenance level	Quality and frequency of maintenance, accessibility for maintenance

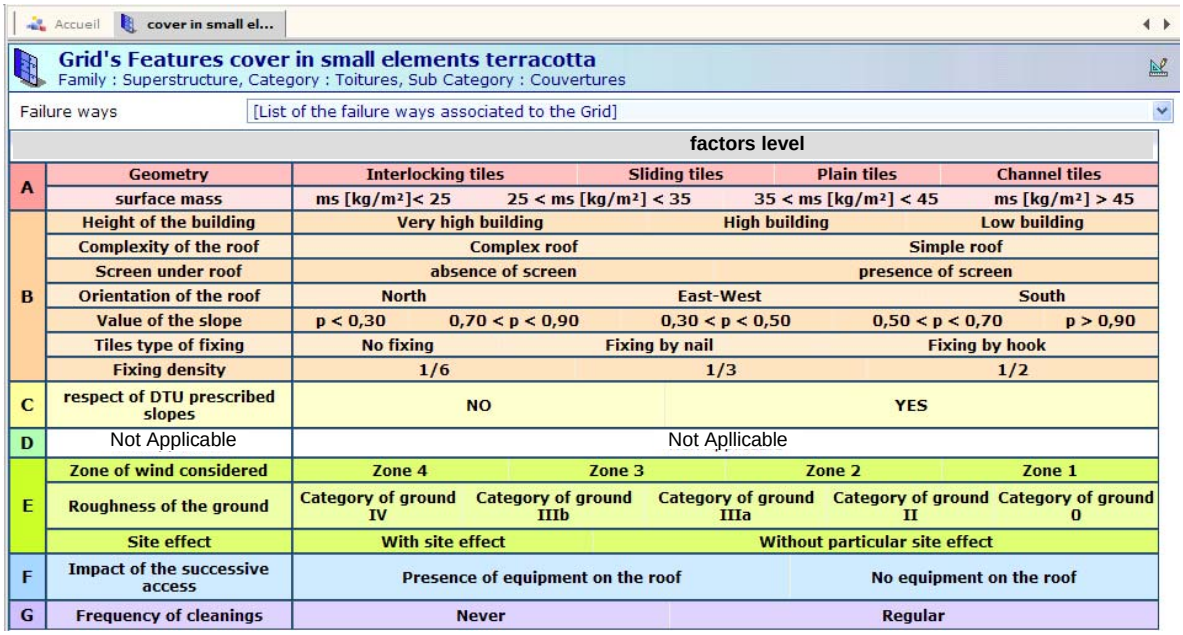

Figure 2. Illustration of possible grid for building components' Service Life (ex: roof covered with small clay tiles)

2.2 Collection of building components' Service Life data

Every Service Life data stored for a building component can be referenced while assigning it a range of values for determining each factors in the corresponding grid and for characterizing its specificities 'Fig. 3'.

Other information are associated to Service Life data:

- The format of Service Life value distribution (deterministic, range, asymmetric range, Gaussian distribution, etc.), see'Fig. 4'.

- The quality of the data: this information allow to determine data's reliability, important especially for merging all data. The quality of the data is related to the data source. If it acts of a test it is related to the type of test on which it is based, see 'Tab.2'

- Further information, such as :

- Year
- Place
- Bibliographic references
- Reason of the damaging
- Further observations

A	Geometry	Interlocking tiles	Sliding tiles	Plain tiles	Channel tiles
	surface mass	ms [kg/m²]< 25	25 < ms [kg/m²] < 35	35 < ms [kg/m²] < 45	ms [kg/m²] > 45
B	Height of the building	Very high building	High building	Low building	
	Complexity of the roof	Complex roof	Simple roof		
	Screen under roof	absence of screen	presence of screen		
	Orientation of the roof	North	East-West	South	
	Value of the slope	p < 0,30	0,70 < p < 0,90	0,30 < p < 0,50	0,50 < p < 0,70	p > 0,90
	Tiles type of fixing	No fixing	Fixing by nail	Fixing by hook	
	Fixing density	1/6	1/3	1/2	
C	respect of DTU prescribed slopes	NO	YES		
D	Not Applicable	Not Apllicable			
E	Zone of wind considered	Zone 4	Zone 3	Zone 2	Zone 1
	Roughness of the ground	Category of ground IV	Category of ground IIIb	Category of ground IIIa	Category of ground II	Category of ground 0
	Site effect	With site effect	Without particular site effect		
F	Impact of the successive access	Presence of equipment on the roof	No equipment on the roof		
G	Frequency of cleanings	Never	Regular		

Figure 3. Selection of factors level characterizing the ageing scenario of one reference service life

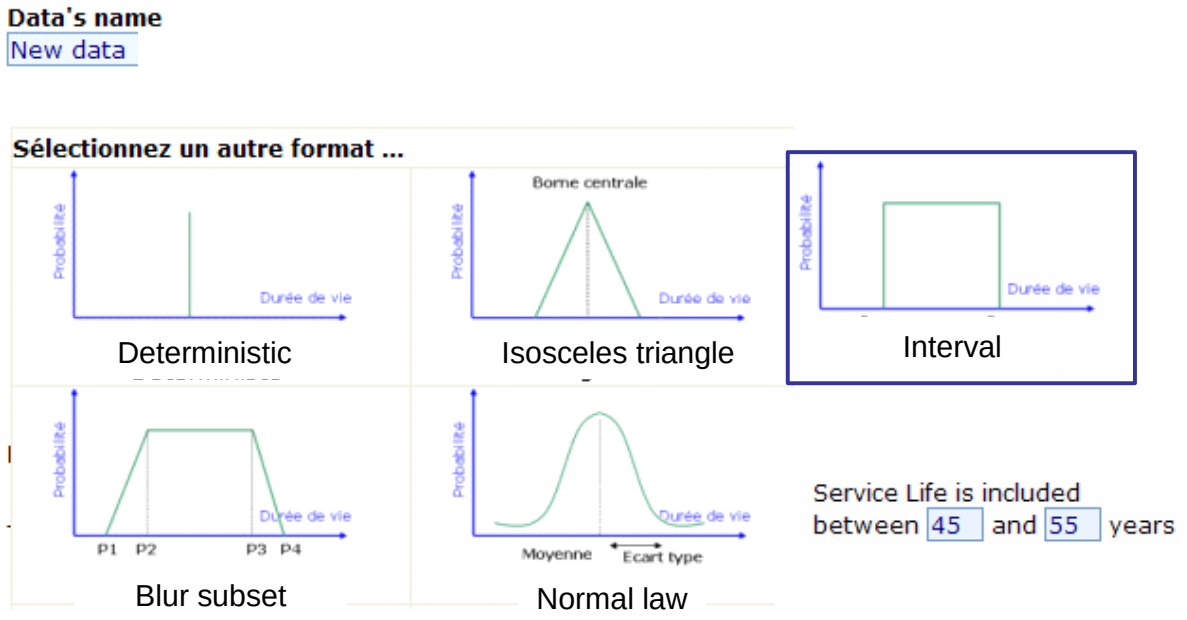

Figure 4. Formats of Service Life data value

It is important to define the data benchmark.

The capitalized data will have to enable us to limit the component Service Life. It is indeed necessary to born Service Life boundary and to know that it lies between 20 years (the most unfavourable case)

and 50 years (the most favorable case) for a failure mode. Intermediate data we will allow us to approximate our case of study. For example to reduce the interval at 25-35 years.

Table 2. A life tests comparison of the constructive entities. [Talon, 2006]

Tests	Scale	Interests	Limits
Exposure on the ground (long duration)	Material Products	real climatic Conditions	**(1)** Uncertainties on the climatic conditions (nature, intensity, frequency). **(2)** Extrapolation with other products or other sites difficult.
Inspection of the buildings (long duration)	Materials products buildings	**(1)** Material /Produces /real Building **(2)** Weaker experimentation cost	**(1)** climatic conditions and of use not measured . **(2)** Problems of censure. **(3)** Extrapolation with other constructive entities or other sites difficult. **(4)** Conditions of maintenance sometimes badly known.
Exposition in experimental buildings (long duration)	Materials products buildings	**(1)** real climatic conditions. **(2)** Knowledge of the total behavior.	**(1)** Uncertainties on the climatic conditions. **(2)** Extrapolation with other constructive entities or other sites difficult.
Exposure in service (long duration)	products buildings	**(1)** Produced / real Building. **(2)** climatic conditions and of use real **(3)** Knowledge of the total behavior. **(4)** weaker experimentation cost.	**(1)** Many uncertainties on the climatic conditions and of use. **(2)** Extrapolation with other constructive entities or other sites difficult.
Exposure of short accelerated duration	Materials products	**(1)** Control of the climatic conditions. **(2)** Time and reduced cost of experimentation.	Possible inaccuracy at the time of the passage to the real time.
Exposure in service of short duration	Products	**(1)** climatic Conditions and of use real. **(2)** Time and reduced cost of experimentation.	**(1)** Many uncertainties on the climatic conditions and of use. **(2)** Extrapolation with other constructive entities or other sites difficult.

For that it is necessary to determine :

- a number of relevant data per failure mode,

The number of data capitalized by failure mode will be related two parameters:

- homogeneity of the Service Life to reach the failure. More they will be near, less there will need data to obtain our kit of reference;
- More the failure mode is frequent more we will retain data.

It is necessary to study the impact of the various factors over the Service Life per failure mode. Indeed, if the impact of the factor is weak it will not be essential to vary the factor in the benchark data. On the contrary if the impact of the factor is important over the Service Life it will be necessary to vary the factor.

- a relevant choice of factors level selection to identify the representative extreme cases, see 'Fig. 5'.

The representative extreme cases are not case where all the factors are at the maximum or the least. Indeed, these extreme cases do not represent reality (red line on the 'Fig. 5'). It is necessary to make a small preliminary study to determine which case would be most unfavourable while remaining possible. This case is represented in green on the 'Fig. 5'.

- an identification of available data sources.

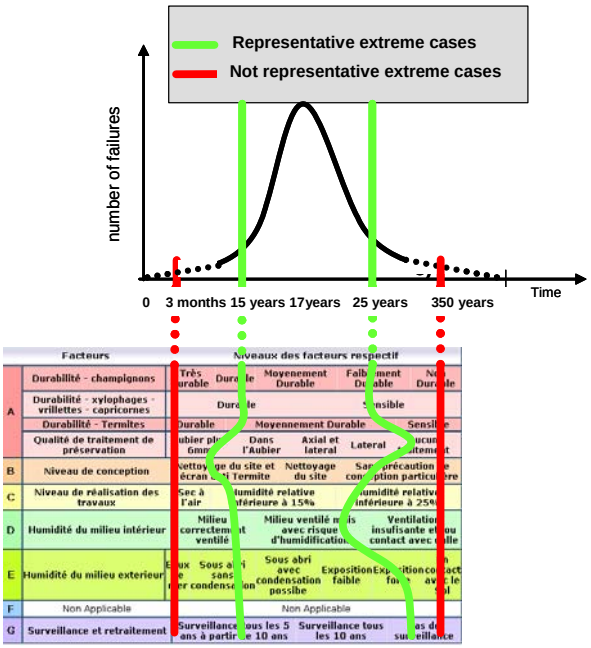

Figure 5. Identification of the representative extreme cases

To help us to make this study it can be interesting to set up an experimental plan.

2.3 Consultation of reference Service Life

Once these data capitalized in the platform, the originators will find there the Service Life which the investors could ask them. The managers of works will be able to draw information relating to maintenance there. The platform will be able for example to make it possible to check that the foreseeable Service Life of a constructive solution is adapted to the destination of the work, with its economic model.
The database allows the consultation of Service Life stored, in order to estimate Service Life of a component in similar conditions.
Three types of possible studies:

- Systems of prediction starting from the play of factors of the study;
- Decision-making aid starting from the play of some factors and the DDV concerned;
- Information starting from the play of factors of the study.

CONCLUSION

Components Service Life is an essential data to conceive and manage buildings. Creating a tool to capitalize and share information is needed for the knowledge of construction products Service Life. It

is required by the "French national service life information platform", financed by the French ministry for housing and carried out by the CSTB.
To go further in the capitalization of the data, an international extension of the platform is in project. It is carried out by Politecnico di Milano which works on Service Life Estimation using Reference Service Life Databases and Enhanced Factor Method [DANIOTTI, 2008].

Quantification of Façade Defects Using Photogrammetry within the *BuildingsLife* System

Pedro Vaz Paulo [1]
F. A. Branco [2]
Jorge de Brito [3]

T 41

ABSTRACT

In several studies on buildings pathology, the main objective is to define and characterize the observed defects and its quantification. However, in major cases, the success of these actions depends upon the observer's procedures and subjective interpretation. To establish a regular and unique information database, independent of the inspector's experience, it is important to focus on the treatment of this non-homogenous data collection in order to be able to make universal comparisons. This paper shows a study related to Buildings Management, which is a part of a PhD research project at Instituto Superior Técnico, Technical University of Lisbon - Portugal. The investigation defines a methodology to quantify the different existent defects (with independent parameters, such as area, length, location and orientation) in a building façade such as cracks in mortar, cracks in paint, paint flaking and mortar spalling, using photogrammetry images to avoid inspection errors based on personal interpretations or estimations. The photogrammetric process has the capability to use manual, semi-automatic and automatic measurement techniques, which were applied in more than 300 Portuguese buildings with an average age of 70 / 80 years. The orthophoto image is used in the web system *Buildings Life* (www.buildingslife.com) and it is being developed according to ISO 15686 which allows the characterization of the different phases such as analysis of the building, inspection, register and samples information, as well as validation model and results. This paper also describes the different types of defects and their quantification in façade buildings that occurred along the service life time related with maintenance interventions.

1 INTRODUCTION

In the last years the principal intent of the investigators had been to predict the service life and durability of materials or constructive elements applied in buildings, railways, bridges, etc to optimize all the existing costs *Life Cycle Assessment (LCA)* before, during and after the construction [ISO 1997]. It will also give important information to the contractor, owner and designer, and will assure a better construction and durability. Due to this, the PhD thesis "Building management - BuildingsLife" was developed at Instituto Superior Técnico, Technical University of Lisbon - Portugal.

2 BULDINGSLIFE SYSTEM

The BuildingsLife architecture is based on ISO 15686 Buildings and Constructed Assets – Service Life Planning with different packs: desktop, external loads, building, survey checklist, defects, surveying, maintenance, prototype applications, settings, reports and degradation models. The BuildingsLife system can be accessed by internet, after login and password. The principal goals are:

- to help the owner on the management of his buildings indicating the best choice (temporal instant and appropriate technique) for maintenance;
- to help the designer defining the better constructive solutions and materials for the owner needs applied in known exterior load, such as, ambiental and environmental conditions;
- to establish a database of defects, building information and the best techniques to repair them and the costs involved;
- to classify the degradation states of different constructive elements;
- to estimate degradation probabilities of different constructive elements applied in different exterior loads;
- to define estimated degradation models (EDM) for buildings [Jernberg et al. 2004];
- to establish procedures to buildings survey;
- to predict the building maintenance with the parameters defined by the owner and according to Multi-Criteria Decision-Making (MCDM) in order to support their decisions.

To reach these objectives, different methods have been developed to assure that information surveys, done by different professionals, were uniform and produced equal results. This paper presents the PhotoMeasure prototype application to quantify any measurable defect over an orthoimage façade.

3 DESCRIPTON OF THE METHOD

The photogrammetric modelling technique is an interactive tool that allows the user to build a geometric model of an architectural façade based on a set of photographs. The technique is convenient, efficient, and robust and it allows the exploitation of the geometric structures common in architecture. The prototype implementation of this modelling technique is called *PhotoMeasure* (Fig.1).

The technique is powerful because it solves directly the architectural dimensions of the façade: the length of the walls, the width of the doors and windows, areas of mortar defects and the lengths of cracks.

As a result, the quantification defects problem becomes simpler through some orders of computational complexity and, more important: in the criteria analysis it's the only way to avoid surveying errors. This method had a field work and a laboratory phases that will be describe in the following paragraphs.

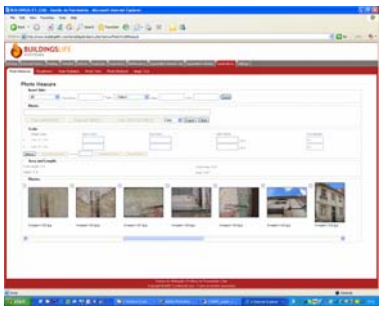

Figure 1. Application *PhotoMeasure* in www.buildingslife.com

4 GEOMETRIC DOCUMENTATION METHODS FOR BUILDINGS

According to Scherer [2002a] there are four principal methods used to compile metric data: traditional manual methods, topography, photogrammetry, and scanning. The choice of one method or another will depend on several factors: end use, accuracy required, budget available, characteristics of the structure to be documented, etc.:

- manual measurements methods determine dimensions by measuring angles and distances. The equipment used is very simple, for example, training. The fieldwork and data collection stages are inevitably time-consuming. Accuracy in locating points is above 8 cm [Scherer 2002 a];
- tacheometric (topographical) methods, which require specialized equipment, are based on three-dimensional (X,Y,Z) determination and coordination of specific points of an object in order to establish its geometry. Accuracy in locating points using the total station is generally above one centimetre [Scherer 2002 a];
- photogrammetric methods apply the classical techniques and methods of close-range photogrammetry. One of the great advantages of photogrammetry, compared to other techniques, is the short period of time spent measuring the object. Another feature is that it is performed without being in contact with the object. The accuracy of these methods goes from 1 mm (highly accurate methods) to 5 cm (simple photogrammetric methods) [Gardiol 2002];
- scanning methods have become popular recently due to the commercial availability of laser scanners, which automatically and very rapidly (1000 points/second) measure the angles and the distances from point to point. Accuracy in the locations of the points is between 5 mm and 5 m. The main disadvantage of these methods is the high cost of the equipments [Scherer 2002 a].

The choose method is influence by the precision need. For documentation for analysis of buildings and surveying artefacts (materials defects) 3 mm to 1 cm, for preservation of historic buildings and monuments, archaeology 1 cm to 2 cm, for architectural surveying, as built documentation 2 cm to 5 cm and for facility management 3 cm to 10 cm [Scherer 2002 b]. Thus, the photogrammetric method was choice to obtain the orthophoto façades images.

5 FIELD WORK

The fieldwork phase is further divided into orientation and scaling stage and photography stage. Close range photogrammetry is a technique for obtaining geometric information, e.g. position, size and shape of any object. There are two different strategies for image processing [Grussenmeyer 2002]:

- Single images, when the shape, the attitude of the façade surface in space (digital surface model – DSM) is known but the details on this surface, such as, blistering paint, cracking paint, cracking mortar, spalling mortar, etc. are not.

- Stereographic processing, when the building's geometry can't be defined with one image 2D. In this case the best way to characterize the façade is a 3D view with at least 2 images, a pair of "stereo images" with a stereo base (distance between the cameras).
- Bundle restitution, in cases that one single stereo pair is insufficient to reconstruct a façade building (frequently is a complex geometry building).

In this study all the façades images were processed in single method. The point of taking photos is that each point to be determined can be intersected by at least two rays with horizontal, vertical or oblique photos. The camera has fixed one point in the middle and at the far end of the façade (Fig.2). Approximately 45.5% of the building samples analysed had a maximum distance (street width) of object (façade) about 5 and 10 meters which result a difficult work to obtain correct photographs.

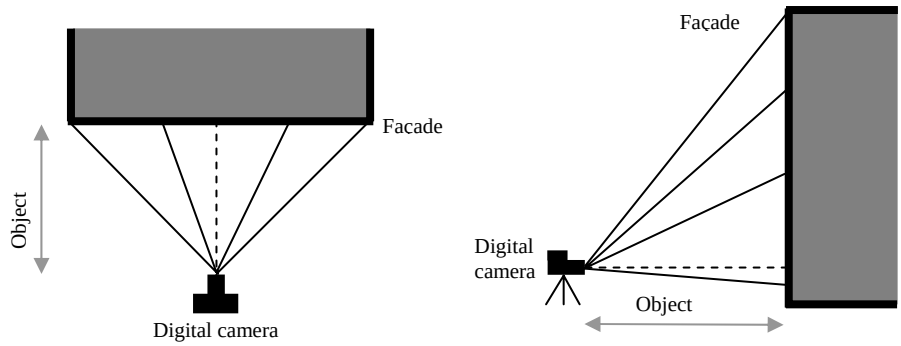

Figure 2. Position of digital camera.

Façade Alignment and Geometry
True position in space (alignment) and the scale of the models are performed as follows:

- to define vertical lines. If the building doesn't have any vertical elements (normally windows and sills are crucial in this work) it is necessary to use the plumb lines in order to define the direction of the Z axis in the absolute orientation process. The plumb lines should be suspended from any projecting element on the walls of the building. The length of the plumb lines will depend on the height of the construction to be surveyed, but should be as long as possible;
- to measure distances. Marks are made in the plumb lines at known distances. These should be visible enough to avoid confusion while photographing the building. The precise distance between marks should be known (for example, height and width building), as this is essential to obtain the scale of the model in the absolute orientation phase. Lengths should be proportional to the size of the construction, i.e. they should increase in line with building size [Valontová & Dolansky 2002].

Photographs Capture
Images can be taken with analogical or conventional low-cost digital cameras. If digital cameras are used, they should have focal length constant, they should be sufficiently stable internally, and resolution should be set at the maximum to obtain a good quality photograph on final process. Shots should be taken applying the principals of photography and photogrammetry, taking into account that restitution is carried out by using monoscopic equipment (Fig3.) and more important that,

- photographs should be taken in one single position and should be aligned with the half of the façade;
- overlaps between photographs should be at least 20%;
- the shots should be taken in a way that the photographed object covers most of the photogram surface;
- a large number of photographs should be taken, including general shots and close-range shots of items of interest (blistering or peeling paint), given that the redundancy of images facilitates the detection and elimination of error;

- it is important to eliminate the error caused by the sun light in the photographs of façade and sky.

The equipment used was a Canon G7 digital camera offering SLR-like functionality and high-end features such as fast lenses and external flash capabilities, with 10.0 Megapixels, 6x optical zoom lens with optical Image Stabilizer and SR coating, and DIGIC III and iSAPS with Advanced Noise Reduction and Face Detection AF/AE. The distances were measured using a Laser Distance Measurer – Stanley with an accuracy: ± 6mm at 30m, a range of 0.6m - 30m, and a laser: 650 nm, class IIIA. It was registered the height and the width of each building.

Figure 3. Six photographs, with overlap, of a façade building.

6 LABORATORY WORK

The laboratory phase involves analysing and processing the photographs taken (several commercial software can be used to reconstruct and create the orthophoto façade image). Processing the information requires the execution of two sequential processes:

- alignment photographs: The perspective rays are reconstructed in conditions similar to their formation within the camera. In this phase it is important that there are between the images, at least, 20% overlapping in order to analyse similar points in different photographs (Fig.4);

Figure 4. Interior photograph orientation.

- exterior photograph orientation: In this stage the rays generated in the inner orientation process are positioned, in relation to the ground, in the very same position adopted at the moment of exposure of the photographs. Each photograph is marked with a minimum of 4 points (depends of image complexity) to orientate the image horizontally (2 points) and vertically (2 points) with respective corrections (Fig.5). Exterior orientation includes two operations arranged in sequence known as relative and absolute orientation.

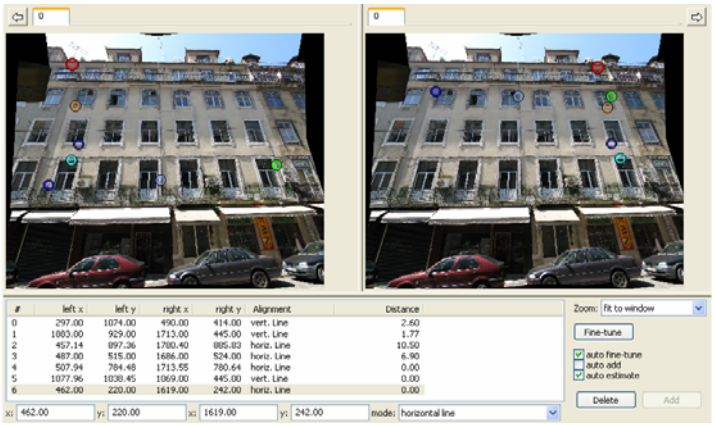

Figure 5. Exterior photograph orientation.

In the end of process the orthophoto image is processed and is necessary verify his quality by the doors, windows or balconies alignment (Fig.6).

Figure 6. At left the façade image reconstructed, at right the orthophoto façade image.

7 BUILDING SAMPLES

The proposed methodology was applied (until this moment) to 302 residential buildings in Lisbon, Portugal. In general, these buildings were constructed in the beginning of 1900, the façade wall is in stone and solid clay bricks with lime or cement mortar and with one or more paint layers of different quimical binders and resins. Although, to analyse the different degradation levels it is important to know and to distinguish the different characteristics of the materials but, this paper will not focus on this important systematization. When the façade orthoimage is placed at www.buildingslife.com server, on PhotoMeasure it's possible to define a horizontal and a vertical scale into image and then, measure any intended area or length. The analysed buildings had an average façade area of 127.2 m^2 and the distribution of buildings according to their area of façade is defined in table1.

Also, it is important to guarantee a high quality image to analyse any detail on it (Fig.7). Normally, these orthophoto images have 2600 x 3000 pixels that are enough to detect spalling mortar area, dirt collection area, fungal area, cracking mortar and paint length. This method has an accuracy of 3 % on any measure.

Table 1. Distribution of façade area.

Level	*Façade area [m2]*	*Percentage of buildings* [%]
1	[0;50]	11.8 %
2	[51;100]	41.8 %
3	[101;150]	25.7 %
4	[151;200]	11.2 %
5	[201;1000]	9.5 %
Average	113.9	

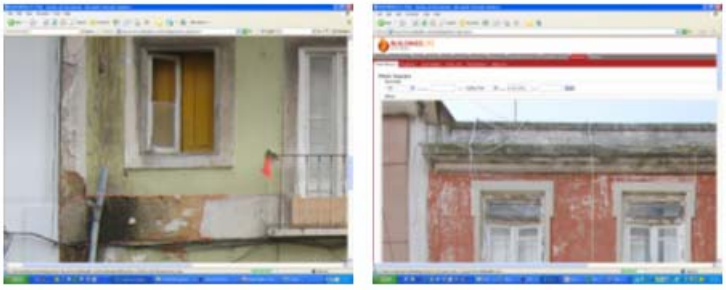

Figure 7. The measured area in PhotoMeasure is defined by a red line.

It is important too, to analyse table 2 and to verify that the average building height is about 12.6 meters, which represents a 4-floor building, and there are few buildings (1.7%) whose height is lower than 6 meters.

Table 2. Distribution of building height.

Level	*Building height [m]*	*Percentage of buildings* [%]
1	[0;6]	1.7 %
2	[6.1;9]	17.2 %
3	[9.1;12]	30.1 %
4	[12.1;15]	20.6 %
5	[15.1;1000]	30.4 %
Average	12.8	

8 RESULTS

The proposed methodology allows us to establish homogeneous orthophoto images and, more important, to quantify façades defects independently of surveyor analysis and interpretation. One of the defects is mortar spalling that was measured in 302 buildings and that obtained an average value of 6.86 m². For all these buildings the average maintenance (the intervention consists of applying the necessary action to bring back the original conditions) is about 28.6 years (Table 3).

To generate the degradation curve for the defect “mortar spalling”, the different values obtained in Photo Measure were aggregated in different degradation levels (Table 4) and the BuldingsLife system calculates the average maintenance for each level. These results are very important to understand the behaviour of buildings along their service life years, defined by the degradation curve in Fig 8.

Table 3. Distribution of maintenance period.

Level	*Maintenance period [years]*	*Percentage of buildings* [%]
1	[0;5]	11.2 %
2	[5.1;15]	32.2 %
3	[15.1;25]	17.4 %
4	[25.1;50]	33.9 %
5	[50.1;1000]	5.3 %
Average	28.6	

Table 4. Distribution of buildings in degradation levels for mortar spalling.

Degradation Level	*No. of buildings*	*Percentage of buildings* [%]	*Average maintenance buildings [years]*
0	151	50 %	9.9
1	62	21 %	27.2
2	57	11 %	36.1
3	11	4 %	45.3
4	15	5 %	48.7
5	6	2 %	56.7

Analysing this curve, we could define two distinct phases [Paulo *et al.* 2008]:

- Phase 1: before 27.2 years the degradation is more slow (end of state 1)
- Phase 2: after 27.2 years the degradation rate increases and between states 3 and 4 shows the maximum value.

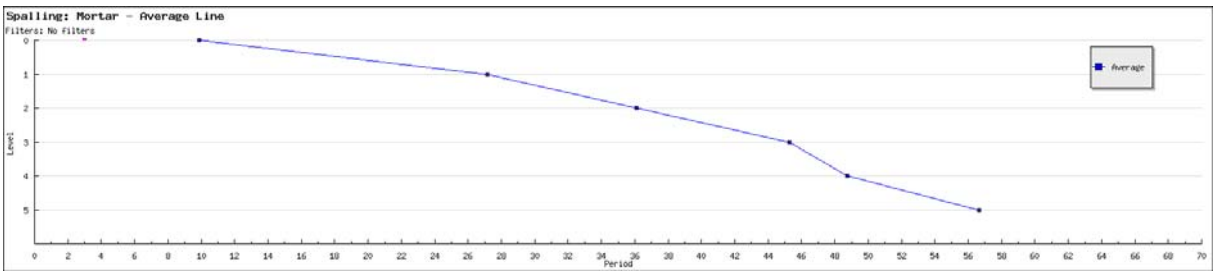

Figure 8. Degradation curve for defect: mortar spalling [Paulo *et al.* 2008].

Thus, at the end of this research project the buldingslife system has to be able to establish several correlations between materials characteristics, environmental and ambient loads and defects quantified on PhotoMeasure, and present degradation model curves and obviously analysed in detail each obtained degradation curve.

Homes in Iceland--Flexibility and Service Life Fulfilment of Functional Needs

Björn Marteinsson [1, 2]

T 41

ABSTRACT

The main requirement of any structure, apart from requirements of safety and health aspects, is fulfilling functional needs at an economical cost to the owner/user. As the structure grows older it is required to satisfy other needs than may have been foreseen at the start. The adaptability of the structure and its surroundings to changing requirements, while still satisfying the user's wishes, will largely determine the market price. The interest and willingness of the owner to invest in maintenance and refurbishments is, thus, dependent on this flexibility and may easily be the determining factor for effective service life of the structure. This paper presents the answers from about 250 owners of houses of different ages, located in two different cities in Iceland. The owners were asked to estimate the quality of houses and surroundings, together with maintenance and refurbishment needed to keep the standard desired.

1 INTRODUCTION

The economical value of the built environment is very great, and monetary and environmental impact accompanying rebuilding this environment would be a heavy burden for the future. Therefore, it is of general interest to assess if the widely assumed economic service life of buildings, of at least 50 to 60 years, is at risk of being shortened due to obsolesce. This will be the case if the functionality of the buildings does not fulfil the requirements of generations to come, and has earlier been discussed by Aikivuori (1999).

It has sometimes been stated that "design for the future is not a problem as the future takes what it gets" (Deplazes, 2005). However, this will not necessarily be the case, as needs have certainly been changing for some time at a faster rate than often before. People have more possessions or "stuff" than ever, requirements for personal space are increasing, wishes for more spare time are always increasing, and automobiles are no longer a luxury. Even work tends to be done more at home, than has been customary for a long time. All of these changes put extra demands on the functionality of homes and environments of these buildings. For existing houses to be of any value in the future, it may easily be the case that generations to come will wish to modify them to their own requirements, and then in turn have to adapt themselves to the result.

It is therefore considered of interest to evaluate how adaptable the houses already built have been, regarding changes in requirements, and this can be most naturally measured as the performance of these houses, according to the owners'/users' opinions.

2 THE HOUSING INVENTORY AND SAMPLE OF HOUSES IN THE STUDY

This study is a part of a larger research project where the effect of various parameters on degradation and need for maintenance will be considered. The main parameters studied are: climate, age of buildings, type of building materials and earlier maintenance actions.

Information was gathered from two different municipalities: Reykjavik, the capital city of Iceland, and Akureyri, the main city on the north coast of Iceland. Reykjavík has about 110,000 inhabitants and Akureyri, a little more than 15,000. Due to the very different size of the municipalities, the level of strain on inhabitants is different (and even culture varies to some extent, though this is not a research question to be addressed by this paper). The two communities have considerably different climates. Reykjavik has a shore climate, typical of islands: wet, windy and temperate, whereas Akureyri has a more continental climate, with a greater difference between summer and winter temperatures, as well as being drier and less windy. The two places were chosen exactly for this reason, that is, to get a comparison between two different climatic locations.

The research is largely based on a questionnaire. The recipients of the survey where chosen by statistical methods from all house owners in the two municipalities, such that the chosen lot would be statistically representative for the houses in general, regarding type, age, owners and location. It was realised from the beginning, that the response ratio would be low, and the results, therefore, would not be statistically representative for all houses in the municipalities. In total, 1,850 houses were chosen from houses built after 1950 and having a maximum of three flats in each house. The restriction on the sample regarding building period was made because the average age of houses in Iceland is less than 30 years, and it was seen as necessary that at least 10 houses be in each age group of ten years in order to get comparable data amounts between age groups. In earlier works of similar nature it was difficult to get reliable information on refurbishment and maintenance for bigger houses, since no specific person had the responsibility of gathering the necessary information.

It is most customary for Icelanders to own their own homes, and at least until now, it is customary for the owner to personally participate in the maintenance and refurbishment work. The direct cost for

such works is therefore lower than if all workmanship was professionally contracted for, this then resulting in that maintenance in Iceland is often more or less a continuous process.

Homes in Iceland are mainly made of concrete, pored in-situ. Houses built until 1960 are often more than one storey high, and the floor slabs are usually made of concrete. In the period 1960-1990, a single-family home was typically only one storey, but later houses of two or more floor levels increased in popularity. Multi-family houses are always two storeys high or higher. Houses built in the 1950s and 1960s usually all have inner walls of concrete, and these have a load-bearing function. Later, only selected parts of the inner walls are load-bearing, the rest often being made of wood or light, ballast concrete stones. Room size differs somewhat between age groups, but especially in the 1960s and 1970s children's bedrooms are often rather small. At present, residents often wish for an open house plan; the spaces for kitchen, living room and dining room often flowing into each. Indoor-outdoor spaces or openings are also popular, as are glazed-in areas.

2.1 Research Questions and Questionnaire

In the study, the house owners/users were asked to answer a questionnaire with 48 questions regarding their houses and earlier maintenance and refurbishment.
The questions of interest to the paper presented are as follows:

- The building period and type of house
- How long the present owner/user has been living in the house
- What refurbishment actions have been taken to the knowledge of present owner/user
- How does the owner/user classify the performance of the house and its environment, on a scale from 1 (poor) to 5 (excellent)

The questionnaire was posted early spring 2006 and answers have been arriving until recently, although the bulk of them came early winter 2006. So far, 279 answers have arrived, and have been analysed regarding specific parts of the main study. However, this analysis is far from finished. For example, it is not currently known if houses in the two municipalities are comparable, age group for age group, or if the effect of some local traditions makes such comparison difficult. The number of answers is rather limited considering the size of the initial, randomly selected housings sample. The results are, therefore, not necessarily representative for all buildings in the two municipalities, but should give a reasonably good idea about the general situation.

3 RESULTS AND DISCUSSION

A total of 258 house owners gave answers to the questionnaire, which were useful to the study presented. The answers are not equally distributed by age groups or between the two municipalities, and therefore, comparison of results between groups must be done with care.

For more reliable results, it is important to get answers from inhabitants with diverse experiences, that is, both long-term residents and short-term residents. The information on occupation duration, Table 1, shows that the answers represent opinion of both long-term and short-term residents, and the distribution in occupation time spans a very broad range, or often almost the entire service time of each building age category. The average occupation time is near the middle of each span, and it can be said there is a considerable change of users, as the buyers on the market are clearly willing to consider houses in all age groups for residency. Information from real estate agents (not presented here) generally shows that prices of homes in Iceland are less affected by age of the houses, than by condition and location.

The home-owners' answers regarding previously done refurbishment of their homes, or planned actions, are shown in Table 2. The information in the table regards only refurbishment or changes in

layout of the houses or flats. Changes in fixtures and furnishings of kitchens or bathrooms, for example, are not included.

Table 1. Occupation time of present owners in houses from different building periods

Building period	No. of answers	Occupation time (years)			
		Max. possible occupation in buildings	shortest	average	longest
Reykjavik					
1950-59	10	56	2	8.1	14
1960-69	32	46	1	13.9	44
1970-79	20	36	2	19.5	35
1980-89	21	26	1	13.8	25
1990-99	17	16	1	7.8	14
2000-	10	6	1	3.4	6
Akureyri					
1950-59	12	56	7	27.7	50
1960-69	34	46	1	16.4	44
1970-79	28	36	1	15.8	34
1980-89	23	26	2	16.8	26
1990-99	27	16	1	8.2	16
2000-	24	6	1	2.5	6

Table 2. Refurbishment of houses in different age categories: already done or planned

Building period	Refurbishment		
	Already done (%)	Most frequent actions	Planned (%)
Reykjavik			
1950-59	70.0	Inner walls moved or removed	20.0
1960-69	46.9	Inner walls moved or removed	21.9
1970-79	40.0	Inner walls moved or removed	15.0
1980-89	23.8	Inner walls moved and/or house enlarged	23.8
1990-99	11.8	Inner walls moved or removed	11.8
2000-	10.0	Access for handicapped persons	10.0
Akureyri			
1950-59	66.7	Inner walls moved or removed + added insulation	25.0
1960-69	61.8	Inner walls moved or removed	11.8
1970-79	39.3	Inner walls moved and/or house enlarged	14.3
1980-89	26.1	Inner walls moved or removed	13.0
1990-99	22.2	Inner walls moved and/or house enlarged	11.1
2000-	0		4.2

As can be seen from Table 2, extensive refurbishment has already been done on a considerable number of the houses in the oldest age groups, and even more actions are planned. In the newer age groups, a much lower fraction of the houses have been refurbished, which may naturally be taken as an indication that the newer the houses are, the better they fulfil owners' needs. The most frequent refurbishment done is to move or even remove some inner walls. As these walls are often load-bearing, this often means considerable changes to the structural system, and the action is thus often

expensive. The amount of changes made, independent of age of houses, shows how willing owners, both short-term and long-term, are ready to invest in their houses. The houses are, therefore, seen as an economically sound investment by the market. Furthermore, the owner usually highly praises the performance of their house; see Table 3, where usually more than 70 % of houses get a very high mark on both indoor and outdoor performance. It is interesting to note that more houses generally get highest mark on performance in Reykjavik than in Akureyri, but the reason for this is currently unknown.

It may be seen as likely that the greater involvement in refurbishing of the older houses is at least partly responsible for the generally high opinion of performance of older houses. Even outdoor performance of older houses is highly praised, although less than is the case for new houses.
The location of older houses is often regarded by the general public as better, and these are usually more centrally located than newer houses. However, residents have a different insight towards location. Their view may be influenced by difficulties in parking of autos, which are more apparent in older quarters, built when private cars were not so numerous.

Table 3. Performance of buildings and environment, percentages of total in each age group
Performance marks: 1- poor … 5- excellent

Building period	Indoor performance					Outdoor performance				
	1	2	3	4	5	1	2	3	4	5

1980-89	0	0	17.4	47.8	34.8	4.3	4.3	17.4	34.8	39.1
1990-99	0	3.7	7.4	40.7	48.1	0	7.4	11.1	29.6	51.9
2000-	0	0	0	33.3	66.7	0	0	4.2	37.5	58.3

4 CONCLUSIONS

There will always be an interaction between the inhabitants and their houses, as so wittingly said by W. Churchill (1943): “We shape our buildings and afterwards the buildings shape us”.

Requirements for personal space have been, and possibly still are, increasing. However, at the same time, family size has been diminishing, so the total space in older living houses is clearly often sufficient for the modern family. However, the inhabitants have a strong desire to shape their houses to their own needs and are clearly willing to invest in the houses to meet these needs, regardless of how old the house is. The houses perform rather well according to residents and they are also pleased with the outdoor space around the houses. Thus, there are no signs of the houses becoming obsolete with age, and service life will therefore, mostly be decided by technical – economical reasons.

The willingness of the average resident to continuously shape his environment according to his or her needs must be duly regarded in the design of new buildings, and flexibility of buildings must be ensured, so that new buildings will be of value for the future.

ACKNOWLEDGMENTS

The research project presented is funded in part by RANNÍS – the Icelandic Centre for Research and also Íbúðalánasjóður- The State Housing Board, whose financial support is gratefully acknowledged.

Information System and Interworking for a Durable Inheritance

Boulekbache Mazouz Hafida [1]

T 41

ABSTRACT

Important problems affect the management of the territory. This one relates in particular to management of the activities and specific information to this management and with human and material resources affected there. In this context, the article suggested aims to describe and to set up a methodology to accordingly improve management of the territories we present two principal parts :
A) a part of methodology, namely the use of systemic to describe and analyze a territory
B) a proposal of tool support to be also left a study of the existing Information Systems ; we apply that to a territory in the north of France (valenciennes with project SIGL) making of a tool of decision-making aid as regards management of the inheritance aims to manage and develop existing space built and not frames in a development prospect durable relates to the whole of the territory. SIGL is thus a conceived Information system in a generic way, in order to facilitate an unquestionable capacity for a transposition on other territories. In addition, the step is based on a participative approach associating the professional partners of the sector. The analysis, the evaluation and the confrontation of the existing approaches made it possible to work out a methodology to manage the territory in a "durable" way

1 INTRODUCTION

The managers of the inheritance are confronted with problems which do not cease being important with the increase in housing stock. They must thus manage several related aspects with the good performance of the buildings and equipment of company or community (large surface, hospital, school, town hall, stage…).
To contribute to answer these problems, our work aims the definition of an effective information system. This system includes/understands a structured human organization and tools of assistance to the definition, the exchange and the information management suitable for real management.
In this article, we treat in particular the installation of this communication system dedicated to a durable management of the inheritance, by the professionals of the real estate and its users.

2 MISSIONS AND DESCRIPTIONS OF THE ROLE OF THE MANAGER OF THE REAL INHERITANCE

The managers of the inheritance must play a crucial role for the comfort and the safety of the occupants whose they take care not to disturb the activity. They carry out the maintenance of first level: control and repairing of lighting, plumbing, air-conditioning, doors and windows, furniture… But they are also brought to follow the intervention of outside firms for more specialized work.
Their missions consist with:

2.1 To Take Note:

- to prepare work to be carried out using documents (plane buildings, programs of maintenance…) ;
- to create these documents if they do not exist, on the basis of of the observation and regulation;
- to count the equipment and installations regulated (apparatuses with pressure, production of heat, elevators, hoists, extinguishers, circuits sets fire to, etc) and their instructions of maintenance

- to take note of the instructions of hygiene and safety suitable for the intervention: to make sure of the consignment of the installation (electricity, compressed air, warm water…), to identify the risks related to the maintenance products and tools used, to use the protective gears envisaged (helmet, safety shoes, gloves, glasses, helmet antibruit, respiratory protection…), in particular in the presence of certain substances such as asbestos in the buildings.

2.2 To Control and Diagnose:

- to visually control the state of the walls, ceilings, grounds, doors, windows, roof…
- to carry out operational tests of the equipment: telephone electrical communications and, materials of lighting (socket-outlet, fuses, lamps, switches, engines), equipment of kitchen, plumbing (taps, joints, piping), furniture, etc
- to include/understand the origin of a breakdown and to determine work which you will be able to carry out yourself or which you will have to entrust to a specialized outside firm

2.3 To Give in State: To Make and Do

- essentially to replace the worn or defective parts (fusible, bulbs, joints, taps, locks…), disassembling/reassembly of equipment being generally entrusted to a specialized speaker;
- to manage a store of spare parts and the consumable ones allowing to avoid any stock shortage;
- to follow the intervention of specialized outside firms from a technical point of view.

2.4 To Audit and Return Account:

- to make sure that the equipment given in state functions suitably;

- to fill and sign the card with intervention of the outside firm which attests result of the Service;
- to constitute the file of maintenance allowing to find the whole of the interventions carried out;
- to inform the GMAO (Management of the maintenance computer-assisted) if necessary to give an account of the progress of the work to its department head.

3 PROBLEMS AROUND THE REQUIREMENTS OF THE TRADE OF THE MANAGER OF THE REAL INHERITANCE:

A survey carried out near a certain number of managers of real inheritances (local government agencies, administrations, large companies, airports,…), the description of the principal problems allowed with which they are confronted. We present below the difficulties which affect, directly or indirectly, the organization and the communication related to the actions of maintenance and maintenance of the inheritance Indeed, the manager of the real inheritance must be able of:

- to plan activities very different from/to each other
- to control the diversity of the equipment;
- to supply at the appropriate time and with the need spare parts and consumable;
- to communicate as well with the users of the buildings as with the outside contributors

4 DURABLE MANAGEMENT OF REAL MAINTENANCE

To contribute to answer the problems exposed previously, our objective of treatment and follow-up, by the qualified technical structure, of the estimate and applications for a job carried out by the users of an inheritance, the communication system that we propose makes it possible to ensure an optimal and durable reflexion of the management of the real inheritance. It is elaborate starting from the three following concepts:

- the concept of actor, with which one associates a role and a right of access with information,
- the concept of process of data processing, which describes the successive interventions of the various actors, each one of them enriching information suitable for the treatment and the follow-up by the request,
- the concept of document which gathers in a centralized way information which will be successively indicated.

This system must in addition be supported by a simple and powerful tool for information management, and we propose an application Intranet with this intention.

5 WHAT IS WHAT A DURABLE APPROACH FOR THE MANAGEMENT OF THE REAL INHERITANCE ?

Real technical management is an optimized organization of the elements necessary for the operation and the maintenance of an inheritance, within the framework of definite orientations [PERRET-[1995].

On another plan, concerning the buildings to be built, in particular the problem of the bad definition of the requirements locally, often too fast remains, sometimes neglected. This is reflected on later maintenance, because these users modify their buildings and their envisaged use initially, or maintain them badly. The use of the buildings is also modified in production run, to meet new needs. It is the case for example at the time of the decision to use a room given like a room of files, catch at the end of a certain duration of occupation of the building, and which consequently is not always integrated in the program. This modification satisfies the users, but it is not very probable that this room fulfills the lawful requirements of the safety-fire.

This being, of the tools exist at the present time to help the managers in the achievement of their tasks, in particular of the computer tools.

6 COMPUTER TOOLS : A DURABLE ANSWER

The main aims of the computer tools for the management of the urban inheritance are:
- to provide a decision-making aid exploitation maintenance of the buildings, equipment and networks,
- The software of assistance to the managers of real inheritances is mainly of four different types:
- geographical Information systems (SIG) for the decision-making aid starting from data charted, for a total sight on the scale multisite or a site scale, district, city where of a vaster zone, and for a help with the management and the maintenance of external spaces and elements which compose them (green areas, networks,….),
- management software of the Maintenance Computer-assisted (GMAO) for the assistance with the management and the organization
- the management software Technique of Inheritance Computer-assisted (GTPAO) for the management and/or the assignment of surfaces, the diagnosis of the works,…,
- The tools available on the market integrate several of the functions described above and propose high level graphic functionalities, in particular for the seizure of plans, the calculation of surfaces or the representation in three dimensions.
- Nevertheless, a certain number of managers use yet at the present time only worksheets drawn up on spreadsheet, for the assistance with the management of their receipts and expenditure.

The difficulty for the managers who wish to acquire software tools is to carry out a wise choice, and to carry out a good analysis of their needs as regards patrimonial management, with the possible assistance of a consulting expert. The acquisition of these tools requires investments out of computer material, the recruitment and/or the training of the potential users. In addition, it is necessary to seize the database patrimonial, this long and generating stage being of costs. Thus, a certain number of experiments failed, in particular for lack of investments or organization. This irrefutable fact is all the more regrettable as these investments represent a tiny part of the costs of maintenance and maintenance of a real inheritance.
One will note that the most powerful systems at the present time combine SIG and GTPAO, via “gates Intranet” (or Internet) for the users (users, decision makers) wishing to reach the database patrimonial from their work station.

6.1 System for The Durable Management of The Real Inheritance

Within the framework of this study, we stick to the requests carried out by the users of the buildings near the persons in charge of the engineering services. These requests relate to estimates which the technical structure can establish or make establish by qualified companies, or of the interventions of corrective or preventive maintenance.

Lastly, according to the state of the document (three states: “request carried out by a user”; “request treated by a technical manager”; “completed and filed request”) and its type (three standards: “action of corrective maintenance”; “action of preventive maintenance”; “estimate”), the application classifies it in different and clearly identifiable repertories by the users: “new not yet examined requests”; “estimate in progress”; “actions of corrective maintenance in progress”; “actions of preventive maintenance in progress”; “requests for filed actions of corrective maintenance”, “requests for filed actions of preventive maintenance”, “requests for estimate filed”.

6.2 Protocol of Application

The objective of the "communication System for current real maintenance" being to be able to re-use without having to redefine them each time, of generic information.
He proposes to simplified cards, the access to the various actors of the process of maintenance:

- identification of work to be carried out on a card specifying the name of the applicant and his administrative or geographical membership as well as the date and the type of intervention.
- after validation by the person in charge of the engineering services, work of maintenance is carried out and filed after an update to facilitate the later consultation on the whole of work and the costs that those generated.

7 CONCLUSION

At the present time, important problems affect the management of the real inheritance and the information management which is attached there. In this context, our work aims to define and set up methods and tools for a powerful management of the real inheritances built and not built.
Within the particular framework of this article, we propose an effective communication system based on the one hand on a simple and robust human organization, on the other hand on an application Intranet dedicated to the treatment and the follow-up of the applications for a job and estimates carried out by the users of an inheritance.
This application is reinforced by others, of comparable nature, but dedicated to different uses, such as for example the document management of construction projects new, or with descriptive of a real unit.

Service Life of a Building in Environmental Assessment of Buildings

Appu Haapio [1]
Pertti Viitaniemi [2]

T41

ABSTRACT

The aim of this study is to analyse how the service life of a building should be taken into account in the environmental assessment of buildings. Over the past decade, various building environmental assessment tools have been developed for different needs and purposes. Many of these tools require an estimation of the building's lifetime. However, the service life of a building has not been emphasised within the tools. Therefore, the research results of the service life of a building need to be combined closely with the development process of the building environmental assessment tools.

1 INTRODUCTION

The field of environmental assessment tools, developed for the building sectors, has become a popular research area over the past decade [e.g. Haapio & Viitaniemi 2008a; Peuportier & Putzeys 2005; Todd *et al.* 2001]. Numerous tools have been developed by various institutes and for different purposes. A variety of different tools exist for building products and components, whole buildings, and whole building frameworks. [e.g. Edwards & Bennett 2003; IEA Annex 31 2001]

In addition, the building environmental assessment tools cover different phases of the building's life cycle and take different environmental issues into account [Haapio & Viitaniemi 2008a]. Building environmental assessment tools are not all commensurable. Consequently, the comparison of the results calculated with different tools is difficult, if not impossible. [Haapio & Viitaniemi 2007] The building environmental assessment tools often require an estimation of a building's lifetime. However, the service life of a building has not been emphasised within the tools [Haapio & Viitaniemi 2008a]. And yet, a building may comprise over hundreds of different materials and products, all with different service lives [Kohler & Moffatt 2003].

1.1 Standardisation

The International Organization for Standardization (ISO) and the European Committee for Standardization (CEN) have been active in defining standardised requirements for the environmental assessment of buildings [see Haapio & Viitaniemi 2007]. ISO Technical Committee (TC) 59 *Building construction* and its Subcommittee (SC) 17 *Sustainability in building construction* have prepared standardised requirements for the environmental assessment of buildings. The standardised requirements concerning service life planning are also prepared by the same Technical Committee (TC 59), but by a different Subcommittee (SC 14 *Design life*). The principles for the service life planning of buildings are published in ISO 15686 series *Building and constructed assets – Service life planning* and it consists of the following parts:

- Part 1 (ISO 15686-1:2000): *General principles* [ISO 2000]
- Part 2 (ISO 15686-2:2001): *Service life prediction procedures* [ISO 2001]
- Part 3 (ISO 15686-3:2002): *Performance audits and reviews* [ISO 2007]
- Part 4 (ISO 15686-4): *Data requirements* [ISO 2004] under preparation
- Part 5 (ISO/DIS 15686-5.2): *Life cycle costing* [ISO 2007] under development
- Part 6 (ISO 15686-6:2004): Procedures for considering environmental impacts [ISO 2004]
- Part 7 (ISO 15686-7:2006): Performance evaluation for feedback of service life data from practice [ISO 2007]
- Part 8 (ISO/DIS 15686-8:2006): *Reference service life and service-life estimation* [ISO 2007] under development
- Part 9 (ISO/NP 15686-9): Guide on the inclusion of requirements of service life assessment and service life declaration in product standards [ISO 2007] under development
- Part 10 (ISO/WD 15686-10): *Levels of functional requirements and levels of serviceability – Principles, measurement and use* [ISO 2007] under development.

1.2 Aim of The Study

The aim of this study is to analyse how the service life of a building should be taken into account in the environmental assessment of buildings. Over the past decade, various building environmental assessment tools have been developed for different needs and purposes. Many of these tools require an estimation of the building's lifetime. However, the service life of a building has not been emphasised within the tools.

1.3 Content of The Study

In the first section, the research area, the standards are briefly introduced, the aim of the study is stated, and the content of this study is listed. The second section focuses on forecasting service life. The third section focuses on service life planning in the environmental assessment of buildings, and how it should be taken into account. In the fourth section, the future of service life planning and the environmental assessment of buildings is speculated.

2 FORECASTING SERVICE LIFE

The length of the service life is not precisely known in advance. Due to this, the objective becomes to make '*an appropriately reliable forecast of the service life using available data*'. The forecasting of the service life of a building (or a component) is to assure whether it can be expected to exceed the required design life with adequate reliability. [ISO 2000] Standard ISO 15686-1 gives the following definitions regarding forecasting service life [ISO 2000]:

- **Service life** is 'a period of time after installation during which a building or its parts meets or exceeds the performance requirements'
- **Reference service life** is 'service life that a building or parts of a building would expect (or is predicted to have) in a certain set (reference set) of in-use condition'
- **Predicted service life** is 'service life predicted from recorded performance over time'
- **Estimated service life** is '*service life that a building or parts of a building would be expected to have in a set of specific in-use conditions, calculated by adjusting the reference in-use conditions in terms of materials, design, environment, use and maintenance*'

Forecast service life is based on either predicted service life or estimated service life. The service life prediction procedure is described in ISO 15686-1 clause 8, and detailed in ISO 15686-2. ISO 15686-1 clause 9 provides a method, a factor method, for estimating service life. [ISO 2000, ISO 2001] According to Davies and Wyatt [2004], ideally service life should be predicted according to ISO 15686-1 clause 8, and ISO 15686-2. Where the ideal cannot be achieved, estimations using the factor method, described in ISO 15686-1 clause 9, might be required. A clear distinction between predicted and estimated service life should be made when forecasting service life. [ISO 2000]

2.1 Predicted Service Life

In the predictions of service lives, the evidence from previous use, the knowledge of service lives of similar components, the tests of degradation in specific conditions, and combinations of these, are utilised. In an ideal prediction, service life is expressed as a function of the in-use condition (environmental condition under normal use). There are two methods of testing degradation; long-term exposures and short-term exposure, and normally they are used in combination [ISO 2000, 2001]. Ideally, a service life prediction based on exposure tests provides the reference service life for a factored estimation. [ISO 2000]

2.2 Estimated Service Life

The purpose of the factor approach, according to Davies and Wyatt [2004], is to provide a rough-and-ready means of estimating service life. As stated in ISO 15686-1 [ISO 2000], '*the factor method does not provide an assurance of a service life: it merely gives an empirical estimate based on what information is available*'. The factor method is based on a reference service life and a series of modifying factors. [ISO 2000] These factors are:

- Factor A: Quality of components

- Factor B: Design level
- Factor C: Work execution level
- Factor D: Indoor environment
- Factor E: Outdoor environment
- Factor F: In-use conditions
- Factor G: Maintenance level

The estimated service life of a component can be expressed as a formula, where the reliability of the reference service life figure is critical:

*ESLC = RSLC * factor A * factor B * factor C * factor D * factor E * factor F * factor G*

where ESLC is the estimated service life of a component and RSLC is the reference service life of a component [ISO 2000].

3 CONSIDERING SERVICE LIFE PLANNING IN ENVIRONMENTAL ASSESSMENT OF BUILDINGS

Numerous tools have been developed for the building sector to help decision making and improve the environmental performance of buildings and building stocks. The variety of the tools is wide; LCA based tools, rating systems, technical guidelines, assessment frameworks, checklists and certificates. [e.g. Boonstra & Pettersen 2003; IEA Annex 31 2001] Many of these building environmental assessment tools require an estimation of the building's lifetime. The service life of a building, however, has not been emphasised within the tools. Rather, the service life is taken as given without further analysis [Haapio & Viitaniemi 2008a]. And yet, a single building may comprise over 60 basic materials and circa 2000 separate products, all with different service lives and unique production / repair/ disposal processes. [Kohler & Moffatt 2003]

3.1 Environmental issues within service life planning

Service life planning can be performed for several reasons. The economical and the technical aspects, including safety related issues, are quite obvious reasons. The economical viewpoint has been pointed out quite strongly in ISO 15686-1; General parts: *'Service life planning is a design process which seeks to ensure, as far as possible, that the service life of a building will equal or exceed its design life, while taking into account (and preferably optimizing) the life cycle costs of the building.'* [ISO 2000]

The environmental viewpoint has been taken into consideration in the standards ISO 15686-6 *Procedures for considering environmental impacts*. The standard defines how to assess relative environmental impacts of design options, and furthermore, it identifies the interface between environmental life cycle analysis and service life planning. [ISO 2004] However, the standard does not take a position on the balance between environmental and other aspects. It is suggested in ISO 15686-6 that the environmental assessment of design option should be done parallel with the technical and economical assessments. According to the standard, the environmental assessment allows the design team to include environmental aspects into decision making. [ISO 2004] However, the standard does not make it mandatory to include the environmental aspect into service life planning.

The field of building environmental assessment tools is vast, as mentioned earlier. These tools are specifically for the environmental assessment of buildings. Different tools use different criteria and different indicators to correspond to these criteria in the assessments. Furthermore, the tools take different phases of the building's life cycle into account. [Haapio & Viitaniemi 2007, 2008a]If the tool does not include all the phases of the life cycle, it is difficult to consider the effect of the service life on the results. On the other hand, life cycle assessment (LCA) is highlighted as a technique for assessing environmental aspects and potential impacts of a product in ISO 15686-6 [ISO 2004].

3.2 Maintenance of A Building

During the building's service life, the building needs to be maintained, and some components need to be replaced. The service lives of the components are different. The service life of inaccessible parts should be the same as the service life of a building, but the service life of accessible parts may be shorter [ISO 2000]. If the service life of accessible parts is shorter than the service life of the building, these parts need replacements. As an example, if the design life (intended service life) of a building is 150 years, the suggested design lives are [ISO 2000]:

- 150 years for inaccessible or structural components
- 100 years for components where replacement is expensive or difficult
- 40 years for major replaceable components
- 25 years for building services
- (easy-to-replace components may have design lives of 3 or 6 years)

Maintenance and replacements have environmental impacts. In proactive maintenance, the action is taken in advance – before the damage occurs. In reactive maintenance, the action is taken afterwards – after the damage has occurred. There is a possibility the remaining service life of the components is lost if the replacement is done proactively. If the replacement of the component is done reactively, the component may have damaged its surroundings. The maintenance of these damaged surroundings has economical and environmental consequences.

The time between the needed maintenances and replacements differs between different components, and also, the demands for the maintenances are different. In addition, the quality of the maintenance, i.e. the workmanship, influences the forthcoming maintenances and may reduce the remaining service life. Poor maintenance, or disregarded maintenance, may cause damage elsewhere, and thus influence the whole building. For example, as a consequence of missing out the oil change of a car, the engine of the car may seize up. The repair of the engine is far more expensive than the oil change would have been. Also, wide repair is always more challenging and exposed to further damages.

3.3 Obsolescence

Obsolescence is a condition of being antiquated, or out-of-date. What was modern ten years ago is probably old fashioned today. An obsolete item simply does not meet a condition of the current requirements or expectations. [ISO 2000; Lemer 1996] However, this does not indicate the item is broken or dysfunctional. In other words, the service life of the item is not necessarily over, even if the item is obsolete. Currently, the number of renovations caused by obsolescence is increasing, as the requirements and needs of tenants grow. These renovations have environmental impacts; if the component is replaced before its service life is finished, the remaining service life is wasted. [Haapio & Viitaniemi 2008b] It seems a waste, especially if the replaced building materials and components are not recycled. In a case like this, the environmental viewpoint is often forgotten.

The service life of a building is usually long – decades or even centuries. The service lives of the components vary from a few years up to the service life of the whole building [ISO 2000]. But during the building's long service life, manufacturing processes and products are developed. This causes problems in the maintenance; matching old and new techniques and products does not always go smoothly. Often at least some applications or compromises have to be made. For example, in the older buildings in Finland, the pipes are laid in concrete. If the pipes need renovations, the traditional renovation of the pipes is possible, or the service life of the pipes can be extended by lining the inside of the pipes with a newish technique.

The development of the techniques, processes and products has been overemphasised, and the importance of the implementation of the techniques has been underestimated. The requirements of the occupants have increased tremendously in recent decades, and there is no end in sight. In addition to

these factors, the development of information technology and HPAC set requirements for buildings. It is challenging to adjust these requirements in a sustainable way. These issues need to be taken into consideration in the design process. The focus should be on the development of easily replaceable components since the needs and requirements of the tenants grow and change constantly. The accessibility to the components during the maintenance and the replacement should be considered already in the design phase, in order to minimise the possible damages to the surroundings.

3.4 Experimental Building

To develop the construction processes, the buildings and the maintenance of the buildings, new designs, new products and new techniques are used occasionally. New designs and developments can be tested and studied in experimental buildings. These experimental buildings are important, since sometimes the experience from real construction sites is essential for the development process. Karjalainen [2002], for example, studied multi-story timber apartment buildings as pioneers in the development of timber construction. However, from time to time experimental building is regarded as a financing method. In these projects, nothing is necessarily experimented. These projects detract the reputation of the idea of experimental building.

The knowledge gathered during and after these on-site experiments is not utilised as well as it could be. Most of the knowledge stays with the people working in that particular project – it is not shared with others. The same mistakes might be made more than once. The knowledge gathered from experimental building should be taken to the next level. In order to be able to analyse building processes, solutions and components more thoroughly, at least some of the experimental buildings should be demolished before the end of their service life. Demolition, however, seldom takes place, even though it would provide more intimate knowledge of environmental performance and service life, and their interaction. How building solutions and components perform as part of a building should be studied by analysing them from demountable or demolished buildings.

4 DISCUSSION

Currently, most of the building environmental assessment tools are used towards the end of the design process to evaluate the environmental results. However, the assessment tools are not used simultaneously with the design tools. The later the evaluation of the results in the design process is made, the fewer possibilities it has to influence the design itself. In addition, optimising one structural solution may not be the ideal solution for the building. [Haapio & Viitaniemi 2008b] If the assessment tools and design tools are integrated, the task would be facilitated. Lützkendorf and Lorenz [2006] are expecting it to happen in the future.

The surroundings and the other components affect the component and its service life. The width of the ventilating slot between the wooden cladding and the exterior wall structure, for example, affects the maintenance and the service life of the cladding. When the distance between the wooden cladding and the exterior wall structure is adequate (i.e. the width of the ventilating slot is maximised), the situation can be compared to a fence in the field. On the other hand, when the width of the ventilating slot is miniscule, the wooden cladding acts as part of the exterior wall structure. Another example is the remarkable difference in the condition of the old and new wooden buildings in the town of Porvoo, in Finland. The cladding of the new buildings had to be renovated a few years after the completion. The cladding of the old buildings is in much better condition, even though the buildings are decades old. A controlled thermal leakage through the exterior wall structures could be one of the explanations for the better condition of the old wooden houses. In the new buildings, the thermal leakage through the exterior wall structures is much lower, but the cladding needs renovations more often. Which alternative is better from the economical viewpoint, and which is better from the environmental viewpoint? Which alternative is the best considering health related issues? If the observation time changes from 50 to 100 years, how does it affect the choice?

The service lives of building components, their effect on a building and its service life should be analysed in-depth. Currently, the effect of the service life has not been analysed thoroughly in the environmental assessment of buildings. [Haapio & Viitaniemi 2008b] The building environmental assessment tools often take the service life as given – no further analysis is made. It is not fully recognised how the service lives of the components and a building affect the results of the environmental assessment. Different building environmental assessment tools take different phases of the building's life cycle into account. If the tool does not include all the phases of the life cycle, it is difficult to consider the effect of the service life on the results. There is a need to properly include the service life into the environmental assessment of buildings. Only then, will the integration of the assessment and design tools (suggested by Lützkendorf & Lorenz 2006) maximise the benefits.

ACKNOWLEDGMENTS

The authors wish to thank the Finnish Cultural Foundation and the National Graduate School of Timber Construction and Design (coordinated by University of Oulu) for funding this research.

Whole Life Cycle Costing as a Decision Tool for Use in French Healthcare Facilities

Samer Sliteen [1]
Orlando Catarina [2]

T 41

ABSTRACT

Whole Life Cycle Costing is increasingly becoming an important decision making tool for managers of French Healthcare Facilities. The life cycle of hospitals, analysed in this study, covers the period from construction to deconstruction and as well, the operation and maintenance phase. Over the course of the study on French healthcare facilities, several questions arose: e.g., what does the investment cost of health care facilities represent; in the management of health's building, what does the operation cost of health care facilities represent; which items are important to optimize future operational costs of health care facilities? The data necessary for this study was collected from 5 cases studies of 4 public hospitals and one private hospital. To reduce partially disparities among the cases studied and provide uniform information necessary to a transversal analysis, the investment costs were updated on the basis of the index BT01 to conduct in November 2004. To identify the relationship between operation costs and investment cost/activities an innovation methodology was developed. Some limitations of this research included the fact that the hospitals included in the study were recently constructed and there has not been any additional investment since construction. The study has yielded information on healthcare facility investment costs, and operation-maintenance cost as well as provides key performance indicators and information on benchmarking.

1 INTRODUCTION

The principal aim of the construction of hospitals is to provide healthcare to patients; the Hospital Plans (2007 to 2012) initiated by the French government, consists of a set of measures intended to in offer a new dynamic to the operation of hospital facilities. The principal objectives of this plan of investment are to allow the modernization and the reorganization of healthcare facilities as a means of improving the operation and management of these facilities and rationalising resources to obtain better efficiencies within the healthcare system. The modernization of the hospital sector is not only intended to decrease the overall consumption of energy of these facilities, but also provide changes to every construction related element of such projects such as accruing savings in the design, construction and operation of the facilities.

The complexity of healthcare construction projects requires a systematic planning to carry out heterogeneity (room of patient, cuisine, operating rooms, offices, etc.) and a flexibility of the operation. Indeed, the planning team has to provide the client not only with answers to architectural problems, but also a response to the requirements for technical and economic programs. This requires many different competencies such as those of architects, doctors, nurses, specialized engineers and representatives of the administration. For the project to be successful, these groups must work together during the duration of the project and indeed from the design phase to its commissioning and eventual exploitation ass a healthcare facility.

In France there are 6500 public and private healthcare facilities. Apart from receiving patients, they also accommodate healthcare professionals (persons in charge, frameworks of health, techniques and medico-techniques, biomedical engineers, heads of department and medical teams, etc.) and as well the administrative staff (e.g. hospital director). For this reason, it is important to study the life cycle of these establishments.

As suggested by Boussabaine and Kirkham [2001], 'Whole Life Cycle Costing' (WLCC) is a dynamic and ongoing process that enables the stochastic assessment of the performance of constructed facilities from feasibility to disposal. The WLCC assessment process takes into account the characteristics of the constructed facility, re-usability, sustainability, maintainability and obsolescence as well as the capital, maintenance, operational, finance, residual and disposal costs. The result of this stochastic assessment forms the basis for a series of economic and non-economic performance indicators relating to the various stakeholders interests and objectives.

2 METHODOLOGY

This study deals with the variation in the operation and investment costs to French healthcare facilities. The ISO standard FDIS 15686-5 had been applied to calculate the different costs. It provides techniques and methodologies that facilitate the practical implementation of whole life cycle costing as applied to healthcare facilities in France. Based on the WLCC data, one can estimate the operational costs for the building for each year of its expected life. 'The estimated yearly costs must be discounted to make proper allowance for the time value of money thus enabling comparison of alternatives on a common basis [Flanagan et al. 1989]'. As indicated by Ashworth [1999], the most common measure used to compare alternatives in Life Cycle Costing is the Net Present Value (NPV), although other measures, such as the Equivalent Annual Cost, Payback Period, Return on Investment, and Saving to Investment Ratio, could be also used.

Historically, hospitals have focused on increasing bed capacity and the number of patients treated per day by providing better services and advanced medical technology. But they have not considered strategies related to the building operations nor reflected on the importance of operating non-medical equipment in accruing savings and performance enhancements. The cost of hospital services or their impact on the overall profitability of the healthcare facility has not been widely considered. For

example, factors such as the number of occupied beds in relation to the age of the building, equipment capacity, period of maintenance and replacement has not typically been of importance.

The WLCC has now been applied to the development of healthcare facilities to help make investment decisions at the pre-construction phase of proposed new hospital projects, and to help in the organisation of building maintenance.

A two-step analysis was employed in this study:

1. The collecting data for the year 2004 (French Health Ministry does not hold a database; required information was obtained from the hospitals).
2. The data was then clustered by building maintenance, grounds maintenance, engineering maintenance and utilities.

The input data is representative of the principal operational and maintenance costs incurred in French healthcare facilities, it does not however include cleaning costs.

3 RESEARCH DATA

Certain costs such as water, energy, salaries, occur every year, whereas the level of replacement and maintenance costs depend on the quality of the facility. The research data used in this study are the costs and characteristics that are common to all French healthcare facilities. MAINH [2006] has shown the components that relate to the total service charge and illustrates that the average space of patient rooms in public hospital is more important than the plate form technique but on the contrary in private hospital.

Table 1. Basic Data on hospital size, capacity and related investment, operational and maintenance costs

Establishment	**Public**				**Private**
	Hospital 1	**Hospital 2**	**Hospital 3**	**Hospital 4**	**Hospital 5**
Gross internal floor area (m²) (GIA)	39083	31825	61300	63567	35312
Bed capacity or equivalent	395	320	635	469	271
Gross internal floor area /capacity (m²/ bed)	99	99	97	136	129
Year of construction	1994	1997	1991	2000	1990
% individual room	35%	83%	30%	73%	50%
Investment budget (K€ Net of taxes)	53458	38548	62527	76693	45559
Operation and maintenance budget(k€ net of taxes)	2267	1685	3433	2562	1072

3.1 Investment Costs

The investment cost in this study includes costs for: site and grounds works, structure and substructures, sewerage, water and gas systems, ventilation systems, heating installation, automated transport, medical supply system for medical fluids. It does not take into account such items as biomedical equipment, penalties for delay of execution of construction, replacement costs, or the funding of grand works and causes supporting the future development of the hospital.

The WLCC approach identifies all costs benefits and reduces them to the present value by using typical discounting methods. The appropriate discount rate varies according to the organisation and its choice largely depends on past experience. In this study, investment costs were discounted to a value dated to February 2004 and reported in k€, net of taxes by using index BT01 (i.e. in France, price factor index covering all building activities - base 100 in 1974):

Table 2. Descriptive statistics of the investment cost (€ / m²)

Descriptive	External works/m²GIA	Engineering works/m²GIA	Building/m²GIA	Total Investment/m² GIA (€/m²)
Mean	62.1	444.7	694.6	1201
Standard Deviation	15.5	30.9	92.6	123.2
Sample Variance	320.4	1273.6	11446.	20239
Minimum	43.5	394.7	581.7	1020
Maximum	82.3	478.9	839.7	1368

The following results include outputs from the Excel based WLCC tool. The pie chart shows the distribution of investment costs. It shows that the percentage of costs varies from 5% to 37% and illustrates the importance of both the finishing works and engineering works in respect to overall investment costs. Figures 2 and 3 illustrate that there is no clear relationship between investment costs and the number of beds or the GIA. Furthermore, investment costs relate more closely to the GIA than the equivalent number of beds.

3.2 Operation and Maintenance Costs

The operation-maintenance costs in this study are costs net of taxes for the year 2004 and include the exploitation budget, salaries of personal working on operation and maintenance of the hospital, operation-maintenance contract provided externally, the energy and fluids contract. Items not taken into account include costs of biomedical equipment, cleaning, some works of the parking area, fire safety services, waste removal, medical fluids, the major portion of linen services, and replacement costs.

From the following figures, it is very noticeable that the relationship between the operation-maintenance cost and the number of beds is more evident from that of the GIA. Hence, it may be easier to estimate future operation-maintenance costs based on the number of patient beds. The distribution shows that the engineering and building maintenance costs form more than 50% of the overall operation and maintenance costs; the actual proportion would depend on the kind of technical equipment used at the hospital and the quality of its construction.

3.3 Relationship Between Investment and Operation-Maintenance Costs

The consequence of investment choices made during the planning and design phases will be of great importance to the total future costs of the facility. As suggested by Bjorberg [1996], the calculation of annual costs is a way of evaluating investments versus the consequences of operating and maintaining buildings. All hospitals in the sample set have been in service from less than eleven years. These buildings have not yet begun their replacement cycle for components and equipment as these typically take place primarily between the fifteenth (15-yr) and sixtieth (60-yr) year of the building's life. From Figure 7 it is evident that the correlation between investment costs and operation-maintenance costs of these five cases is not entirely satisfactory, as the linear correlation coefficient is less than 0.5 indicating perhaps only an intermediate degree of correlation.

4 EXAMPLE

The following example of WLCC of Hospital 4 are based on [The Whitestone Building Maintenance and Repair Cost 1999, Facilities Maintenance and Repair Cost Data 13th annual edition 2006] to complete the data, in application of Excel based WLCC and ISO 15686, the hospital has been analysed. The assumed life is 60 years. According to Woodward [1997], errors of five or ten years in the predicted life will not make very much difference to the predicted equivalent costs when the life is fifty to sixty years.

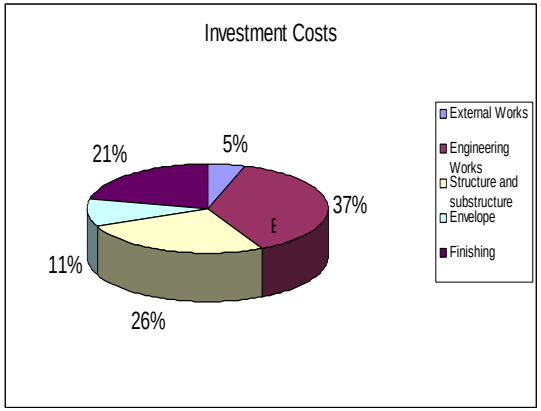

Figure 1. Distribution of the investment costs

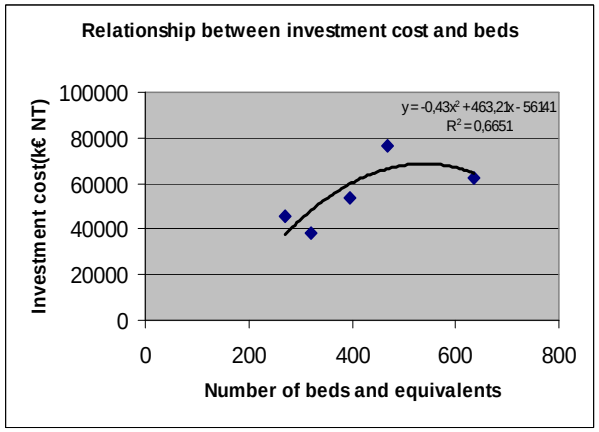

Figure 2. Relationship between investment cost and beds

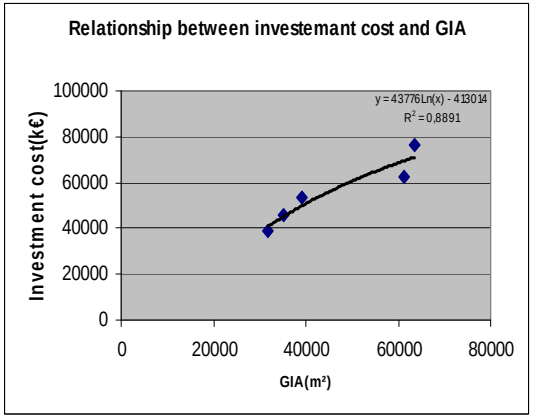

Figure 3. Investment cost and GIA

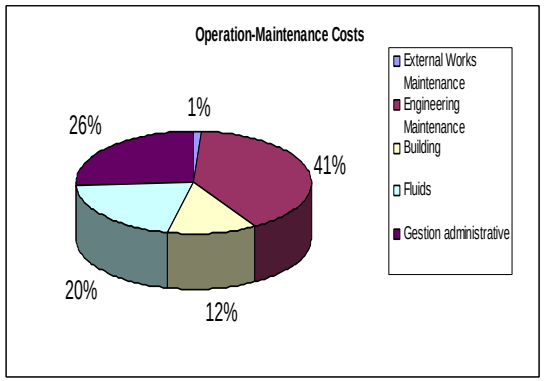

Figure 4 Allocation: operation-maintenance costs

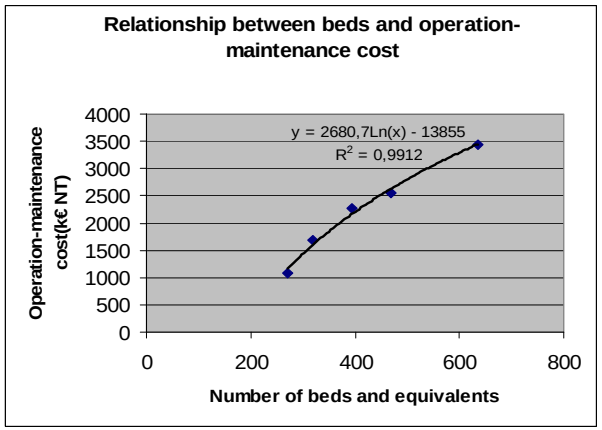

Figure 5 Operation maintenance cost vs. number of beds

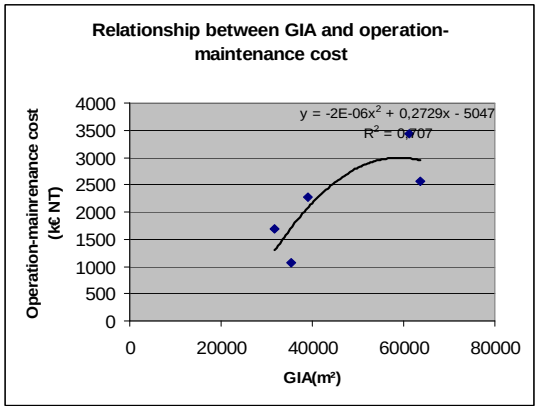

Figure 6. Operation maintenance cost and GIA

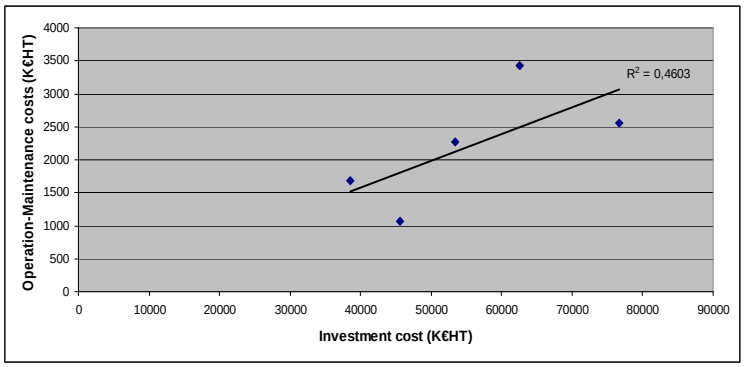

Figure 7. Relationship between investment and operation–maintenance costs (without replacement and cleaning)

The errors in the predicted costs, and hence design decisions, are likely to be greater when the life of the asset is taken substantially shorter than conditions warrant than when longer than justified. The WLCC plan provides a year by year the budget for the hospital and highlights the pattern of expenditure and works to be carried out and allows the directors to make tactical decisions to organize the flow of work and the expenditure form every year. It will also help to highlight where work can be grouped or delayed for the special situations of hospital. It also shows where planned replacement occurs, that helps in the strategic planning of the hospital (the budget, the capacity of the hospital during the period of works and the model of distribution work sites). For each year it will be easier to prepare the plan of detailed required works the budget for each item which will help in the planning and ordering of the work. The analysis shows that the distribution of costs for Hospital 4 over its life cycle are as follows: design, 2%; construction, 24%; operation and maintenance, 39%; replacement, 19%; utilities, 15%; demolition, 1%

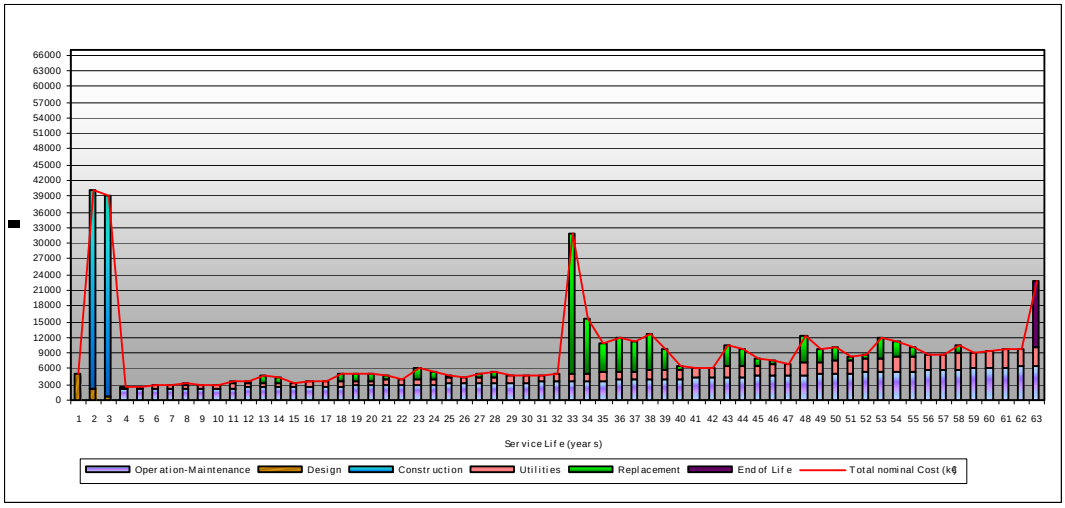

Figure 8. Total nominal cost per square metre

5 BENCHMARKING

Given diversity and complexity of hospitals and their related activities, it is unlikely that the mean values obtained from such type of studies accurately estimate the costs for the majority of development projects. By contrast, average values obtained in this study appear to be quite consistent with those presented in different observatories. Therefore, a methodology is proposed that gives hospital directors the principle

items required for estimating investment costs and operation-maintenance costs for their project or property. The approach takes the average value as input and then to estimate the existing hospital costs following the criteria listed in the benchmarking table (Table 3). The allocation of targets between the lower and upper ranges allows evaluating the cost compared with the average. Benchmarking for investment, maintenance and for the consumption of utilities has been carried out to help reduce operational costs.

Table 3. Benchmarking to estimate real estate investment costs

	Factor	Low bracket	High bracket	Wt.
Ground Works				
Ground Works	Rate of occupation of area	High, outdoor space limited	Low, outdoor space larger than floor area of building	5%
	Garden	Flat, mostly natural and grass	Little grass, various types of cover, fences	
	Roads and outdoor amenities	Normal materials	Materials/ high quality	
	Parking	Exterior	Garage	
Building				
Structure and substructures	Compactness	High	Low	26%
	Foundations	Normal	Special

site	**Climate**	Oceanic		Continental	1,2	4	
	Exposure aux risks exterior	Low		High	0,9	2	5200X1.032=5366

6 CONCLUSION AND PERSPECTIVES

This work concerns the whole life cycle costing of hospitals without cleaning and without specifying more elaborate operational elements. As an extension to this study on healthcare facility-wide costs, it may be useful to carry out research on other more reliable indicators. Additionally, risk assessment tools could provide a more thorough comparison of alternatives.

From another point of view, the development of this work raises four important issues perhaps worth further investigation. The first issue concerns collecting enough data to develop a model that can relate to such variables as the cost of time as might be carried out in a Monte Carlo analysis. The second issue concerns the relationship between building components and operation-maintenance costs. The third issue concerns the relationship between operation-maintenance cost and hospital's activity. The forth issue concerns the personnel who work in the hospital. One of the problems encountered over the course of this study was that there is insufficient amount of similar data. As well, there is always the problem of the misinterpretation of data. As well, it is acknowledged that the changing external economic environment may in certain instances invalidate much of the usefulness of past experience.

Finally, based on the results obtained in this work, it is clearly apparent that the relationship between investment cost and operation-maintenance costs is not evident. As such, additional work is required to establish the relationship between operation-maintenance costs and relevant hospital activities or other indicators.

ABSTRACT

The ability to quantify changes in condition over time is important to ensure sustainable development in the built environment.The current 'state of the art' Factor Method [ISO 15686-1:2000] for service life prediction calculates an estimated service life, but not changes in condition.The application of the stochastic Markov Chain is restricted by limited availability of historic performance data on degradation of building materials required to populate transition probability matrices.This paper, based on a PhD thesis, looks at the application of neuro-fuzzy artificial intelligence to translate expert knowledge into probability values to supplement historic performance data for the development of Markovian transitional probability matrices, towards prediction of service life, condition changes over time, and effects of maintenance levels on service life of buildings. Expert knowledge is used to express durability and degradation factors in "IF-THEN" rules, which are translated into crisp probability values with neuro-fuzzy artificial intelligence to populate the Markovian transitional probability matrices.A case study is presented to proof that the limited availability of historic performance data on degradation of building materials can be supplemented with expert knowledge, translated into probability values through the application of Fuzzy Logic Artificial Intelligence, to develop transition probability matrices for the Markov Chain towards calculating the estimated service life of a building or component, quantifying changes in condition over time and determining the effects of maintenance levels on service life.

1 INTRODUCTION

The global importance of and need for sustainable socio-economic development demand an informed decision-making process from the built environment. Resources and non-renewable resources in particular, should be used as responsible and best possible to ensure optimum service life and life cycle costs, which depend on the ability to quantify the changes in condition of building fabric and components over time in any given physical and operational environment. If the change in condition over time can be defined mathematically, it will be possible to calculate the service life and remaining service life of buildings and components, and the consequences and risks of maintenance budget allocations and decisions to defer maintenance. The ability to predict changes in the condition profile of buildings or components is essential for cost-effective maintenance and rehabilitation decisions.

The current state of the art method for building service life prediction, the Factor Method [ISO 15686-1:2000], applies seven factors to a reference service life to estimate an empirical service life. Although the Factor Method calculates the estimated service life, it does not provide information on the degradation process, change in condition or condition profile.

A number of studies [Lounis et al, 1998a, p.1; Madanat et al, 1995, p.120; Morcous et al, 2003, p.353; Rudbeck, 1999 cited by Hövde and Moser, 2004, p.40] identified the Markov Chain, a stochastic approach used for simulating the transition from one state [condition] to another over time, as the preferred method for predicting service life and calculating changes in condition. The population of the Markov transitional probability matrix is a problem due to the lack of reliable and consistent historical performance data on the actual degradation rate of materials and components. Lounis et al [1998] cited by Moser [Hövde and Moser, 2004, p.66] stated: "The Markov model considers steadily degrading systems, where for each property, during each time period, a probability of deterioration is defined. This method thus requires sophisticated inputs in the form of probabilities, which are not easily estimated, as they cannot be read directly off the real behaviour of the structure in the field. The Markov model requires an in depth knowledge of the system dealt with or on the other hand has to rely on significant simplifications."

The development of a reliable and consistent database through regular field assessments is however a very slow process. In general, the best available source of information on degradation is the knowledge and reasoning of experts on material degradation in the built environment. However, as Negnevisky [2002, p.15] stated, "A major drawback is that human experts cannot always express their knowledge in terms of rules or explain the line of their reasoning. … experts do not usually think in probability values, but in terms as often, generally, sometimes, occasionally and rarely." On the interim, a system is needed to translate the verbally expressed knowledge and reasoning of experts into probability values, while using the assessment database as it grows to calibrate, learn and improve the system's reliability and ability to simulate the degradation process, providing for various combinations of the factors effecting degradation.

2 DEGRADATION PROCESS

A building is a complicated three-dimensional human-made configuration of a diverse range of fabrics, materials and components, each with its own characteristics, which interacts differently to the influences of its environment, could be old or brand new, raw or processed, come in different forms, shapes, sizes and finishes, and its applications could vary considerably. The environment acts on a building or component through mechanical, electromagnetic, thermal, chemical and biological agents causing degradation over time. The degradation process, as illustrated in Fig. 1 below, is a continuous interaction between durability factors, which counters degradation, and degradation factors, which promotes or cause degradation. These factors are the same as used in the 'state of the art' Factor Method.

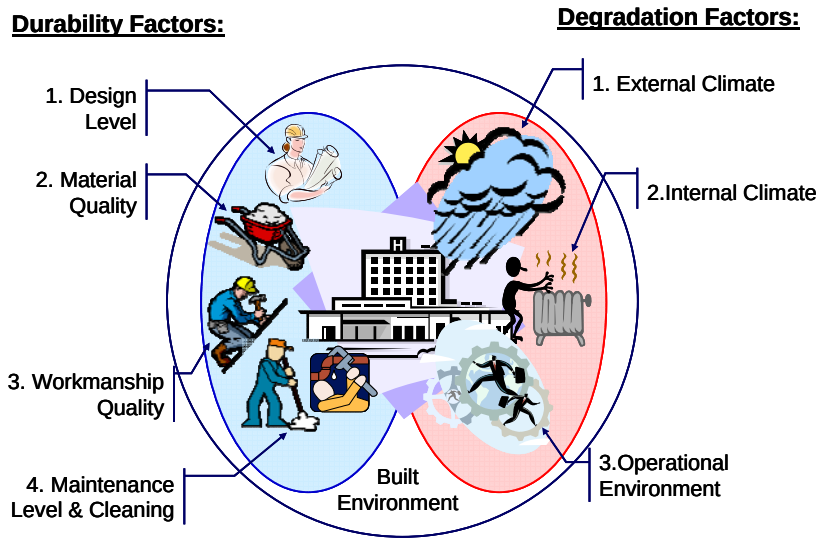

Figure 1: Degradation and Durability Factors [Mc Duling, 2006]

Durability is the ability of a building or component to resist the adverse effects of exposure to its environment. Degradation is determined by the environment, which can be divided into a physical and operational environment. The physical environment in and around the building or component comprises of a macroclimate [gross meteorological conditions], mesoclimate [terrain and local built environment] and microclimate [absolute proximity of a material surface]. The operational environment or 'user culture' is determined by the level and extent of the utilisation of the building by the occupants. Mechanical processes play a major role in the operational environment. The level of maintenance and cleaning is sometimes also taken into consideration with utilisation to determine the operational environment of a building. In the case of the 'Factor Method' this approach could result in 'double counting', because maintenance level is a factor in its own right.

3 NEURO-FUZZY ARTIFICIAL INTELLIGENCE

According to Negnevisky [2002, p.1-21] "Fuzzy logic is concerned with the use of fuzzy values that capture the meaning of words, human reasoning and decision making". It encodes and applies "human knowledge in a form that accurately reflects an expert's understanding of difficult, complex problems." An integrated neuro-fuzzy system has been selected to translate expert knowledge and reasoning into probability values because it "can combine the parallel computation and learning abilities of neural networks with the human-like knowledge representation and explanation abilities of fuzzy systems. … It can be trained to develop IF-THEN fuzzy rules and determine membership functions for input and output variables of the system. Expert knowledge can be easily incorporated into the structure of the neuro-fuzzy system." [Negnevisky, 2002, p.266-267]. The Mamdani-style fuzzy inference technique is used and performed in four steps: fuzzification of the input variables, rule evaluation, aggregation of the rule outputs, and finally defuzzification.

3.1 Structure of the Fuzzy Logic System

The system structure in Fig. 2 below identifies the fuzzy logic inference flow from the input variables to the output variables. The fuzzification in the input interfaces translates analogue inputs into fuzzy values. The fuzzy inference takes place in IF-THEN rule blocks, which contain the linguistic control rules. The output of these rule blocks is linguistic variables, which are translated into analogue variables through defuzzification in the output interfaces.

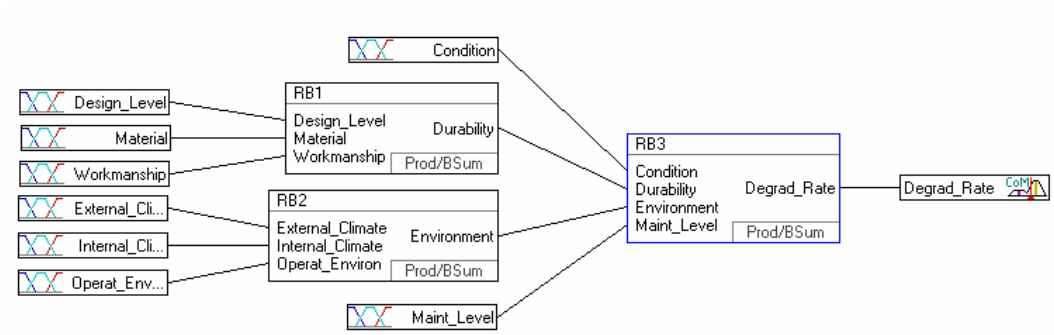

Figure 2: Structure of the Fuzzy Logic System [Mc Duling, 2006]

The input variables are the durability and degradation factors influencing the degradation of the material or component, defined in linguistic or fuzzy terms. These factors are similar to the factors used in the Factor Method, except for the valuation or rating of the factors. A five point colour-coded rating system is used based on a similar rating system used for condition assessments.

The input, intermediate and output variables are defined in Tables 1, 2 and 3 below:

Table 1: Input Variables for Fuzzy Logic Model [Mc Duling, 2006].

No	Variable Name	Rating	Term Names	No	Variable Name	Rating	Term Names
1	Condition	1 2 3 4 5	Very Bad Bad Fair Good Very Good	5	Maintenance Level	1 2 3 4 5	Very Low Low Normal High Very High
2	Design Level	1 2 3 4 5	Very Low Low Medium High Very High	6	Material Quality	1 2 3 4 5	Very Low Low Medium High Very High
3	External Climate	0 1 2 3 4 5	Internal Element Very Aggressive Aggressive Slightly Aggressive Less Favourable Favourable	7	Operational Environment	1 2 3 4 5	Very Aggressive Aggressive Slightly Aggressive Less Favourable Favourable
4	Internal Climate	0 1 2 3 4 5	External Element Very Aggressive Aggressive Slightly Aggressive Less Favourable Favourable	8	Workmanship Quality	1 2 3 4 5	Very Low Low Medium High Very High

Table 2: Intermediate Variables for Fuzzy Logic Model [Mc Duling, 2006].

No	Variable Name	Term Names
9	Durability	Very Low Low Medium High Very High
10	Environment	Very Aggressive Aggressive Slightly Aggressive Less Favourable Favourable

Table 3: Output Variable for Fuzzy Logic Model [Mc Duling, 2006].

No	Variable Name	Defuzzification method	Unit	Rating	Term Names
11	Degradation Rate	Centre of Moment	Percentage	0 25 50 75 100	Very Slow Slow Medium Fast Very Fast

The output variable, degradation rate, is expressed as the percentage of the material or component that changes from one condition to the next worst condition during one time interval. This interval, which could vary from material to material, is determined by the time required for the material to change from one condition to the next worst condition without jumping more than one-step at a time in order to keep the model as simple as possible and dictates the assessment frequency. The degradation rate is the transition probability required for the Markov process.

There are three rule blocks in the proposed system; an extract from Rule Block 3 [Fig. 2] is shown in Table 4 below as an example of a typical rule block.

Table 4: Extract from 'IF-THEN" Rule Block 3 [Mc Duling, 2006].

IF				THEN	
Condition	Durability	Environment	Maintenance Level	Degree of Support	Degradation Rate
Fair	Medium	Slightly Aggressive	Very Low	0.50	Very Fast
Fair	Medium	Slightly Aggressive	Very Low	0.50	Medium
Fair	Medium	Slightly Aggressive	Low	0.25	Very Fast
Fair	Medium	Slightly Aggressive	Low	0.25	Fast
Fair	Medium	Slightly Aggressive	Low	0.50	Medium
Fair	Medium	Slightly Aggressive	Normal	0.25	Very Fast
Fair	Medium	Slightly Aggressive	Normal	0.75	Medium
Fair	Medium	Slightly Aggressive	High	0.25	Very Fast
Fair	Medium	Slightly Aggressive	High	0.50	Medium
Fair	Medium	Slightly Aggressive	High	0.25	Slow
Fair	Medium	Slightly Aggressive	Very High	0.25	Very Fast
Fair	Medium	Slightly Aggressive	Very High	0.50	Medium
Fair	Medium	Slightly Aggressive	Very High	0.25	Very Slow

While the other variables were kept constant during the simulation, the maintenance level and condition ratings were adjusted to obtain degradation rates for various scenarios. The motivation for this is that design level, material, workmanship, and external and internal climate are largely predetermined during planning, design and construction, while operational environment could vary slightly but mostly stay relatively constant over the service life of the building or component.

Subsequent to completion of construction, the degradation rate is controlled mainly by the maintenance level. There is also an increase in the rate of degradation as the condition deteriorates.

3.2 Transition from Artificial Intelligence to Markov Chain

Degradation rate is defined as that percentage of the building or component that will 'transit' or change to a condition of worse degradation in one time interval. In the case of buildings, this time interval is normally one year, but could be months, weeks or even days, depending on the reference service life of the component under consideration. Due to the influence of the degradation and durability factors on the building, the transition to a condition of worse degradation is probabilistic with the transitional probabilities depending on the current condition of the building. Therefore, degradation rate is defined as the transition from condition i to the next worse condition j in one time interval:

Degradation rate = transitional probability P(ij)

A five-point condition rating system is used, with Condition 5 the initial condition, progressively worsening towards Condition 1, where the material or component has failed and needs to be replaced.

Based on the assumptions that under normal circumstances the condition will only deteriorate and not improve and a one year interval is short enough to ensure the change in condition will not jump more than one condition rating, or P(ij) = 0 when i < j and j < i - 1, the transitional probability matrix is defined as:

$$P = \begin{array}{c|ccccc|l} & [5] & [4] & [3] & [2] & [1] & \\ (5) & P(55) & P(54) & 0 & 0 & 0 & \sum P(5j) = 1 \\ (4) & 0 & P(44) & P(43) & 0 & 0 & \sum P(4j) = 1 \\ (3) & 0 & 0 & P(33) & P(32) & 0 & \sum P(3j) = 1 \\ (2) & 0 & 0 & 0 & P(22) & P(21) & \sum P(2j) = 1 \\ (1) & 0 & 0 & 0 & 0 & 1 & \sum P(1j) = 1 \end{array}$$

The transition probabilities P(54), P(43), P(32), and P(21) are obtained from the Neuro-fuzzy simulation, while P(55), P(44), P(33), and P(22) are obtained from ∑P(ij) = 1. These transition probabilities are then used to populate the Markov Transitional Probability Matrix.

Table 5: Markov Transition Probability Matrix for 'base-line' Model [Mc Duling, 2006].

Markov Transition Probability Matrix		Condition at time t = 1				
		5	4	3	2	1
Condition at time: t = 0	5	0.578	0.422	0	0	0
	4	0	0.516	0.484	0	0
	3	0	0	0.391	0.609	0
	2	0	0	0	0.453	0.547
	1	0	0	0	0	1

In the 'base-line' Neuro-fuzzy model, it was assumed that the variables in each rule block carried the same weight, and this resulted in deterioration rates being too high, as shown in Table 5 above. After evaluating the results and adjusting the weights based on expert knowledge and reasoning, more realistic values were obtained as shown in Table 6 below:

Table 6: Markov Transition Probability Matrix for revised Model [Mc Duling, 2006].

Markov Transition Probability Matrix		Condition at time t = 1				
		5	4	3	2	1
Condition at time t = 0	5	0.950	0.050	0	0	0
	4	0	0.915	0.085	0	0
	3	0	0	0.900	0.100	0
	2	0	0	0	0.875	0.125
	1	0	0	0	0	1

3.3 Calibration of the Neuro-Fuzzy Model

Although there are currently approximately 27 tertiary hospitals and 380 other government hospitals in South Africa, only six academic hospitals were chosen as pilot and control sites to calibrate the model because they are of similar age, were all built within a seven year period during the 1970's, have similar construction types, design, material and workmanship levels and operational environments, and their condition have been assessed at least twice since 1995. In Fig. 3 below the average assessed condition of the six hospitals are shown on performance over time curves for five levels of maintenance:

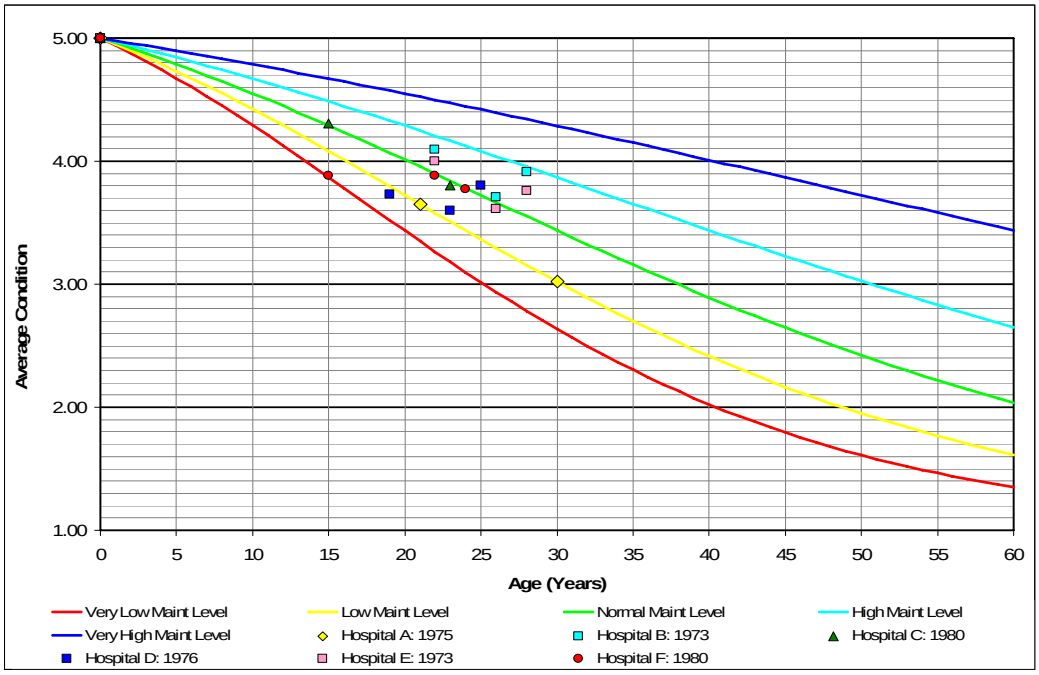

Figure 3: Performance over Time Curves [Mc Duling, 2006]

4 SERVICE LIFE PREDICTION

For service life prediction, the condition of a building or component is a relatively easy to assess and ideal to use performance indicator. The minimum performance requirement for academic hospitals should be Condition 3. Below a level 3 the building or component is simply not able to provide an environment supportive of proper health care. There are areas in hospitals where the performance requirements are higher [e.g. operating theatres and intensive care units]. For other building types, this performance standard may be different. The performance requirements for buildings and components should be determined by clearly defined and appropriate policies and codes.

5 CONCLUSION

The proposed model, based on the Markov Chain approach, translates expert knowledge and reasoning into probability values through the application of Neuro-Fuzzy Artificial Intelligence to supplement limited historical performance data on degradation of building materials for the development of Markov Chain transitional probability matrices to predict service life, condition changes over time, and consequences of maintenance levels on service life of buildings. Due to the limited availability of reliable historic performance data, expert knowledge and reasoning were used to develop initial transition probability matrices for the proposed model. However, the initial model produced unrealistic results and available historic performance data was used to calibrate the model. After calibration, the model produced realistic results, which compared well with historic performance data for other hospitals.

According to Lounis et al [1998b, p.5] "The development of the Markovian model requires a relatively limited amount of historical performance data at two or more points in time." This statement is supported by the results of the proposed model. But, instead of using the limited available historic performance data to develop the Markovian transition probability matrices, the proposed model reverses the process by using expert knowledge and reasoning, and supplements it with available historic performance data to calibrate the model. Historic performance data should however not be used indiscriminately. The degradation and durability factors could vary considerably between assessments and these potential variations should be taken into consideration.

Evolution of Degradation and Decay in Performance of ETICS

Bruno Daniotti [1]
Riccardo Paolini [2]

T 42

ABSTRACT

This paper provides initial results from experimental work on laboratory accelerated ageing of external thermal insulation composite systems with rendering (ETICS) undertaken at the Building Environment Science and Technology department of the Polytechnic of Milan. The work forms part of a broader experimental programme seeking to develop knowledge on the relationship between critical properties affecting long-term performance and test parameters that reveal the process of degradation.
The performance evaluation of ETICS specimens consisted of several different types of tests conducted on non-aged specimens and specimens subjected to accelerated environmental ageing. The ageing procedure consisted of exposing specimens to different environmental macro-cycles comprised of ageing under ultraviolet radiation and warm and cold temperature cycling that replicated temperature cycling occurring in winter or summer in Italy. Non-destructive tests were carried out that included obtaining photos to characterise the evolution of surface degradation of specimens and conducting absorption tests to determine the degree of moisture uptake in the specimens. Other tests were used for assessing hygrothermal performances including dynamic thermal response, thermal inertia, thermal resistance and dynamic response to variations in moisture content of base and finish coat. In this paper the tests methods are described and initial results analysed following two ageing macro-cycles used to discern the process of degradation of the specimen, in terms of monitoring changes in capillary water absorption, thermal resistance and rendering degradation (photo survey). The long-term aim of this study is to develop a method to evaluate the Serviceability Limit State of building components based on understanding relationships between performance attributes and physical properties of building components.

1 INTRODUCTION

The aim of this paper is to portray the initial results of an experimental programme to evaluate the thermal performance of ETICS, introduced by Daniotti & Paolini [2008]. The specimen being evaluated has a vinyl resin-based base coat and an acrylic resin-based finish coat. Performances have been surveyed on the non-aged specimens and every ageing macrocycle (i.e. 5 x (25 UV cycles + 10 winter cycles + 25 summer cycles) with non-destructive tests: i.e., photos of the evolution in surface degradation, capillary absorption tests and cycles suited for assessing hygrothermal performances (dynamic thermal response, thermal inertia, thermal resistance and dynamic response to variation in moisture content of base and finish coat). In this paper the tests methods are described and initial results analysed following two ageing macrocycles used to discern the process of degradation in the specimen, in terms of monitoring changes in capillary water absorption and thermal resistance. The long-term aim of this study is to search for a relationship between single performances and properties in order to develop a method to evaluate the Serviceability Limit State of building components.

2 PERFORMANCE LOSS IN THERMAL RESISTANCE

2.1 Preliminary Analysis of System Performance

As an initial step, the thermal performance of the building component being studied was evaluated in accordance with different reference standards, namely: EN 12524 for specimen type A.1; steady state properties calculated according to EN 6946; and, dynamic properties calculated according to EN 13786. These values are provided in Table 1.

2.2 Test Description

Before being exposed to ageing cycles and after every ageing macrocycle, the thermal insulation performance was evaluated with a steady state test (referred to as CON, i.e. thermal conductance measurement). Data provided in this paper relate to: (i) initial conditions determined according to EN 12524, (ii) non-aged specimens (ageing time, T0), (iii) aged specimens, following two macrocycles (i.e. ageing time T1, T2 and T2+); and, (iv) data (ageing time T2+) concerns loss in thermal performance after a rain cycle (last part of RHst cycle), while the other measuring cycles have been performed after three cycles suited for evaluating thermal dynamic properties in summer conditions (SINa, SINb and TI cycles). This was to ensure that the loss in thermal performance was not influenced by an excessive amount of water gained during the ageing cycles that included rain.

The CON measurement cycle consisted of exposure of the specimen for 96 hours to the following conditions:

Climatic chamber	T [°C] = – 20 constant; RH [%] = 0 constant
Laboratory	ΔT_{MAX} [°C] = 2; RH [%] = 40 ÷ 60 [acceptance intervals during test]
Recording	180 [s] between readings

Laboratory conditions are not fixed, however tests are considered valid because:
- temperature and relative humidity oscillations are not large;
- tests having high T [°C] or RH [%] oscillations (beyond acceptance intervals) were rejected;
- dynamic calculation to filter the contribution due to small oscillations in environmental conditions was adopted.

In order to observe the loss in thermal insulation, only the conductive portion of the thermal resistance of the wall assembly was determined (total values – thermal transmittance and total thermal resistance – are reported only with the aim towards completeness and for comparison purposes), because of the fact that surface heat transfer coefficients:
- are different in laboratory and outdoor and are different for a one square meter specimen;
- show great variations due to different conditions during the same test and different tests and are strongly influenced by radiative boundary conditions;
- are not obviously influenced by degradation.

The calculation of conductive thermal resistance of the substrate, of the ETICS and of the entire specimen has been performed according to ISO 9869, using the average and storage effect methods. The data that was analyzed was that of the main section profile, whereas the loss in thermal performance coincidence with thermal bridges located at joints between insulation panels and bed mortar joints were evaluated with IR thermography that permitted assessing the changes in thermal gradient across the face of the specimens.

An analysis using the average method (av in figures) provides a value of thermal resistance assessed over a period of 24 hours, when steady state thermal conditions are reached and as well, conditions specified in the standard are met. On the other hand, using the storage effect method, a correction to the mean heat flow rate was introduced that takes into account dynamic effects (using a resistance-capacity method). In this study, the correction to heat flow due to storage effects was performed by considering both the thermal capacity of the dry layer and the total thermal capacity of the layer, including the contribution of water present in the pores. EPS has been divided into six layers of 1 cm (referring to the outer section as EPS 6) and the thermal resistance of each layer and respective water contents were obtained from a numerical solution starting from an estimate of the moisture distribution and thermal gradient in the building component from the interior side of the assembly. It is important to highlight that the aim of this test was not to obtain a deterministic measurement of the physical properties of the specimen, but to evaluate the loss in thermal performance.

2.3 Discussion of İnitial Results of Loss in Performance of Thermal İnsulation

The initial results are useful to highlight the difference between the values for thermal resistance calculated with the standard reference and those measured that show an evident loss in insulation performance. At the same ageing conditions, and after a rain cycle, a significant loss in thermal resistance was observed.

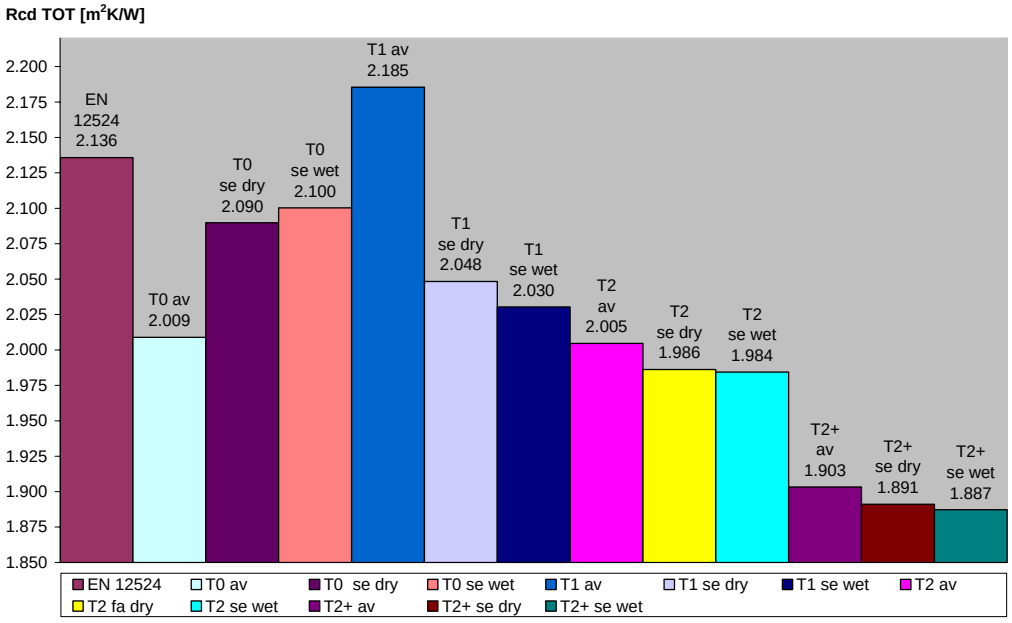

Figure 1. Loss in total conductive thermal resistance.

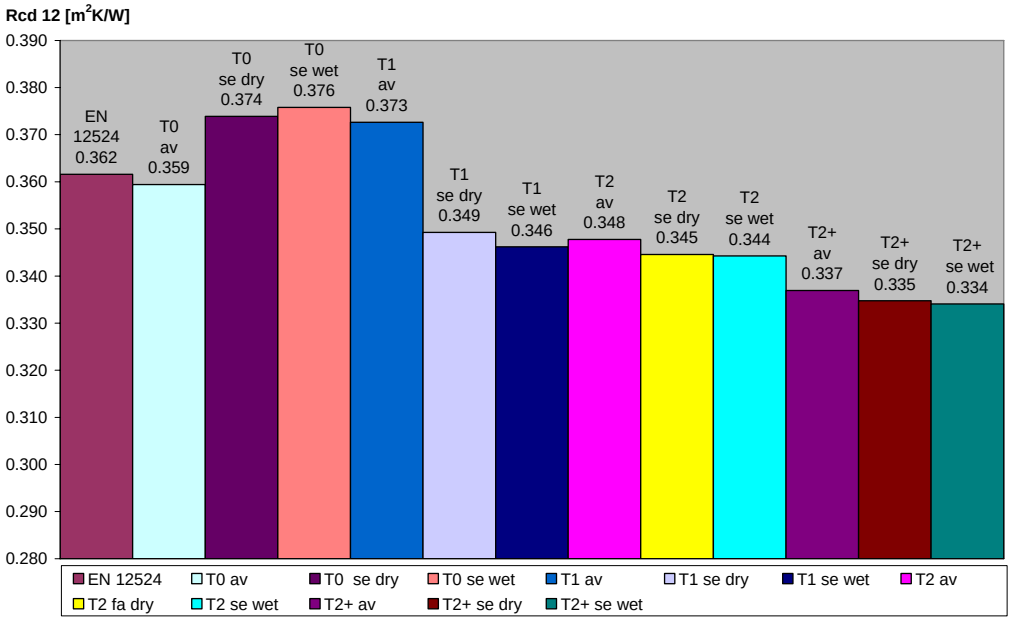

Figure 2. Loss in thermal resistance of masonry wall and plaster substrate.

In Figure 2 a limited reduction in thermal resistance of the substrate is noticed, that is due to an increase in moisture content; this increase in moisture was brought about by water that permeated the ETICS. It is estimated that construction water would be taken up prior to initiating tests (6 months later than fabrication of the substrate). On the other hand (see Figure 3), the thermal resistance of the ETICS suffers a pronounced loss, that could be explained by the increase in moisture content in the

outer layers of the EPS where water is in the solid phase at most exterior portion of EPS, and in a physical transition phase in the middle section of the EPS. Even if the thermal resistance of the base and finish coat are set to zero, the loss in thermal could not be reached.

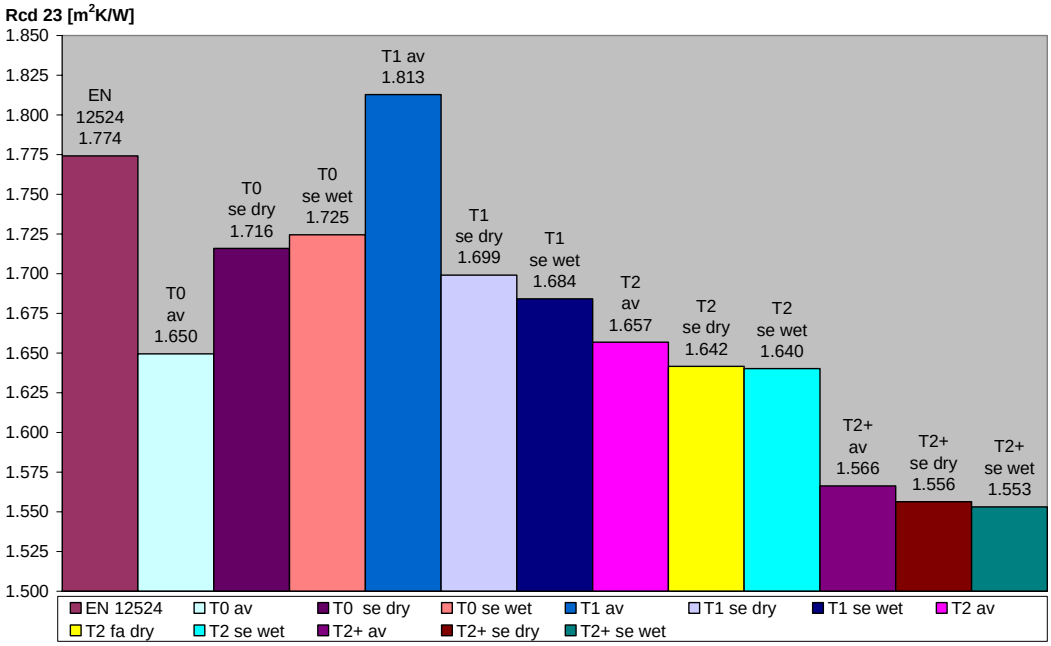

Figure 3. Loss in thermal resistance of ETICS (EPS, base and finishing coat).

Table 2. Values from standard and values measured at T0 and after two ageing macro-cycles.

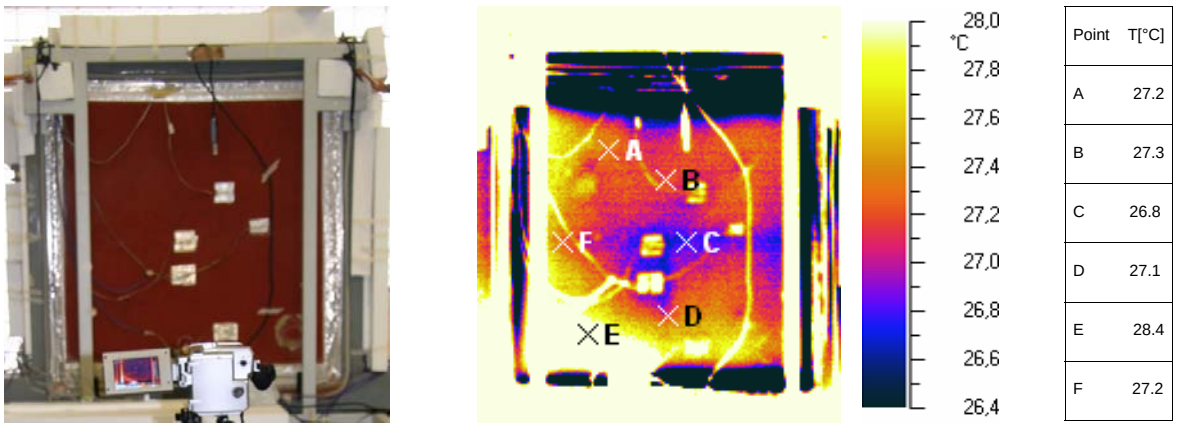
Performing a test with ice water or water in a transition phase does not introduce a useless complication in the analysis of data, but allows determining a more evident loss in thermal performance. Without the use of ice presence, it would be difficult to separate the loss in thermal resistance from measurement errors and other experimental uncertainties.

2.4 Infrared Thermography

The development of a thermal bridge coincidence with joints between insulation panels, in particular horizontal joints, is noticed from analysing the data provided by the infrared thermography performed at ageing time T2+. At the vertical joints the accumulation of water tends to spread at the base of the joint and not remain close to the joint line.



Point	T[°C]
A	27.2
B	27.3
C	26.8
D	27.1
E	28.4
F	27.2

Figure 4. Infrared thermography at ageing time T2+; Laboratory air temperature $T_{A.LAB}$ = 29.0 °C. Surface emissivity ε = 0.92. IR-camera distance from specimen: 4 [m].

3 CAPILLARY WATER ABSORPTION

In order to survey the water absorption evolution at different ageing times, the test on the same specimen was repeated a specified times using Karsten's method that is given in NORMaL 44-93. This method is a non-destructive test for water absorption using low water pressure. During the test, the volume of water [mL] absorbed by the exterior surface of the complete specimen was recorded at different times. The degree of water absorption [L/m^2] is expressed as a function of the square root of time [s$^{1/2}$].

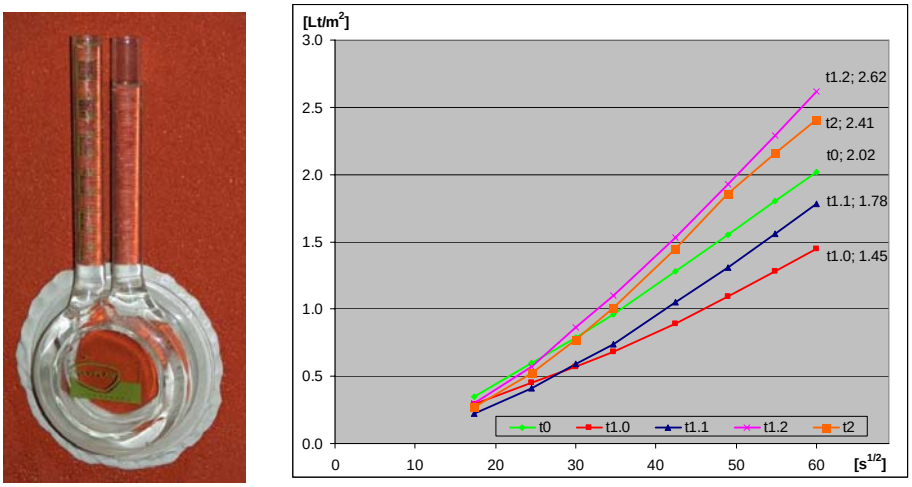


Figure 5. Measurement apparatus and initial results showing water absorption as a function of absorption time.

At ageing time T1.0 a relevant loss in absorption was noticed, that could have two possible causes: water saturation conditions and increase in cross-linking of polymeric binder of finish coat and curing of cement matrix of base coat. At ageing times T1.2 and T2 an increase in water absorption was measured. It is important to stress that this kind of test is useful because it is non-destructive; however, a significant standard deviation of results is obtained in this test. As such, it would require validation with other tests, in particular, tests such as the capillary absorption test, which is a disruptive test.

4 PHOTO-SURVEY OF SURFACE DEGRADATION

A photographic survey of the degradation of the surfaces of ETICS has shown that the most significant evolution in degradation at ageing time T1 is evident by the development of blisters on the surface of the finishing coat. As well, at all ageing times it has been observed that there is an increase in the dimension of pores of the finish coat.

Figure 6. (Left side) Photograph of ETICS finish coat at ageing time T1; blisters (larger ones: 10 cm diameter circa) are evident on the surface of the sample; (Right-side) dimension of pores and surface appearance are changed (aggregate dimension 0/1 mm); Localized fading due to rain-wash is shown.

5 CONCLUSIONS

5.1 Initial Results

Following on the analysis that was implemented and initial hypothesis for causes of degradation , decay in thermal performance is mainly due to an increase in water content of the EPS; hence an apparent rise in thermal conductivity of the EPS layer is evident. A first hypothesis for the evolution of ageing could be the following:

- UV cycles: UV degradation (i.e. progressive chain scission), of the polymeric binder of the finishing coat brings about an increase in cracking of capillary size and likewise an increase in the depth of penetration of UV rays;
- Winter cycles: the base coat and finishing coat are both subject to tensile forces that result in increases in the width of capillary cracks that in turn during rain events allow water penetration; such penetration also causes rain-wash. As well, wet rendering, having a reduced tensile strength, is susceptible to freeze-thaw cycling; this deteriorative effect contributes to the degradation of the cementitious matrix;
- Summer thermal shock cycles: base coat and finish coat are subjected to compression and adhesion stresses resulting in deformation of the finish coat that can lead to the formation of voids between layers that potentially can fill with moisture and cause blistering as water vapour intrudes the voids during a heating phase.

The cycle of degradation can be summarized as:

- Increase in capillary crack width; followed by,
- Water absorption; thereafter,
- Reduction in tensile strength; from which ensues,
- Reduction in thermal resistance; thereby bringing about an,

- Additional increase in capillary crack width
- Continued cycling of the degradation phenomena

5.2 Future Development of Research Programme

Future activities of this research programme that focuses on ETICS will be the evaluation of dynamic tests, performing destructive tests and exposure of specimens to exterior conditions to establish re-scaling factors useful for relating results derived from accelerated and long-term exposure tests. On the other hand the Performance Limit Method developed by the BEST will be used to experimentally assess ETICS such that the basic functional properties of ETICS and their respective performances can be linked to one another. This will permit moving towards an initial draft of a generic Serviceability Limit State Method suitable for assessing building components.

A Multi-Performance Approach for Service Life Prediction

Aurélie Talon [1]
Daniel Boissier [2]
Julien Hans [3]

T 42

ABSTRACT

The service life is defined in the ISO 15686 standard as "the period of time after installation during which a building or its parts meets or exceeds the performance requirements" and a performance requirement is "the minimum acceptable level of a critical property (property of a building or a building part that has an acceptable value if its required function is to be fulfilled)".
In this context, a methodology to evaluate the service life of building components is proposed. It is based on the knowledge of evolution of their multi-performance profiles (representation of performance levels of their required functions and combinations of their required functions).

The methodology compounds four parts: (1) a qualitative analysis that reviews in an exhaustive way the possible degradation scenarios of a building component, (2) a quantitative analysis applied temporally that evaluates the service life and the probability of occurrence of the scenarios, based on unification and aggregation approaches, (3) a quantitative analysis of criticality that orders by degree of criticality the scenarios, this phase allowing to reduce the application of the fourth phase to the most critical scenarios, (4) a quantitative analysis of performance that permits to obtain multi-performance profiles of the building component based on the knowledge of the relation between degradation states of phenomena and performance levels of required functions.

This communication will focus on the fourth part of this methodology and will be applied to the case of a brick wall covered by an isolation complex.

1 INTRODUCTION

The continuous maintenance of acceptable performance levels of buildings and their components represents primary economical, political and sociological importance. Maintaining performance at an acceptable level requires an on-going evaluation throughout the service life; this corresponds to the global approach of "Performance-based building" as conveyed by the PeBBu network since 2001 [Lee & Barrett 2003] where "the basis of all building activities may be the building performance in service rather than the prescription of the manner that the building will be built".

Several methods and methodologies can aid evaluating the performance of materials, building components and buildings. At the material level, developed methods aim to define the performance criteria that *a priori* seem to best characterize the behaviour of the studied material; then these criteria are measured via experimentation in order to propose models of ageing mechanisms. The formalisation of this method is presented by Jernberg *et al.* [2004]. At the building component level, two typical approaches are identified. The first approach consists of testing the building component's ability to mechanically, physically and chemically resist predefined actions during a given period. This is the approach taken for building component certification. The testing protocols are standardized, such as the NF EN 1365-1 standard [AFN, 00] that specifies the fire resistance of load bearing walls. The second approach consists of evaluating the performance level of the critical function overtime, that is to say the function that is first to reach its threshold, such as the Performance Limits Method proposed by the BEST of the Polytechnic of Milan [Iacono 2005]. At the building level, the performance assessment regards the capacity of ensuring the six essential requirements as defined by the Construction Products Directive (1. mechanical resistance and stability, 2. fire safety, 3. hygiene, health and the environment, 4. safety in use, 5. noise protection, 6. energy efficiency and heat retention). This approach essentially aims to study on the one part the structural resistance under exceptional actions or accidental actions, such as fires, earthquakes, explosions, etc. and on the other part the capacity of buildings to ensure a defined level of comfort, such as acoustical comfort, thermal comfort, etc. The research in this domain consist of developing models, generally numerical ones, that aim to be as representative as possible of reality, bringing the building design to be as compliant as possible with master-building and users expectations, such as the method of ventilation control of buildings proposed by Jreijiry et al. [2004].

Existing methods and methodologies of performance assessment, at the material level, at the building component level and at the building level, have the same limitation: they try to study one or several performance criteria relevant to the same concern as, for example, the resistance to exceptional actions or accidental action, thermal comfort, etc.

In this context, we propose a methodology applicable to all building components and that, at each moment of the service life, provides a global vision of all the performance criteria relevant to the users expectations with regard to the building components.

The proposed methodology is presented in Section 2. Section 3 provides a detailled description of the fourth phase of this methodology: the quantitative analysis of performance that enables an examination of the degradation phenomena upon the functional performance levels, to obtain the multi-performance profile of all building components in service, that is to say the representation at a given date of all the performance levels of the functions and the function combinations of the considered building component. Section 4 provides an illustrative application of the methodology, more precisely of phase four; the case study being a brick wall covered by an insulation compound.

2 GLOBAL METHODOLOGY

The proposed assessment methodology of the multi-performance profile of all in-service building components is comprised of four phases as schematised in Fig. 1.

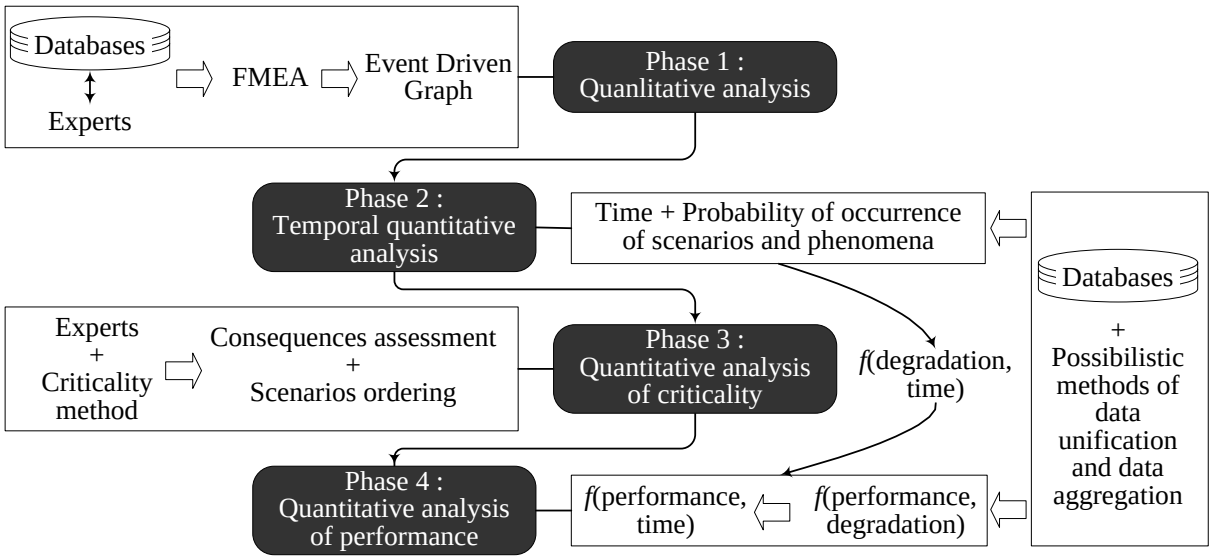

Figure 1. Assessment of the multi-performance profile of all in-service building components.

In the first phase, the qualitative analysis allows for the identification of all degradation scenarios (chains of degradation phenomena) that may damage the building component during its service life, potentially affecting its performance level. For each phenomenon involved in the scenarios, we identify: (1) the causes of this phenomenon, that may be climatic or usage conditions (rain, wind, temperature, impact, etc.) human mistakes (design error) or material incompatibilities (e.g. premature ageing of the silicone in contact with silver oxide), (2) the consequences of this phenomenon, (3) the elements of the building component that may be damaged by this phenomenon and, (4) the functions that may be affected by this phenomenon. This qualitative analysis is based on a structural analysis, a functional analysis and a failure mode and effects analysis (FMEA); these analyses are detailled and illustrated in a case study of a solar panel by Talon *et al.* [2004].

The second phase, the temporal quantitative analysis, consists of assessing the duration and occurrence probability of all identified degradation scenarios (from phase one) as well as the duration and occurrence probabilities for all the phenomena involved in these scenarios. This analysis is based on the use of all available multi-source data (expert opinion, diagnosis, probabilities, statistics, and experimentations).

In the third phase, the quantitative analysis of criticality, the aim is to assess the consequences of the degradation scenarios on the basis of three criteria: (1) the duration, (2) the occurrence probability and (3) the gravity of these consequences on the performance of the studied building component. The aggregation of these three criteria provides a means to order all the identified degradation scenarios by criticality importance in order to select only the most critical scenario, those having a significant impact on the studied building component.

Phase four, the quantitative analysis of performance, consists of assessing, for each triplet {function, phenomenon, element}, the relations between degradation states and performance levels; when combining the formula that link degradation states to time (defined in phase two) the evolution of performance levels overtime can be obtained. On the basis of these results and taking into account all

the phenomena, the functions and the elements at stake, the multi-performance profile of the considered building component can be obtained for any point in its service life.

These four phases of analysis are based upon: developed databases (database of environmental agents, database of functions, database of phenomena [Talon *et al.* 2003]); methods of data treatment based on theory of possibility (data quality assessment [Talon *et al.* 2007] based on NUSAP method [Funtowicz and Ravetz, 1990], data unification and data aggregation [Talon 2006] based on the data fusion method [Shafer 1976], [Lair 2000]); and, representation tools, such as the temporal event driven graph that schematises the most critical degradation scenarios, their common phenomena and their causes; an example of a temporal event driven graph is provided in Section 4.

3 PHASE OF PERFORMANCE ASSESSMENT

The objective of the quantitative analysis of performance (phase 4) is to obtain, at a fixed date during the service life of the building component, the performance levels associated to each of its functions and combinations of functions. This analysis is comprised of four sub-phases: (1) obtaining the mathematical function of performance level μ_i^k of a function F_k (e.g. mechanical resistance, transparency, etc.) associated with the phenomenon Ph_i (e.g. cracking, corrosion, etc.); (2) determination, for each pair {F_k, fixed date}, the corresponding performance level μ^k; (3) definition of the combinations between functions; and (4) obtaining of multi-performance profile.

3.1 Obtaining the Performance Level Function μ_i^k of a Pair {F_k, Ph_i}

The objective of this sub-phase is to model the relationship between mechanical, physical and chemical degradations of an element to its loss of functional performance. The proposed method is based on both the "classical" process of the evolution of the material degradation indicator and on the use of multi-source data. The "classical" process, as explained by Jernberg *et al.* [2004], consists of: (*i*) identifying the degradation indicator to be studied, via an analysis of the environmental actions and the known degradation mechanisms of the material; (*ii*) measuring, by experimentations (accelerated ageing test and natural ageing test), the evolution of this degradation indicator overtime; and (*iii*) determining the relations between the results obtained by the two kinds of tests in order to assess the service life of the material. Our process consists of: (*i*) identifying the degradation indicators associated to all functions, (*ii*) collecting all the available data from various sources (experimental results, theoretical results, such as modelling and numerical simulations, expert opinions, etc.); (*iii*) determining the relationship between these degradation indicators and the performance level of the considered function; and (*iv*) unifying this data in order to obtain a consensual mathematical function of performance level μ_i^k and quality indicators of this result.

Experts in material durability lead the first three items of our process. The fourth item is based on a fusion method detailled by Talon [2006]; the underlying principle is that when data has been collected from different heterogeneous sources , a belief mass that is reflective of the confidence in the data may be attributed to each dataset. Then, all collected data is combined in order to obtain a consensual dataset, regrouping the maximum of consensus and that best represents the available knowledge. The significance of our approach is the capability to base new evaluations upon previous studies that are quite similar and thereby take into account all the triplets {phenomena; functions; elements}; this cannot be done within the classical approaches.

3.2 Determination for Each Pair {F_k, fixed date} the Performance Level μ^k

The first step in determining the performance level is to select all the phenomena affecting the considered function F_k by a fixed date. For example, if one considers the function F_1 in Fig. 2, the function is affected by the selected phenomenon Ph_1, Ph_2 *and* Ph_9 (in black) prior to the "fixed date". Ph_7 is not selected as it starts at t_6, later than the "fixed date". Figure 2 contains three scenarios Sc_i that are respectively compounded actions of 4, 3 and 2 phenomena represented by rectangles; the associated function and the degradation state of this phenomenon at the considered date, as an example the date t_1 for the phenomenon Ph_1 are contained in these rectangles. Next, the degradation states for all phenomena at the fixed date on the basis of the results of the temporal quantitative analysis (second phase of the methodology) are determined. Then the performance levels that correspond to the degradation states on the basis of the mathematical functions of performance levels assess during the first sub phase are deduced. As the third step, the performance level of the considered function is inferred; as being equal to the minimum of the performance levels obtained for all the selected phenomena.

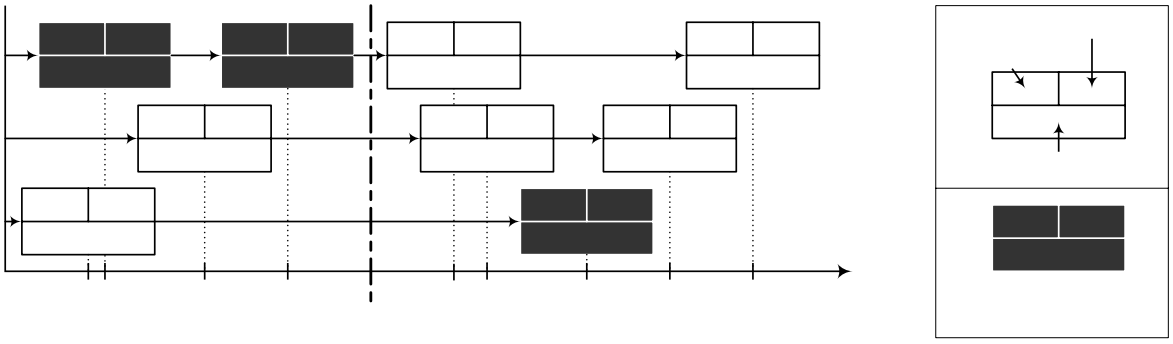

Figure 2. Illustration of the phenomena selection that affect the function F_1 at a fixed date

3.3 Definition of the Combinations of Functions

The objective here is to model the combination between all the functions in order to obtain an assessment that represents the global and realistic behaviour of the considered building component overtime. As an example, the visibility function through a double glass unit may be the combination of the transparency function and of the resistance function against environmental agents. We define the combinations between functions in order to take into account the fact that two functions independently may have an acceptable performance level but globally may lead to the failure of the building component. The functions of the relationship are identified and then that relationship is typically expressed by the following generalised formula:

$$\alpha_1 \times \mu^1 + \alpha_2 \times \mu^2 + ... + \alpha_n \times \mu^n \geq \mu_{threshold} \quad \text{and} \quad \sum_i \alpha_i = 1 \quad [1]$$

where $\mu_{threshold}$ represents a threshold performance level and the α_i represent coefficients.

3.4 Obtaining of the Multi-Performance Profile

In the proceeding steps the performance levels of the functions were considered independently. Now, we want to assess the performance level of each combination of functions; it is obtained by replacing the performance levels of the functions that were independently considered in the combination equations, such as the equation [1]. As an example, considering $\mu^1 = 0{,}6$ and $\mu^2 = 0{,}4$ at a fixed date and in a combination of F_1 and F_2 formalised by the equation $0{,}8 \times \mu^1 + 0{,}2 \times \mu^2$, the performance level of this combination at the fixed date is equal to 0.56.

We represent the performance levels of the functions and the combination of functions, at a fixed date, with radar representation, such as those in Fig. 5.

4 BRICK WALL CASE STUDY

It is to be noticed that the numerical data collected and used in order to perform this application has an heterogeneous reliability. In consequence, the numerical results presented here have only an illustrative value.

The structure of the studied brick wall is presented in Fig. 3 and the materials of the elements of this wall are included in the Table 1. This brick wall fulfils five functions: (1) F_1 – to stop the flow of environmental agents, (2) F_2 – to absorb the infrared radiation, the temperatures and the noises, (3) F_3 – to mechanically resist, (4) F_4 –to resist damaged by the contact of environmental agents, (5) F_5 – to be in accordance with the standards and requirements.

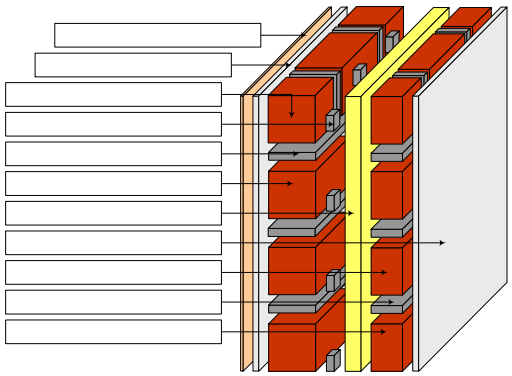

Figure 3. Schematisation of the brick wall structure

Table 1. Materials of the brick wall

N°	Material
1	Acrylic paint
2	Lime, cement, sand
3a-b	Terracotta
4	Mortar
5	Cement, sand, epoxy resin
6	Glass wool
7a-b	Terracotta
8	Mortar
9	Lime, cement, sand

The results of the qualitative analysis and of the temporal quantitative analysis of this wall are presented on the temporal Event Driven Graph of the Fig. 4. The names of the phenomena from Fig. 4 are regrouped in the Table 2 and the legend of each block is as defined in Fig. 2.

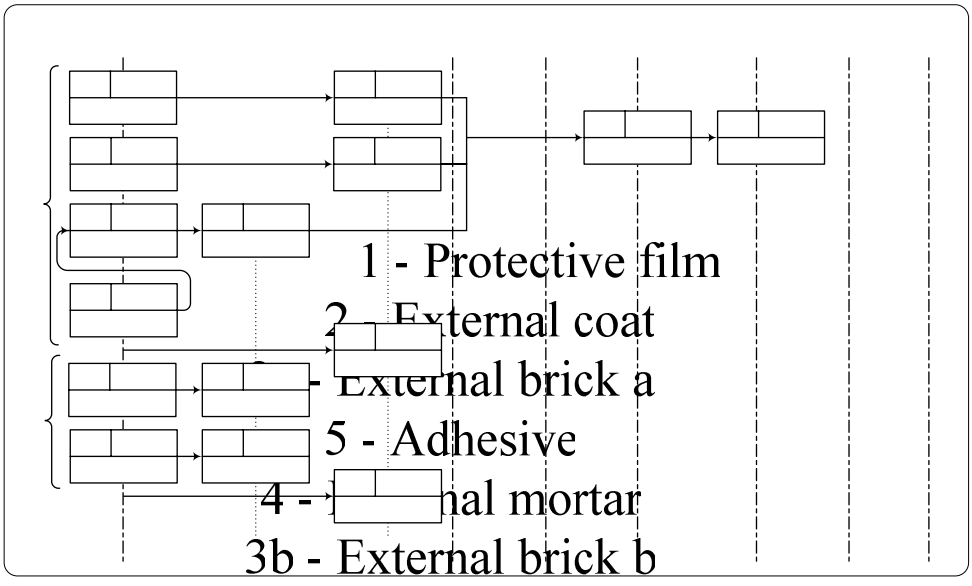

Figure 4. Temporal Event Driven Graph of the brick wall

Table 2. Names of the phenomena of the Fig. 4

N°	Phenomena
Ph_1	Uniform leaching of protective film
Ph_2	Erosion and chalking of protective film
Ph_3	Insufficient resistance of external brick a
Ph_4	Insufficient resistance of external brick b
Ph_5	Drying of external coat
Ph_6	Cracking of external brick a
Ph_7	Cracking of external brick a
Ph_8	Cracking of external coat
Ph_9	Cracking of protective film

N°	Phenomena
Ph_{10}	Unsticking of adhesive
Ph_{11}	Settling of insulation
Ph_{12}	Leaching of external coat
Ph_{13}	Alkali-reaction of external mortar
Ph_{14}	Non planarity of external layer
Ph_{15}	Non planarity of internal layer
Ph_{16}	Breakdown of external layer
Ph_{17}	Breakdown of internal layer

The multi-performance profiles of the brick wall obtained by conducting the quantitative analysis of performances at different points during the service life are presented in Fig. 5.

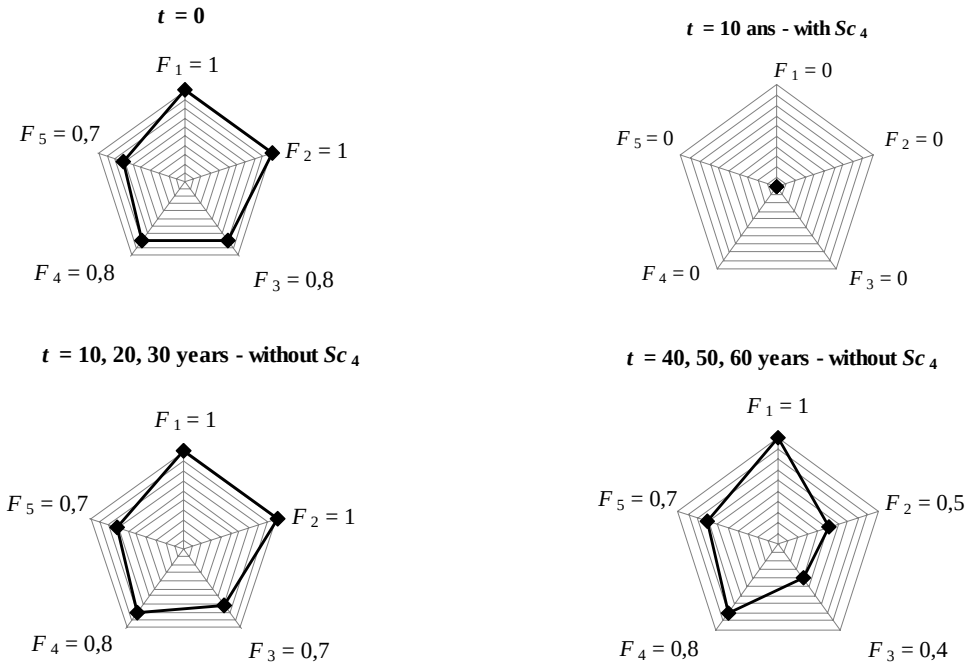

Figure 5. Multi-performance profiles of the brick wall at different moments of its service life

By considering the Sc_4 scenario of breakdown of the brick layers (external bricks with external mortar and internal bricks with internal mortar), a complete failure is obtained before 10 years, that is to say for all the functions of this wall.

This breakdown scenario can begin and end in the observation period of the study if the support of brick layers is significantly out-of-plane while the wall is subjected to a very strong impact. If this phenomenon and cause are not considered to occur, the multi-performance profiles obtained at different dates of the service life of this brick wall are the ones in Fig. 5 named "without Sc_4".

By formulating this hypothesis, one can note that the kinetics of the functions "F_2 – to absorb" and "F_3 – to mechanically resist" increase significantly between 30 and 40 years and that this is due to the complete achievement of the phenomena "Ph_{10} – unsticking of adhesive" and "Ph_{11} – Settling of insulation"; these phenomena may lead to an horizontal mechanical action on the bottoms of the brick layers that may result in crushing.

5 CONCLUSION

We present a methodology of assessment of the multi-performance profiles of all building components at a moment of their service life. This methodology is based on: (1) the identification of the degradation scenarios that affect the considered building component, (2) the quantification of the duration and the occurrence probability of these scenarios and the compound phenomena, (3) the quantification of the consequences of these scenarios and their ordering by criticality importance and, (4) the determination of the relation between degradation states and performance levels of the functions and the combinations of functions of the building component considered for obtaining its multi-performance profile. The main advantages of this methodology are: (1) to take into account all the degradation phenomena and all the functions at stake in the performance assessment, (2) to consider all the available and multi-source duration data, occurrence probability data and performance data, (3) to take into account all the interactions between elements that have a major influence on the performance assessment. The application of this methodology on the case study of a brick wall covered by an insulation compound has proved it is operational. The essential perspectives of this research work are: (1) to apply this methodology to other case studies in order to pursuit the implementation of the phenomena database with duration data, occurrence probability data and performance data in order to develop a knowledge base that allows the characterization of all building components in all environment types and, (2) to conduct a sensitivity analysis of the proposed methodology.

ABSTRACT

Pitting corrosion of the steel bars is a process that strongly jeopardizes the durability of reinforced concrete structures exposed to chlorides. This is a problem widely studied in order to evaluate structural lifetime. Nevertheless, the proper treatment of the noteworthy sources of uncertainty, that affect the numerical values of geometrical and mechanical structural parameters, is still an open question. Such properties, in fact, cannot be considered as deterministic quantities. In many real problems, very few uncertain data are available and new non-probabilistic procedures need to be defined to perform lifetime estimation. In the present study, parameters are modelled using fuzzy set theory and a time-dependent fuzzy safety factor is defined in order to indicate how the critical chloride front is distant from the bars. Moreover, the study provides a more proper mathematical analysis of chloride penetration into concrete and an improved calibrating procedure to estimate sampling model parameters, also accounting of time variability. The analysis confirms that the application of oversimplified Fick's solutions leads to substantial conceptual errors in service lifetime estimation.

1 INTRODUCTION

Economic consequences due to deterioration of reinforced concrete (RC) structural elements are one of the most pressing problems, especially in industrialized nations where maintenance and reparation of these types of constructions are an impelling necessitate. In most cases, it has been established that reinforcement corrosion is the foremost cause of deterioration [Apostolopoulos and Koutsoukos., 2007]. The corrosion process of reinforcing bars is a well known phenomenon as it is also known that the consequences of a pitting corrosion process on structural safety are more serious than that due to general corrosion. For this reason, lifetime estimation of RC subject to chloride exposure deserves particular design attention. The main difficulties that researchers face in the investigation of these problems are due to the noteworthy lack of precise information. For this reason, the service life design methodology should take into account uncertainties. In last years, probabilistic approaches have been used with the aim of conducting a time-dependent analysis of RC structures subject to corrosion under conditions of uncertainty, but it should be observed that not all the uncertainty variables can be treated following this approach. Probabilistic description is not the most adequate way to describe uncertainty for a great part of realistic conditions and sometimes its use may be inadequate for some real problems. This is particularly true when only few data about one or more models and structural parameters are available or when investigating mechanical and geometrical system properties, as well as load conditions, are economically inconvenient or practically impossible. This happens, for example, in historical constructions. In the field of non-probabilistic approaches, different methodologies have been proposed: particularly, the approach based on the concept of fuzzy sets [Zadeh 1965] also for estimating service life of RC structures [Anoop *et al.*, 2002], seems appropriate because it is able to take in account the so-called lexical and informal uncertainties that affect both data and models. In this paper, a fuzzy service lifetime estimation of RC elements subject to chloride ingress is performed considering uncertainty on problem parameters that are modelled by using a fuzzy criterion. It should be noted that the concept of corrosion initiation time is done to coincide with the general service lifetime of the structure which ends when pitting corrosion process starts. Preliminary to this kind of investigation, it has been necessary to examine the state-of-the-art in order to recognize the potential typologies of uncertainties, in chlorides penetration process. The analysis of the bibliography on this theme, have confirmed the high uncertainty in model parameters definition. This substantially depends on the intrinsic variability of some parameters, on the insufficient or inadequate availability of data, but also on the high number of oversimplifications and neglected factors that during the years have been applied on chloride penetration model. Today, a great number of mathematical models have been developed and the application of each of them leads to different values of the main parameters. It is thus clear that sampling parameters are estimated with different confidence level of knowledge. In detail, some geometrical and mechanical parameters are well defined as deterministic or at least probabilistic, because a wide number of experimental data can be available. Other parameters instead are not well defined and therefore affected by different level of uncertainty, because for example few experimental data are available or because the assumed physical model is empirically extrapolated or is oversimplified and therefore less representative of the real process. For these reasons, all the parameters are treated under non-probabilistic assumptions. In this case, the fuzzy approach represents a more suited theory to perform other kind of analysis, properly taking into account of uncertainties. Therefore, another important preliminary point of investigation of the present work, concerns the chosen of the best deterministic sampling parameters by using a more proper calibrating procedure and then use these variable for the fuzzy treatment. With this aim, a more accurate solution of Fick's law have to incorporate the time-dependence of the diffusion coefficient and some researchers have also integrated the diffusion law taking into account time-dependent surface concentration [Mejlbro, 1996]. Two of these improved models [Mangat and Molloy, 1994; Mejlbro, 1996] have been chosen by the authors to be tested with experimental data by mean of a genetic algorithm (GA), in order to obtain the deterministic calibration parameters of model. In the second section of the paper, some of these variables are modelled as fuzzy ones and finally, time-dependent fuzzy safety factor is obtained in order to assess the service life of RC elements in terms of

the critical chloride front closeness to the bars during the time. This tool may be useful in order to support the decision maker (DM) in the planning of the maintenance interventions.

2 CHLORIDE PENETRATION MODELS

2.1 Conventional Model

A simplified model for the chloride penetration procedure is based on the assumption that the chlorides diffusion process can be modelled by means of the Fick's second law, as firstly realised by Collepardi *et al.* [1972]. Having only results available from short time experiments, and probably also due to mathematical difficulties, they only considered the case of constant diffusion coefficient and constant surface chloride concentration. This is a diffused supposition (i.e. it is adopted by Stewart and Rosowsky [1998]). According to this law, the chloride ion content is given by:

$$C(x,t) = C_s\left[1 - erf\left(\frac{x}{2\sqrt{D_a t}}\right)\right] \tag{1}$$

where $C(x,t)$ is the chloride content (in kg/m^3) at a distance x (in m) in a generic time instant t (in s); C_s is the surface chloride concentration (in kg/m^3); D_a is the apparent diffusion coefficient (in m^2/s). Using eq. **Hata! Başvuru kaynağı bulunamadı.**, it is possible to define the corrosion initiation time with reference to an assigned critical threshold chloride concentration on steel bars (denoted as C_{lim}). The chloride diffusion coefficient D_a is assumed a constant value even if it is time dependent. It will typically decrease as time passes since the capillary pore system will be altered as hydration products continue to form [Mangat and Molloy, 1994]. This meant that the diffusion coefficient could be written as a power function [Tang, 1996]:

$$D(t) = D_{ref}\left(\frac{t_{ref}}{t}\right)^m = K_0 t^{-m} \tag{2}$$

where D(t) is the diffusion coefficient at time t; D_{ref}, the diffusion coefficient at some reference time t_{ref} and *m* is a constant that depends on mix proportions. K_0 incorporates all constants and is defined as the effective diffusion coefficient at time t of reference. The application of equation (1) is very common in literature and also in different documents that provide guidelines for the durability design of concrete structures, as for example in documents developed by the EU DuraCrete project [1998]. The *DuraCrete Model* is an empirical model, which also has Fick's second law of diffusion as a theoretical background that has the following form:

$$C(x,t) = C_s\left[1 - erf\left(x \Big/ \left[2\sqrt{\left(k_c k_e D_{ref}\left(\frac{t_{ref}}{t}\right)^m\right)t}\right]\right)\right] \tag{3}$$

It is clear that the presence of the two multiplication factors k_c and k_e, that are two constants introduced in order to take into account the probabilistic nature of the environmental aggressiveness (k_e –environmental factor) and the material properties (k_c – curing factor), does not change the mathematical characteristic of the chloride profile. Indeed, the DuraCrete model has been developed on the simplification that the diffusion coefficient is a constant value and doesn't vary with time.

Nevertheless, in order to take into account also time-dependence effects, it has been suggested to replace the constant value of D_a that appears in equation (1) with the relationship (2).

2.2 Evolutionary Models With Time-Dependent Parameters

Already in the 1980's it was realised that the standard oversimplified model, on which is based equation (1), gave unrealistic rapid transport of chloride ions, especially when long term predictions are based on results from short term tests [Cairns and Law, 2003]. For the accurate prediction of chloride-diffusion in concrete, the time-dependence of diffusion rates needs to be incorporated in the analysis procedure, properly deriving the Fick's second law. This model was developed by [Mangat and Molloy, 1994], leading to the following equation:

$$C(x,t) = C_s \left[1 - erf \left(\frac{x}{2\sqrt{\frac{K_0}{1-m} t^{1-m}}} \right) \right] \tag{4}$$

Other solutions of Fick's second law exist with varying surface concentration. Some researchers observed that the chloride concentration of the exposed concrete surface of a marine structure was time-dependent. Mejlbro [1996] proposes that the chloride penetration model ought to be described by the following function:

$$C(x,t) = \left(\frac{T}{T_0} \right)^p \psi_p(z) \tag{5}$$

where T is the transformed time variable $T = \left(t - t_{ref}\right) D_a(t) \quad for\, t \geq t_{ref}$, with $D_a(t)$, that is equivalent to $D(t)$ as defined in equation (2), and T_0 is introduced in order to to make the ratio dimensionless. The exponent p depends on how fast C_s increases with time, i.e. mainly on the type of binder and the environment and the function $\psi_p(z)$, where $z = x/\sqrt{4T}$, satisfy an ordinary differential equation of second order which can be solved by means of a series expansion.

3 ANALYSIS OF THE BEST DETERMINISTIC MODEL

Modelling the chloride ingress is an important basis for designing reinforced concrete structures and for assessing the service life of structures. Even if the present paper uses a fuzzy approach for the lifetime estimation problem, the authors firstly consider very important to overcome some conceptual limitations and also errors that may occur considering standard oversimplified models as those defined in Eq. (1) and (3) or other functions derived by using equivalent mathematical procedures and assumptions. Indeed, even if in the past years the models used in Eq. (1) and (3) have been applied in a wide number of important construction projects, some authors [Luping and Gulikers, 2007] have observed that it is necessary to evaluate the errors computed in lifetime estimation and therefore in durability design due to these mathematical oversimplifications assumed in simplified models. Several authors in fact (for example, [Maage *et al.*, 1995; Choe *et al.*, 2007]), seem to have simply substituite the constant diffusion coefficient in the error function solution to the Fick's second law by the time-dependent D, without adequate clarifying the mathematical basis of the diffusion. The mathematical mistake so committed results in a significant difference between the diffusion coefficient K_0 that appears in equation (4) and the same coefficient D_a that appears in equation (3), as demonstrated by

Luping and Gulikers [2007]. For the before described reasons and for the great variability whereby the diffusion law has been solved in literature, different values of the main model parameters have been obtained. Starting from this consideration about uncertainty in problem parameters definition, in the present paper an improving in service life assessment goes by two main steps. The first one regards the chosen of the best fit model in order to consider the most refined model to represent the physical process and deterministically determine the main parameters. At this stage, therefore, it tries to avoid some oversimplifications conceptually wrong in model definition, like the most common assumption of the time-independence of the diffusion coefficient. Nevertheless, parameters, which define the occurrence properties of variables, are non deterministic in nature and very often no information is available on their fluctuation. Therefore in the second part of the present paper, uncertainties have been introduced in the model parameters and a fuzzy modelization has been applied as useful tool to perform the lifetime assessment. Final results are obtained for a realistic example.

3.1 GA-Based Comparison Analysis Between Predicted And Measured Chloride Profiles

The model fitting analysis is based on the fundamental experimentation by Thomas and Bamforth [1999], applied to three concrete mixes: Portland cement concrete (PC), fly ash concrete (PFA) and slag concrete (GBS). Even if the proposed procedure followed by the authors used to determine the chloride profile, shows a very good correlation with the experimental data, it suffers of a significant conceptual limitation. This is due to the fact that firstly they assume the standard solution as written in equation (1), founding the values of C_s and D_a as best fit calibration parameters, by iteration. At the same time they assume the relationship (2) that describes the diffusion coefficient with time, in order to take into account time-dependence effects, not accounted in the previous used model. From this last equation, they obtain D_{28} and m values that best fit the data [Thomas and Bamforth, 1999]. Starting from this data, in order to determine the sampling parameters to adopt in the afterwards fuzzy analysis, a new genetic algorithm (GA) based procedure is applied. In the following, adopting the two time-dependence models of equations (4) and (5) and calibrating them also in function of the time variable, it tries to mathematically improve the deterministic estimation of the parameters, so that it is given a meaningful significance to their fuzzy treatment, later discussed. Once assumed these "evolutionary" models, the succeeding improvement in the estimation of the parameters consists in calibrating these one as time function. In this way, the chloride profile is no more defined in a bi-dimensional space that describes the chloride concentration with depth at a fixed time, but has to be dependent also on time. Therefore, the adjustment technique is developed in a three-dimensional depth-time space. Only in this manner, it is possible to rigorously estimate the diffusion coefficient and accounting for its changing with time. In order to simplify the notation, the model at the base of Eq. (4) will be called '*Model A*' and the profile of equation (5) will be called '*Model B*'. For each of these models, the chloride profile that best fit the experimental data is plotted. For the sake of argument, the three-dimensional profile Fig.1(a) and the contour graph Fig.1(b), in function of time and depth is reported with reference to the *Model A*, in case of Portland cement. Results show a good agreement between the model prediction and the experimental data of Thomas and Bamforth. In Tab.1 are also indicated the calibrating parameters values, for the Model A and the Model B. In order to compare these one with the other approaches, also the values of the same parameters referred to Thomas and Bamforth's model application are reported. For all mentioned reasons, the parameters successively treated as fuzzy variables are those obtained by the before described calibrating GA-based procedure, with reference to the mathematically improved model A, because as seen, more rigorously determined by an analytical and conceptual point of view.

Table 1. Main calibrating parameters of Models

Concrete Mix		C_s (%)	*Diffusion coefficient* $\left(cm^2/yr\right)$	m
PC	Model A	0.3775	K_0 = 1.864	0.2528

	Model B	0.3770	D_a = 6.988	0.3459
	Thomas and Bamforth [1999]	0.35	-	0.1
PFA	Model A	0.5259	K_0 = 0.283	0.5807
	Model B	0.3804	D_a = 5.317	0.7017
	Thomas and Bamforth [1999]	0.5	-	0.7
GBS	Model A	0.5267	K_0 = 0.076	0.9941
	Model B	0.5399	D_a = 9.999	0.8624
	Thomas and Bamforth [1999]	0.5	-	1.2

4 FUZZY ANALYSIS OF STRUCTURAL SERVICE LIFE

The following treatment of lifetime prediction is conduct on the base that fuzzy sets are applied on the model variables. These variables, due to their conjectured informal or lexical uncertainties, can be treated by means of fuzzy sets theory [Zadeh, 1965].This can be considered an acceptable assumption due to the considerable semplifications that affect the model and the large variability whereby it is defined. Moreover, it is also necessary to observe that even model parameters may suffer of variations not always capable of being assimilated to specific probabilistic distributions which are tipically obtained on the basis of other models. Indeed, very often in literature is not possible to find probabilistic univocal approachs in order to represent the variables. On the basis of all these

considerations in the following it assumes that surface chloride concentration C_S and critical chloride concentration $C_{\lim}$ are non deterministic variables. Besides, for the before explained reasons, in addition to these parameters, also the age factor *m* and diffusion coefficient k_0 are assumed uncertain. The application of the fuzzy set theory, on the just cited variables, offers the possibility to consider a gradual assessment of the membership grade of an element in relation to the defined set. This degree of membership is described by a so-called membership function (MF). The MF acquisition of every fuzzy variable is one of the problems of structural analysis based on the fuzzy set theory. This is a "knowledge acquisition" problem [Klir and Yuan, 1995]. Generally, it is possible to assert that an unitary approach does'nt exist for the so-called fuzzification, but different procedures can be adopted for each situation. These methods for constructing MF can be either direct or indirect with a single expert or multiple experts [Klir and Yuan, 1995; Klir, 1996]. This work assumes that the MF is known for each fuzzy variable. In other words, we suppose that a knowledge acquisition procedure has been performed preliminary. Standard probabilistic approaches of reliability cannot be used in the presence of fuzziness and so different fuzzy reliability measures have been proposed, for instance by Shrestha and Duckstein [1998], Elishakoff and Ferracuti [2006(a), 2006(b)]. Finally, it is possible to define the central time-dependent fuzzy safety factor as follows [2006(a)]:

$$\beta(t) = \frac{C_{\tilde{c}}(t)}{C_{\tilde{f}}(t)} \tag{6}$$

where $C_{(\square)}(t)$ denotes the abscissa of the center of gravity of the MF (centroide). $\tilde{c}$ and $\tilde{f}$ respectively denote the fuzzy cover and the position of the chloride critical front.

4.1 Numerical Application

The central time-dependent fuzzy safety factor in (6) can be assumed as a valid tool to support the DM in planning maintenance works. Geometrical, mechanical and environmental data are reported in Table 2. In order to show the effectiveness of the proposed procedure, the fuzzy lifetime analysis of a RC column with section 0.3x0.3 m of PFA concrete mix, subject chloride ingress at one side, is performed considering uncertainties. In order for it to assume an unique value, the abscissa of the center of gravity of its MF has been considered.

Table 2. Parameters adopted in the numerical applications

Parameter	*Type of uncertainty*	*Values*
k_0	Fuzzy	$\langle 15,\ 25,\ 35 \rangle$
m	Fuzzy	$\langle 0.45,\ 0.50,\ 0.65 \rangle$
C_S	Fuzzy	$\langle 0.40,\ 0.45,\ 0.65 \rangle$
$C_{\lim}$	Fuzzy	$\langle 0.15,\ 0.20,\ 0.25 \rangle$
cover	Fuzzy	$\langle 15,\ 25,\ 30 \rangle$

In Fig. 2 is plotted the fuzzy safety factor as before defined. In the upper right corner of the figure, the MF (adopted of triangular shape) for the chloride critical front distance from side d_{cr} in five different years is reported with a continuous line. The corresponding safety factors and years are indicated in the principle diagram with the same symbols. The MF of the cover is also indicated with a dashed line for the purpose of comparison. For the same years the fuzzy critical front trend with time is plotted in Fig. 3 (in gray graduation from blank, for null degree of membership, to black, for unitary degree of

membership). The red indicator in figure the shows the centroide of the MF of cover. From the analysis of Figure 2 it is possible to observe that the safety factor reaches a unitary value after about 55 years. First of all, it is possible to observe that, in time, the support of the MF tends to increase. The analysis have been extended beyond the limit state (β <1), in order to prove that the centroide of the critical front MF changes position, during the course of time, depending on the low or high values of the fuzzy safety factor in comparison with the core. The centroide is positioned to the right, with respect to the core, in the safety region ($\beta \geq 1$). This is clearly shown with the circle and the upward-pointing triangle. This trend is not particularly visible in the safety region but becomes more appreciable in the unsafety one. This observation leads to conclude that the uncertainties are such that the deterministic analysis fournishes a more advanced fuzzy position of the chloride critical concentration front (the deterministic value is assumed in correspondance of the MF core), tending to overderestimate the critical front distance d_{cr} from the side, in comparison to a fuzzy approach, therefore it provides a conservative value of the lifetime estimation. Besides, this specific example shows that the effects of uncertainty, over a given time, tend to become more stable, as can be deduced by the approaching of the MF cores with time increasing and also by the stabilization of the centride-core distance.

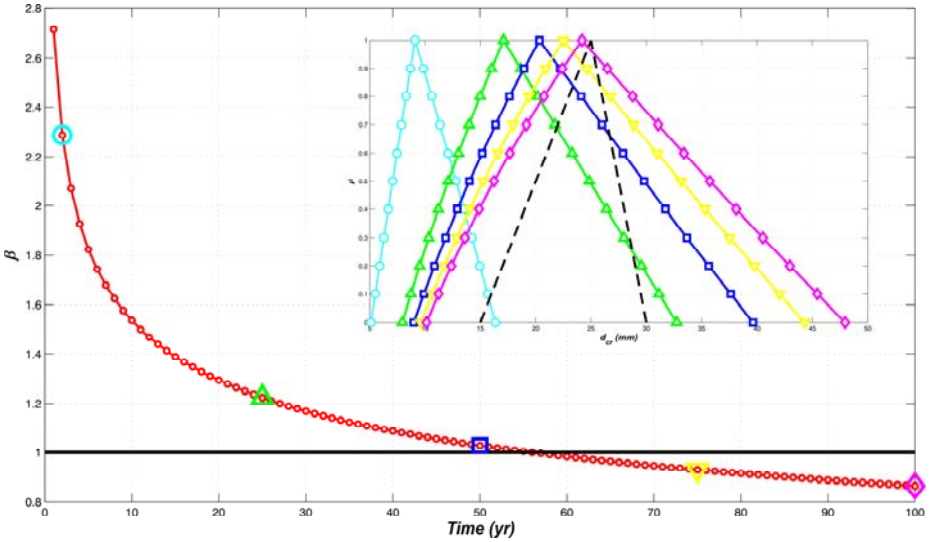

Figure 2. Illustrative example for PFA mix concrete

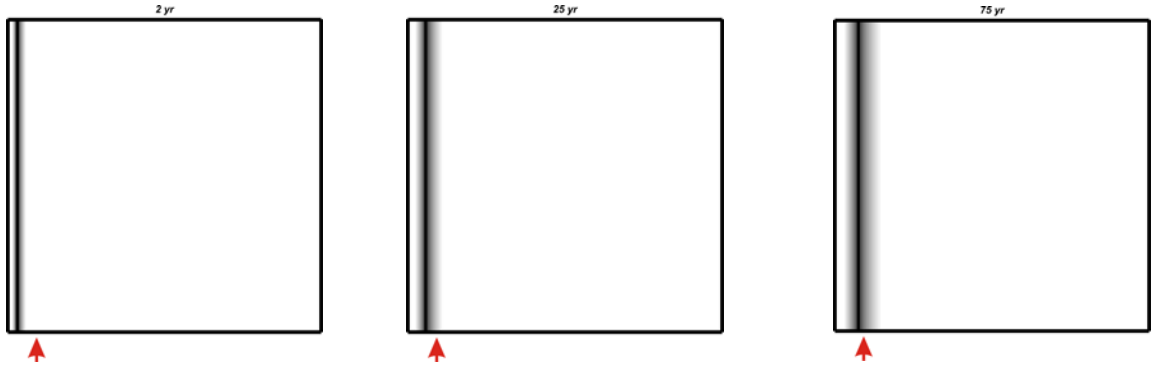

Figure 3. Trend of the chloride critical front at 5 (a), 25 (b) and 75 (c) years.

5 CONCLUSIONS

Service life of RC structural elements subject to chloride ingress has been estimated considering uncertainties in problem parameters. The analysis of the state-of-the-art conditions has shown that geometrical, mechanical and environmental parameters cannot be taken into account neglecting the different sources of uncertainty. Therefore, traditional probabilistic approaches cannot be performed.

This work develops a general procedure in which firstly the most refined deterministic models are selected and then, a calibration procedure GA algorithm-based is used in order to estimate the main parameters that are successively assumed as uncertain and treated as fuzzy variables. The fuzzy safety factor is obtained considering fuzzy variables for both the chloride front and the cover. A numerical example shows the effectiveness of the approach as useful tool to support the DM in economic analysis and planning of interventions, showing that the simple deterministic analysis, not properly accounting of intrinsic uncertainty of model parameters, cannot gather important aspects of lifetime prediction.The present approach is a very robust methodology, because it allows to overcome the notable difficulties that designers may face in real circumstances when non-statistical information, technical judgments and points-of-view have to be considered.

AKNOWLEDGMENT

The authors wish to express their gratitude to ***Prof. Lorenzo Liberti*** for his cultural and economical support to the development of the present work. The authors also wish to thank **Regione Puglia's** Funds, in the field of Progetto Esplorativo PE_017; research project "Valorizzazione di residui del processo di cottura del clinker per la produzione di cementi di miscela" (Det.Dir. Sett. progr. Politiche Com. Regione Puglia 23/0/06 n.13) for their economical support.

Timber Structures Service Life Modelling

Jan-Willem van de Kuilen[1,2]
Nadine Edi Montaruli[1]

T 42

ABSTRACT

Timber has been used throughout the world in structural application from pile foundations to roof structures. As an example, old dutch cities are founded on wooden piles of up to 22 meters long, wheras roof spans in ancient Italian structures may reach more than 20 metres. These structures are slowly decaying, mainly caused by mechanical, physical and biological loads. Different inspection techniques are used to estimate the remaining sound cross sections, to classify the wood quality and to determine the activity level of the (biological) decay. Infrared spectroscopy is used to determine different types of biological decay (brown rot, soft rot, white rot) and in conjunction with the decay, the expected amount strength loss. Very often, questions arise about the remaining service life of such structures. In the paper an overview is given on different degradation mechanisms and the assesment procedure. Then, using an exponential damage accumulation model that takes into account influences of biological degradation, crack formation and mechanical stresses, estimations are given on the remaining service life in relation to current required safety levels. The exponential damage model was verified on long term strength tests for sawn timber and timber connections at diiferent load levels and climates. In the paper, special attention is given to large cracks that are often found in ancient floor and roof beams. Practical examples from existing building structures and hydraulic works will be given both with cracks and with biological decay.

1 INTRODUCTION

Timber as a structural material may be found in many buildings and structures around Europe, with a current age of sometimes more than 500 years. Already in the Roman era the foundations were made with timber both in form of horizontal beams under brick walls and as vertical piles for deeper foundations. The use of timber is widely spread: timber can be found in foundations of famous heritage buildings such as the Royal Palace in Amsterdam, the Netherlands and bridges in Venice [Siviero and Murat, 1993]. Timber foundations are in these cases true foundations of cultural heritage and therefore their economic and technical importance is large. A complication in the assessment is that pile foundations are difficult to inspect and maintain, and yet many thousands of buildings and structures depend on them. The historic centres of many Dutch cities were all built during the Middle Ages and the golden age from about 1400 until recently. Timber with age of up to 500 years can also be found in many floor and roof structures. The Palazzo Vecchio in Florence, Italy is a fine example. Irrespectively of the applications, the assessment of these structures for their safety and serviceability requires models that take into account the history of the structure. Timber species and quality, the loads on the structure over history and the expected future loads are important in the assessment procedure. It will be shown that damage accumulation models, which take into account age, load history and current state of the material properties including decay of biological or physical nature, can be used in such an assessment procedure of timber structures.

2 DEGRADATION MECHANISMS

2.1 Introduction

Timber degradation can be distinguished in four different forms: mechanical, physical, chemical and biological. Mechanical degradation occurs in the form of long term stresses that deform the structure and slowly reduce the strength. This is generally called a duration of load effect and is accounted for in design standards such as Eurocode 5. For long term strength, loads must be classified in a load duration class, which can be either instantaneous, short term, medium term, long term or permanent. It has been shown in Van de Kuilen [1999] that mechanical loads only cause damage when they are short term and very high. Permanent loads are too low to cause serious damage and do hardly influence the service life of the structure, except for pile foundations. Physical degradation occurs either in case of fire (temperature), wind, UV radiation or drying. Especially in older structures, drying cracks may be visible. Depending on the size of these cracks, the structural safety may be at risk. The depth of these cracks depends on factors such as initial moisture content, climate after installation, sawing pattern of the beam and whether the heart of the tree is present or not. Although the stiffness is decreased, the bending strength is hardly affected since the amount of wood material is not changed in the highly stressed zones. For shear however, these cracks are important and the residual cross section has to be taken into account. The by far most important parameter for service life modelling is biological degradation, in combination with mechanical loads. Due to biological attack, structures are affected and cross section may be changed as a result. Examples are piles and poles that are attacked by fungi at ground-air level or at groundwater level, beams with supports in stone walls that are degraded due to high moisture content levels and hydraulic structures in general. Infrared spectroscopy is used to determine different types of biological decay (brown rot, soft rot, white rot) and in conjunction with the decay, the expected amount strength loss.

2.2 Assessment Techniques

Traditional inspection methods combine visual assessment and (sharp) tools, but NDT techniques such as ultrasound and stress waves are becoming more used. Also, techniques with small penetrating elements(Pilodyn hammer , drills) may also be used. The latter are favoured for dry conditions in buildings and are less applicable for wet circumstances. Furthermore, these types of drills must be

operated with great care since they are not always optimised for the wood species under investigation and require an experienced user. Drilling and strength testing of bore cores is also possible or full cross sections from parts of structures also allows for worthwhile information, but is more costly and not always possible. Newer technologies such as (near)infrared spectroscopy allow for a relative fast insight in a possible decay of a structure. In figure 2.1 the molecular degradation is shown of two pieces of basralocus, a sound one and one with decay. The decay becomes clear around 1400 cm-1, indicating a decrease in the amount of lignin. This in itself could be in indication that the type of decay is 'softrot' known to attack lignin.

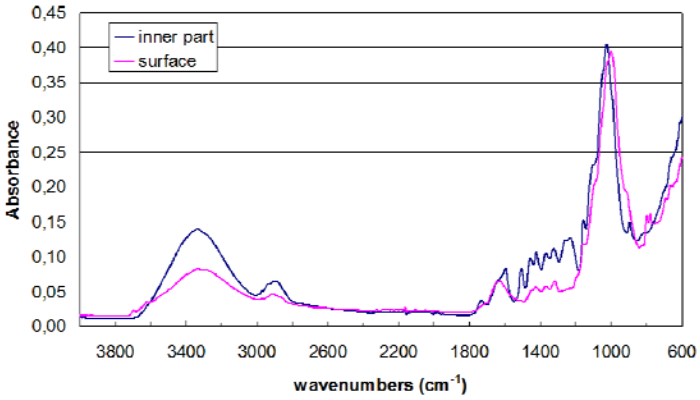

Figure 1. IR Spectrum of Basralocus pile used in hydraulic structure. Changes in molecular structure especially around 1400 cm^{-1}.

2.3 Fungi Growth and Fungi Recognition

Mid and Near Infrared Microscopy are relatively young techniques used to detect and analyse fungi decay in wood. They can give insight in how much decay is present and what is the extent of the decay in terms of molecular changes and consequently changes in mechanical resistance. In order to evaluate the service life of a structure affected by fungi decay, it is important to estimate, besides the strength loss, the rate of decay (or speed) of the process. Experimental data for the activity, expressed as weight loss in time, of different fungi species on different wood species are reported in studies focused on testing effectiveness of wood preservatives against wood decay according to standards such as EN 113. However, those methods have limitations when used for service life prediction of structures. The main limits are concerned with the restricted exposure time (generally up to 16 weeks) and the relatively small size respectively volume of the specimen (max 10x25x250 mm^3). The relation between volume of the wood specimen and the rate of degradation has not been reported in the literature so far. Previous research (Curling et al., 2002) showed that chemical alternations of the cell wall caused by fungi can be related with strength changes. Previous research (Curling et al., 2002) showed that chemical alternations of the cell wall caused by fungi can be related with strength changes. The present study deals with two aspects:
Develop a new protocol for laboratory decay test considering decay value by volume/time relations, together with CATAS Spa Testing Laboratory (Italy). The Attenuated Total Reflection (ATR) IR spectroscopy was used to characterize wood decay. NIR spectra of the samples were acquired after different exposure times and spectral differences were analysed by Multivariate analysis (MVA).

2.4 Materials and Methods

The timber species used was Norwegian Spruce (*Picea abies*) and Japanese Larch (*Larix kaempferi*) grown in The Netherlands. For each species two sets of 20 specimens differing in dimensions were prepared. The dimension of one set of sample was 10x10x100 mm^3 (ministakes) and for the other 44x44x200 mm^3 (stakes). The edges of each sample were sealed with a waterproof coating in order to prevent the fungi attack starting from the cross sections and proceeding along the longitudinal axis. The samples were oven-dried at 103±2˚C and weighed prior to inoculation.
The test fungi used was the brown rot Coniophora puteana (Schumacher ex Fries) Karsten. The inocula was obtained from cultures grown on a malt-agar culture medium.

As culture vessels (incubators) for the ministakes, five sterilized Petri dishes per wood species were used. Each dish was equipped with a basis of moist vermiculite, a plastic mesh and four wood samples, all previously autoclave sterilized. Per sample three inocula were introduced aseptically, so that the mycelium got in contact with the sample surface (Fig. 2.2). The incubators used for the stakes were autoclavable transparent bags. Sterilized moist vermiculite, plastic mesh and two wood samples were put into each bag. Each sample was inoculated with six inolcula (Fig. 2.3).

Figure 2. Inoculated ministakes
(10 x 10 x 100 mm)

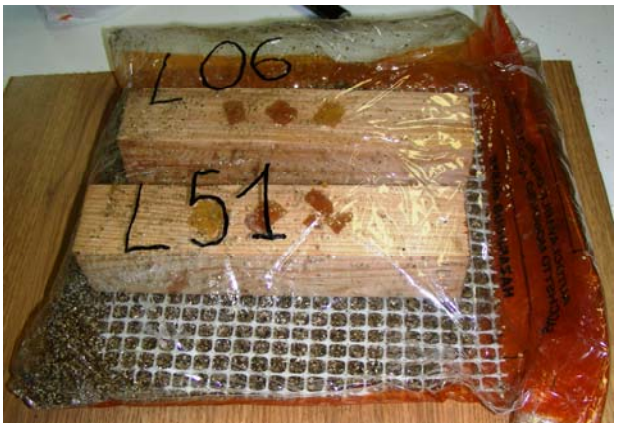

Figure 3. Inoculated stakes
(44 x 44 x 200 mm)

The samples preparation and the inoculation method used in this research aim to simulate fungi attack of timber in reality above ground. In fact, decay problems in buildings are often caused by moisture accumulation, water leakage and water condensation. These generally start from some spots on the surfaces of timber in the structure, and not as a uniform phenomenon of degradation of the whole member. The exposure time intervals for the ministakes were 2, 4, 8, 12, 16 weeks. The degradation of the stakes is still ongoing at CATAS Spa. The planned exposure times for them are longer than for the ministakes, up to 12 month. After each exposure time interval, four samples per species have been oven-dried in order to calculate the weight loss percentage relative to the initial oven-dried weight. For the stakes, compression tests will be performed at Delft University laboratory. For the ministakes, weight loss and NIR spectra were acquired after each exposure time.
Ten NIR spectra were collected from each ministake, so that more than 75% of the whole sample volume was scanned. The mean spectrum for each decayed sample was calculated and Principal Component Analysis (PCA) was performed on the resulting spectral matrix. PCA is a multivariate analysis method that projects the original variables onto a smaller set called Principal Components or PC (Martens et al, 1993). PC scores are the projected locations of each sample onto each PC. Scores can indicate latent structures and clusters of samples.

2.5 Preliminary Results

Weight loss
In the considered period of four months for the ministakes and six month for the stakes, the biodegradiation process by brown rot took place successfully. Figure 2.4 and 2.5 show the average of the weight loss percentage ($\Delta W\%$) for groups of four samples after each exposure time, for the ministakes and the stakes respectively. The weight loss is expressed as the ratio between the difference of the initial weight and the weight after decay over the initial weight, in oven-dry conditions. The data demonstrate that Norwegian spruce undertakes a stronger degradation than Japanese larch after the same exposure period, as the weight loss is more than 2 times higher for the spruce ministakes and almost 3 times higher for the stakes. According to the standard EN 350-2 that result was expected since the natural durability class for spruce is 4 (slightly durable) and for Japanese larch is 3-4 (moderately durable). A more interesting result comes from the comparison between decay process of small and big samples. As expected, the results show that the sample's volume strongly affects the rate of biodegradation. The speed of decay ($\Delta W\%$/days) decreases of a factor 2.3 for spruce and a factor 3 for larch, by increasing the volume of 40 times.

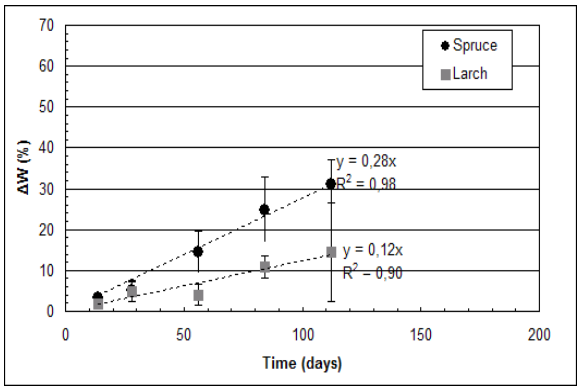

Figure 4. Weight loss in time for ministakes

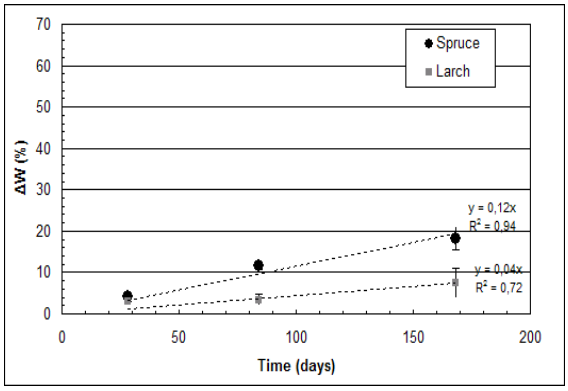

Figure 5. Weight loss in time for stakes

NIR analyses

After different exposure times decayed samples showed considerable differences in chemical composition observed by infrared spectroscopy. Figure 2.6 shows the NIR spectra of spruce ministakes decayed after different incubation time intervals, as well as the reference (sound) sample. Although it is hard to detect differences by visual inspection, it is possible to notice that the absorbance at 4780 cm^{-1} decreases as the incubation time increases. This peak is associated to the cellulose degradation (Kelley et al, 2002). Figure 2.7 shows the score plot for the two first principal components which describe the 96% of the total variance of the spectral data. Each score represents a sample, based on its chemical (spectral) constituents. The samples in the score plot are "labelled" with their measured weight losses. The graph shows clearly three clusters, representing sound samples (ΔW=0), low (ΔW<10%) and high (ΔW>10%) decayed samples (from the right to the left side of the PC1 axis). When the samples are labelled by their exposure time t, the three clusters in Figure 2.7 represent sound samples (t=0), low (t<1 month) and high (t >1 month) decayed samples. Some outliers are present in the score plot as well. These are situated in the upper left part of the plot. Although the outliers are characterized by high weight loss, their chemical changes are different from the other highly decayed samples. They will be further investigated. It seems to be possible that those samples will show a stronger link with clusters in terms of strength losses.

3 SERVICE LIFE AND DAMAGE MODELLING

3.1 Structural Assessment and Basis for Service Life Predictions

Flow charts for structural assesment have been developed by a number of researchers and institutes have been developed in order to be able to make a reliable assessment [Bonamini, 1995], [Görlacher, 1999]. Generally, these flow charts require analysis of the original structure, its uses, localization of defects/degradation and classification. On the basis of an analysis of the (historical) situation, the results of the inspection and the planned future use of the structure, an estimate is made on the residual lifetime and the necessity of repair or replacement. Since timber has a load and time dependent strength, the full short term resistance based on modern design principles may no longer be fully available, especially in the case of foundations, where the ratio between dead and live load is quite different from floors and roofs. In this respect, timber from floor and roof structures can be expected to have 100% strength capacity [Kuipers, 1986]. However, biological decay may affect the load carrying capacity. Decay may be both active or non-active, the effects on the resistance of the structure have to be examinated. The expected future loads can be determined from the new building plans or from current design codes. Depending on the situation and legal requirements, deviations from loads specified in design codes could be accepted in certain cases. The information obtained from the expected loads and the state of the structure allows for calculations of the residual strength of the structure and in conjunction with that the expected 'remaining' service life.
After an assessment of the structure, the final step is to predict the load carrying capacity and the residual lifetime. A new approach for this is the assessment of the strength using a modified damage accumulation model. Damage accumulated models have been used in timber research describing the strength development of timber under long term loads. Several models can be found in literature [Foschi et al. 1989],[Nielsen [1992], [Krausz & Eyring, 1975], Van der Put [1986] but the one from Gerhards [1987] will be used here as an example. Since these models only describe the strength development in time they have to be modified to include the influence of deterioration on the material properties, for instance biological degradation decay of the cross section and this may have considerable effect on the strength capacity of members. By combining durability models with strength models, it becomes possible to model the 'residual lifetime' of structures. Different approaches are possible using probabilistic calculations [Leicester et al., 2002], of kinetic based models [Winandy et al., 2002], but here the exponential damage accumulation model of Gerhards is modified. The limit state function is generally written as:

$$Z = R - S \qquad (1)$$

with Z = the limit state, R = the resistance and S = the solicitation or load. In reality, both the resistance and the solicitation are varying in time and the limit state function can be written as:

$$Z(t) = R(t) - S(t) \qquad (2)$$

A structure is assumed not to have failed while Z(t)>0. In figure 3.1 this is shown schematically. The probability of failure increases, since the resistance of members generally decreases with age. In case of timber, the resistance R(t) depends on the load and the load history. Mositure content and temperature also have an influence, but these are neglected here. Equation (2) can thus be written as:

$$Z(t) = R(s(\tau),t) - S(t) \qquad (3)$$

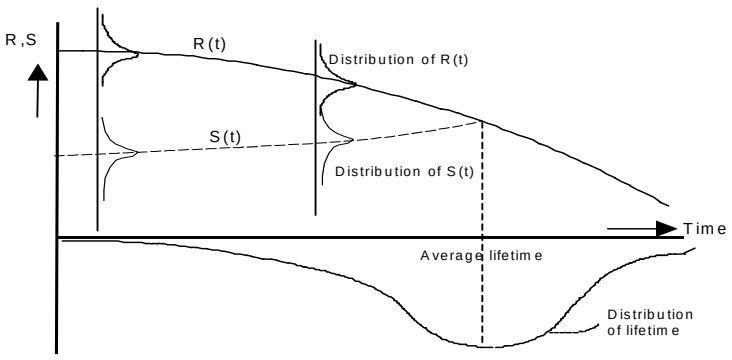

Figure 8. Schematic representation of the distribution of lifetimes of structures [Siemes, T, personal communication]

For the resistance function R(s(τ),t), the Gerhards damage function is used here, which is easy and straightforward to use [Gerhards and Link, 1987], but now the material strength is modified depending on the amount of

decay and residual strength of decayed timber. Thus, a time dependent resistance $f_s(t)$ is introduced in the model:

$$\frac{d\alpha}{dt} = \exp\left(-C_1 + C_2 \frac{\sigma(\tau)}{f_s(t)}\right) \tag{4}$$

The damage α takes a value: $0 \le \alpha \le 1$. By definition, failure occurs when $\alpha = 1$. This means that while $1- \alpha > 0$ the structure is still able to carry the load at that point in time and $Z(t) = 1 - \alpha$. The parameters C_1 and C_2 in the damage model are determined on the basis of time to failure tests on timber [Foschi and Yao, 1986], [Gerhards and Link, 1987] or joints [VandeKuilen, 1999]. The damage function can be used to estimate residual lifetimes of structures when the stress function $\sigma(\tau)$ representing the load path from the time of erection of the structure until the end of the time span under consideration is known as well the strength $f_s(t)$ representing the time dependent load carrying capacity of the material. For example in pile foundations the normal force has to be checked against the load carrying capacity [Van de Kuilen, 2006]. When the cross section is denoted A_{tot}, the value of the normal resistance F_u is determined $F_u = f_{c,0} A_{tot}$. When it is assumed that the pile is decaying, after a number of years the non-decayed cross section will be reduced to A_{rem} (remaining cross section). Denoting $f_{c,0,dec}$ the strength of the decayed timber and A_{dec} the cross section of the decayed area, the pile resistance can be written as:

$$F_u = f_{c,0} A_{rem} + f_{c,0,dec} A_{dec} \tag{5}$$

Equation 5 can be further modified into a more general form, using the rate of decay determined from the ministake and stake decay rates as a function of the volume. When the ratio between the remaining non-decayed cross section and the total cross section is defined as:

$$\delta = \frac{A_{rem}}{A_{tot}} \tag{6}$$

and when the strength ratio between the decayed timber and the non-decayed timber is defined as:

$$\beta = \frac{f_{c,0,dec}}{f_{c;0}} \tag{7}$$

equation 5 becomes:

$$F_u = f_{c,0} A_{tot} \left(\delta(1-\beta) + \beta\right) \tag{8}$$

The value of $f_s(t)$ in equation 4 can be replaced by F_u when the stress function $\sigma(\tau)$ is replaced by the load. Both β and δ are functions of time and wood volume as has been shown in paragraph 2, since the decay rate can be estimated.

3.2 Assessment of Drying Cracks

A similar derivation can be made for shear stresses in a governing cross section. Without drying cracks, the shear capacity can be written as:

$$F_{s,\max} = \frac{2}{3} f_{s,d} bh \tag{9}$$

Figure 9. Drying cracks in timber beam affecting shear capacity

However, when drying cracks occur at the neutral axis, the actual beam width becomes $b-2c_d$ with c_d the crack depth on one side of the beam. Especially in ancient structures, beams are large and generally cracked on both sides. An example is shown in figure 3.2. Vertical cracks in a cross section are not considered to have an influence on the remaining shear capacity. Consequently, the remaining load carrying capacity in shear is:

$$F_{s,\max} = \frac{2}{3} f_{s,d} (b - 2d_c) h \tag{10}$$

4 CONCLUSIONS

Timber structures service life can be estimated combining damage accumulation models with fungi growth models and drying crack growth models. Using such modified damage models, residual lifetimes can be predicted using different scenarios for rate of decay, the remaining strength of partly decayed timber or physical loads such as drying cracks. To adjust for fungi growth, a new test decay procedure has been developed in order to induce decay in two sets of samples differing in volume sizes. It was proven that the rate of degradation is strongly influenced by the volume of the samples: decreasing up to one third when increasing specimen's volume from 10^4 mm^3 to 40 times bigger for larch samples. FT-NIR technique and multivariate analysis were applied to characterize wood decay. The spectral analysis showed that it is possible to discriminate sound and decayed samples by infrared spectroscopy. Within the decayed samples, it was possible to discriminate between "low" and "high" decay.

Performance-based Design for Anticorrosion of Reinforced Concretes under Air-borne Salt Attack

Kai-Lin Hsu [1]

T 43

ABSTRACT

The performance-based design leads the trend recently in the modt of the developed countries, instead of the specification-based design. How to design the structure based on the required performance is dependent on the importance, service level and service life of the design structures. For different performance level, the design structure must be verified to satisfy all the required performance.

In this study, based on the understanding of the trend of performance-based design(abbr. as PBD), by applying the technique of Monte-Carlo Simulation (MCS) on Fick's second diffusion law with the consideration of stochastic behavior of cementitious material as well as the microclimate around the concrete structures like temperature, air-borne salt, etc., one proposal for developing the performance-based design of anticorrosion of RC structures under air-borne salt attack is considered. Through the examples illustrated in this paper, the availability of the proposed performance-based design method can be verified even with different mixing proportion and mixing material for the required service life under various air-borne salt attack environment.

1 INTRODUCTION

At present, RC structures are still the representative construction works at practice. Especially, for the marine RC structures with the threat of the all-year-round sea wind, the rebar corrosion due to salt attack is commonly observed within the sea-island countries, e.g. Taiwan,etc. Thus, how to prevent in the design stage or early stage of corrosion is the key to effectively solve the corrosion problem of RC structures.

As for the investigation of background meterological data related to RC corrosion, some developed countries, e.g. Japan ,etc. has launched some pioneer researches since decades ago. Besides, lots of research results related to how to measure the chloride diffusivity within concrete have been speculated, such as AASHTO T227, ASTM C1202, AASHTO T259, NT Build 449-94,etc[Patrick, F. et al. 1999]. However, even for the so-called known specifications, the uncertainties with the measured chloride diffusivity cannot be fully avoided due to the stochastic behavior of the cementitious material as well as the microclimate around the concrete structures like temperature, air-borne salt, etc [Japan Soc. Civ. Eng. 1997]. Although there already exist several indoor accelerated tests for measuring chloride diffusivities[Friedmann, H. et al. 2004, Wu, L. et al.2006, Yang, C. & Wang, L. 2004], it is still hard to say if the true value of the chloride diffusivities within concrete be measured. Generally speaking, only the rough distribution of the chloride ions can be estimated. With the understanding on this intrinsic problem, one PBD method was proposed on the basis of reliability for designing RC structures under air-borne salt attack. What attempted in this paper is to control the corrosion probability of the rebar in RC structures for the various requried service life.

2 DESCRIPTION FOR PROPOSED PBD METHOD

Based on the trend of PBD, it is indispensible to describe the limit state of the required performance at first, for either safety or serviceability. For simplifying the design issue of RC structures under marine environment, the limit state is preliminarily considered as the occurrence of rebar corrosion. In order to apply Fick's second diffusion law with the consideration of uncertain behavior of material and environmental parameters, the stochastic determination of chloride diffusion coefficient and the surface chloride content are essential [Akiyama,M. *et al.* 2005, Ferreira, R. & Jalali, S. 2004]. In this paper, the diffusion coefficient of chloride ions for the assigned cementitious material is decided by statistically analyzing the published data in the literature within 10 years [Aoyama, M. *et al.* 2003, Japan Soc. Civ. Eng. 2000, Maruya, T. *et al.*1998]. After statistical analysis on the literature data, the mean-value, standard deviation and test for the "goodness to fit" will be set for the designated cementitious material. In addition, as for the surface chloride content, it is obtained by referring to the exiting experimental relationship converted from the surrounding air-borne salt [Maeda, T. *et al.* 2002] while ,for air-borne salt, it is experimentally decided in accordance with the proposed air-borne salt collecting procedure [SBRG of PWRI 1993]. Followed by the development of hazard curve and vulnerability curve according to the assumed structural, material and microclimate details of being-designed RC structures as well as the recognized limit state for rebar, the reliability index of the being-designed RC structure can be calculated by adopting the technique of Monte-Carlo Simulation (MCS). The schematic flow of the proposed PBD method is illustrated in **Fig. 1**. As for the details of the proposed PBD method, it will be described in the following context.

In this paper, Fick's second diffusion law is adopted for describing the migration of chloride ions within concrete, which was formulated by Crank, J. [1980] as eq.(1).

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \tag{1}$$

Where D is the diffusion coefficient (cm^2/year); c is the concentration of transport mass at certain location; x is the depth of diffusion(cm); t is the duration of diffusion(year). With the assumption of

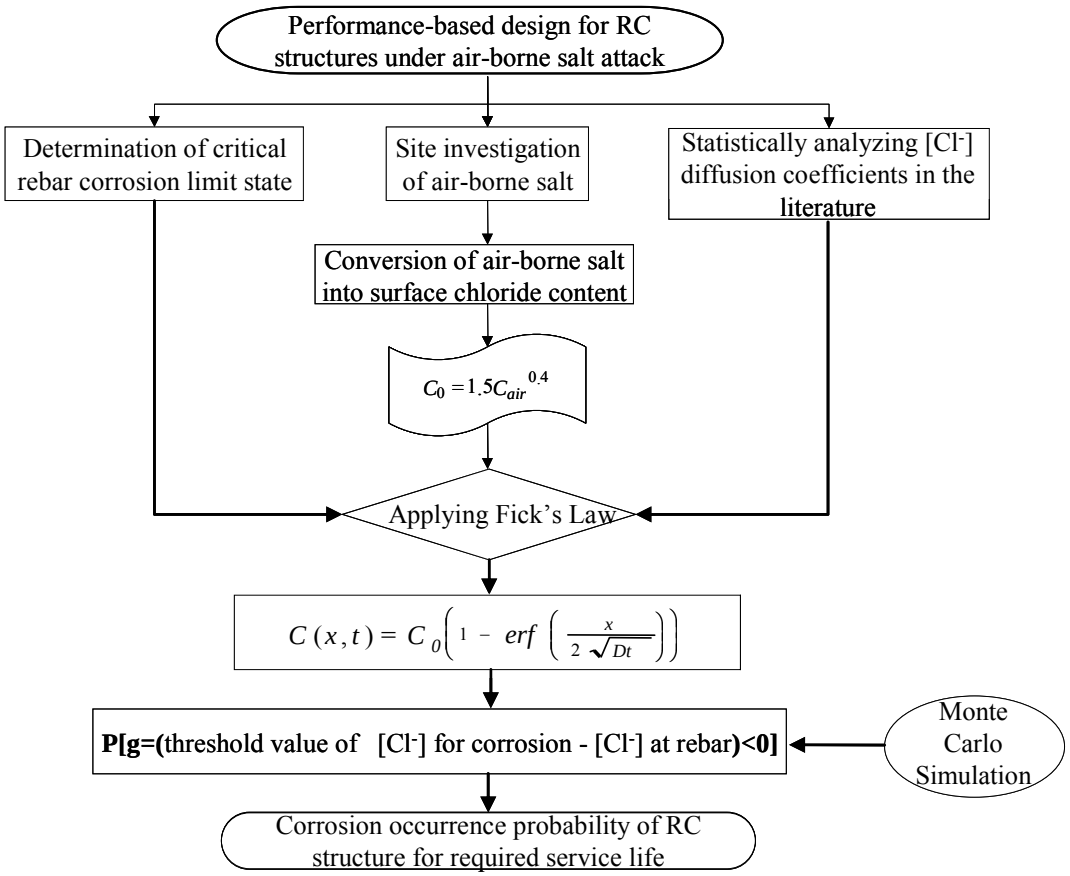

Figure 1. proposed PBD flow for RC structures under air-borne salt attack

initial and boundary conditions, i.e. c = 0 for x = ∞ and t ≥ 0 as well as c = 0 for x > 0 and t = 0, the solution of Eq.(1) can be given in the form of Eq.(2) as follows.

$$C(x,t) = C_0\left(1 - erf\left(\frac{x}{2\sqrt{Dt}}\right)\right) \quad (2)$$

Where C(x,t) is the concentration of chloride at depth x（㎝）and time t (year) (kg/m^3) ;Co is the surface chloride content（kg of Cl^-/m^3）; *erf* means error function. After statistical analysis on the literature data for chloride diffusion coefficients, the mean-value and standard deviation for the designated cementitious material can be used in Eq.(2) while the site-collected air-borne salt is regressed as the empirical function of the distance from seashore in Eq.(3a) and the surface chloride content is converted from the site-collected air-borne salt according to Eq.(3b). [Hsu, K. & Lin,Y. 2007]. Because **Fig.2** shows the uncertainty of the regression analysis for site-collected air-borne salt, one uncertainty factor U_r with lognormal distribution(1.029,1.22) is considered in Eq.(3c)

$$C_{air\ at\ location\ x} = 0.94 * e^{-0.9758d} \quad (\text{with } R^2{:}0.266) \quad (3a)$$

$$C_0 = 1.5C_{air}^{0.4} \quad (3b)$$

$$C_{air\ at\ location\ x} = U_r * e^{-0.9758d} \quad (3c)$$

Where $C_{air\ at\ location\ x}$: the site-collected air-borne salt(mdd of Cl^-);d:the distance from seashore (km). In order to obtain the hazard curve (i.e.exceeding probability for different airborne salt:$q_s(C_{air})$) , it is formulated in Eq. (4).

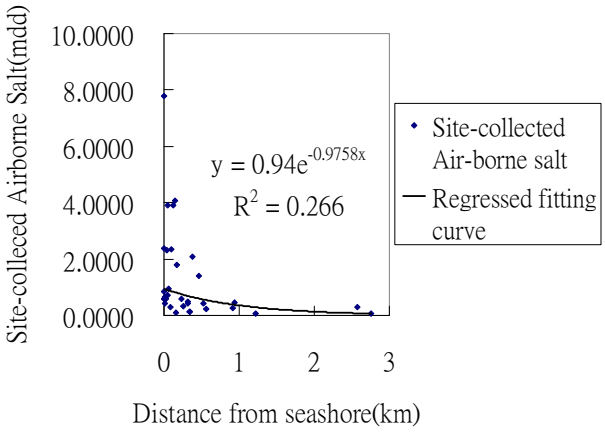

Figure 2. Regression Analysis on Site-collected Airborne Salt

$$q_s(C_{air}) = P(C_{air} > c_{air}) \quad (4)$$

Where c_{air} is the assumed air-borne salt (mdd of Cl^-).Once all the material and structural parameters for the being-designed RC structures can be decided as expressed in Eq.(2), the time-dependent chloride concentraion at rebar surface can be predicted. The fragility curve for assumed air-borne salt $F_r(c_{air})$ is calculated as follows:

$$F_r(c_{air}) = P(C(d_c,t_d) > c_{threshold}) \quad (5)$$

Where $C(d_c,t_d)$ is the chloride concentraion at rebar surface (kg/m^3 of Cl^-); d_c is the cover depth(cm); t_d is the design service life (years) ; $c_{threshold}$ is threshold value of chloride concentration for corrosion occurence (kg/m^3 of Cl^-). After the time-dependent chloride concentraion at rebar surface is available, the probability of Eq.(4) will be calculated by the utilization of MCS, which means the probability of threshold value of chloride concentration for corrosion occurence smaller than the chloride concentration at rebar surface.

***P*$_f$[g=[**threshold value of [Cl^-] for corrosion - [Cl^-] at rebar**) < 0]**

$$= \int_0^\infty \left(- \frac{\partial q_s(c_{air})}{\partial c_{air}} \right) \cdot F_r(c_{air}) \cdot \partial c_{air} \quad (6)$$

Where g means the equation of required limit state. As for the range of the threshold value of chloride concentraion, it differs nation by nations ,ranged from 0.4~1.2 kg/m3. For considering the locality of the proposed PBD method, it is considered as 0.3 kg/m3 due to the requirement in Chinese National Standards 12891 [1998]. After the failure probability is available, the reliability index (β) can be converted from P_f according to Eq.(7).

$$\text{Reliability Index } (\beta) = -\Phi^{-1}(P_f) \quad (7)$$

3 NUMERICAL VERIFICATION

In order to assure the availability of the proposed PBD method, some numerical tests were carried out by virtual design. This design problem under consideration is to build up one RC structure with required service life(50 years) for City A and City B, the air-borne salt at which was collected and

analyzed as shown in **Table 1** [Hsu, K. & Lin,Y. 2007]. The design issue for this problem is to find out the optimum of material type and structural layout.

Besides setting the threshold value of chloride concentration at corrosion occurrence as 0.3 kg/m^3, the surface chloride content was converted from the experimentally decided air-borne salt according to Eq.(3), which was calculated as 1.5kg/m^3,arround 5 times of threshold value of chloride concentration at corrosion occurrence. As for the chloride diffusion coefficients of the designated cementitious material, the mean-value, standard deviation and the distribution type of them are partially summarized in **Table 2** according to the literature review results. According to the settings in **Table** 1 and 2, the exceeding probabilities for City A and B are comparatively illustrated in **Fig. 3** while the fragility curve for different cover depth are calculated in **Fig.4**.

Table 1. Air-borne salt data at City A and B

City	Distribution type	Mean	Standard Deviation
A	Lognormal Distribution	3.1172（mdd）	0.355523
B	Lognormal Distribution	1.0053（mdd）	0.535587

Table 2. chloride diffusion coefficient for ordinary concrete

W/C / Value	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65
Mean	0.93683	1.14686	1.52877	1.85708	2.1781	2.4732	2.61722	3.24936
Standard Deviation	0.48083	0.50829	0.73725	0.72908	1.2730	1.0004	0.83826	0.99650
Distribution type	Lognormal Distribution（cm^2/year）							

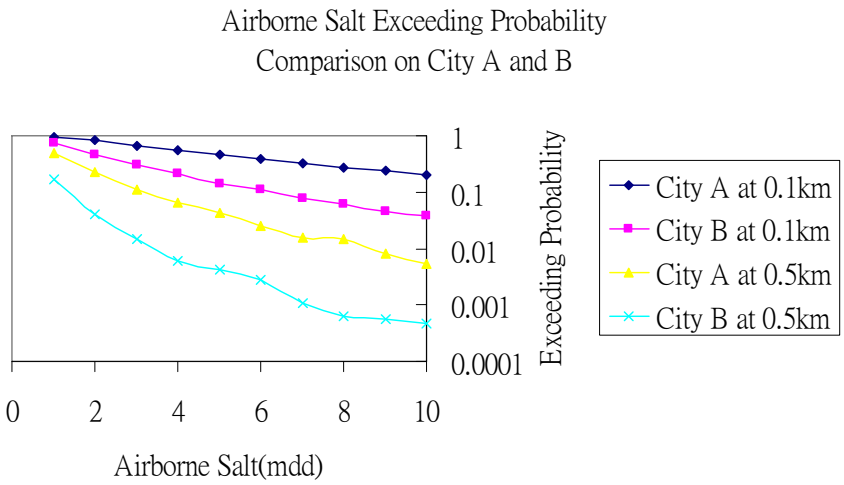

Figure 3. Compariosn of hazard curve on City A and B

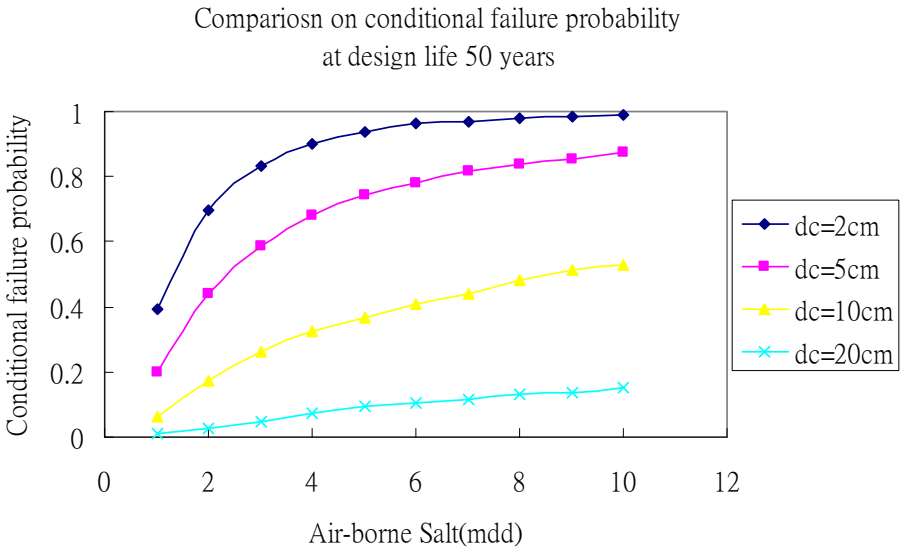

Figure 4. Compariosn on fragility curve for different cover depth at design life 50 years

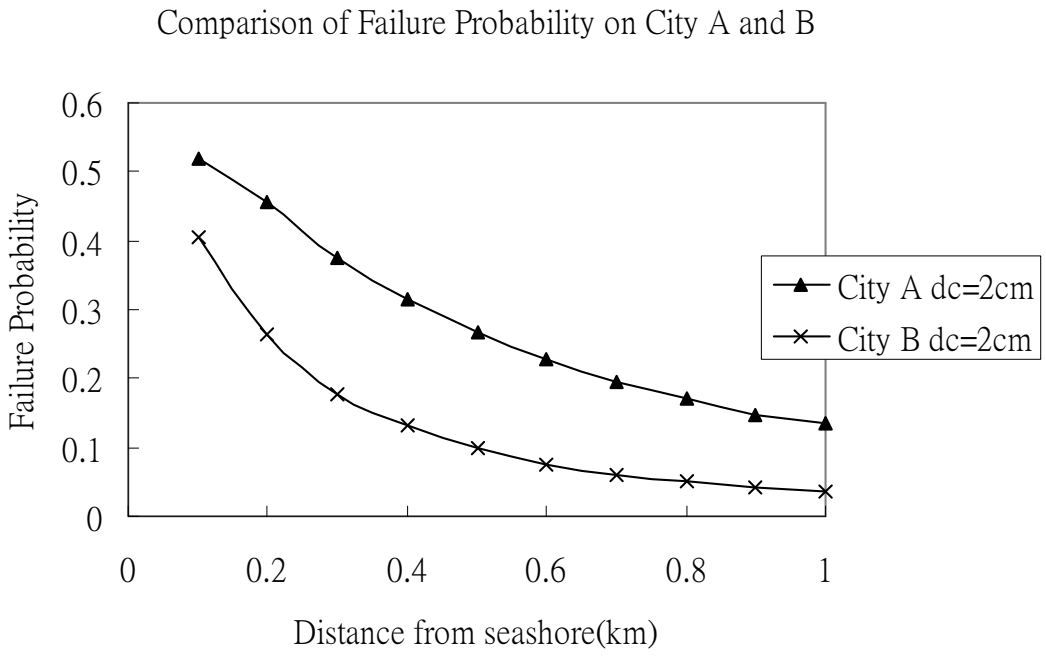

Figure 5. Compariosn of failure probability on City A and B at design life 50 years

Table 3. PBD settings for ordinary concrete on City B

Design Iter. No.	W/C	Cover Depth (cm)	Design Iter. No.	W/C	Cover Depth (cm)
1	0.45	2	4	0.35	2
2	0.45	5	5	0.35	8
3	0.45	10	SLS $\beta = 1.5$		

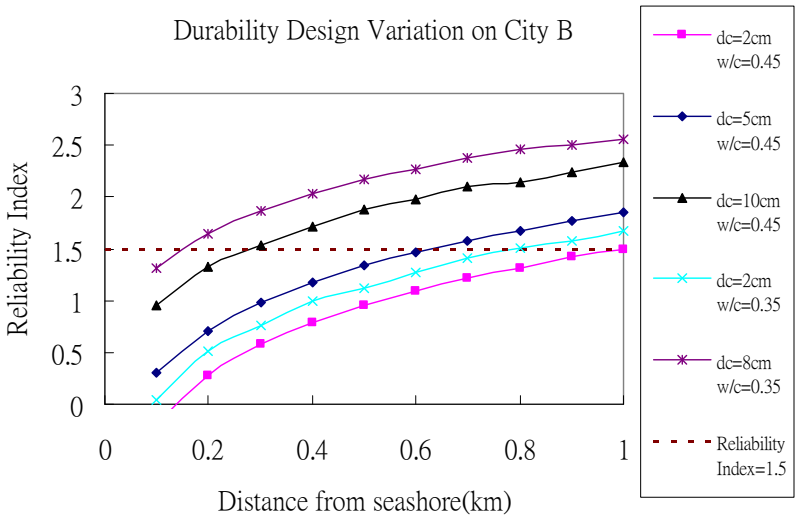

Figure 6. Iterative Process of PBD on City B at design life 50 years

Based on the calculated exceeding probability and fragility curve, the failure probability can be simulated in accordance with Eq.(6). As the threaten from air-borne salt on City A is more severe than that on City B from the site-collected airborne salt data in Table 1, it is expected that the failure probability on City A be larger than that on City B with the same material and structural parameters, as shown in **Fig.5**. Through **Fig.3-Fig.5**, the feasibility of the proposed PBD can be conceptually accepted. In order to illustrate the performance design process with the help of the proposed method, the PBD settings for ordinary concrete are illustrated in **Table 3,** which the acceptable service limit state index β is considered as 1.5 based on the work of Schiessl,P.[2005]. As it can be observed from Fig.6, the difference of location ,even with the same material and structural parameters, not all the design results can be accepted. For example, for the distance from the seashore as 0.1km, because the air-borne salt on City B is around 1 mdd (from **Table 1**), the results given in **Fig.6** indicate that almost all the design results based on the settings for ordinary concrete cannot reach the required service life (50 years) while ,for distance from the seashore as 1km , almost all the design results can reach the required serve life. This comparison re-emphasizes the importance of air-borne salt mapping for all the marine structures. On the other hand, it can also be found that the design result by changing the material and structural parameters simultaneously is the most effective improvement for this design case. How to find this best result without troublesome search process is the another issure for improving the prosposed PBD method.

4 CONCLUDING REMARKS

Through the above discussions, the concluding remarks of this paper can be summarized as follows:

1. the limit state for RC serviceability in this paper is set as the occurrence of rebar corrosion expressed in Eq(4). From the above results, not only the availability of the proposed PBD method was verified but also the extensibility of the proposed method on different definition of the limit state including the start of corrosion crack or loss of the loading capacity.

2. although the availability of the proposed PBD method is verified, it is still necessary to find out the stochastic behavior of the diffusion process for salt attack, for example, the temperature-dependence, time-dependence or material-dependence, etc. In addition, the site investigation at longer timescale for air-borne salt is also essential for the following researches. Based on the further clarified relationship

on these material parameters, the accuracy of the life-span simulation can be improved and the results of the design process can be accepted.

Application of the Reliability Theory to the Assessment of the Corrosion Risk due to Carbonation

Thiery Mickael [1]
Crémona Christian [2]

T 43

ABSTRACT

Atmospheric carbonation is one of the most significant degradation factors in the durability of reinforced concrete structures, since its consequences on the corrosion of steel rebars are disastrous. Due to the random nature of physically- and chemically-based properties of concrete (concerning the carbonation phenomenon) and given the uncertainties involved with the cover thickness and environmental factors, it is necessary to match deterministic carbonation models with probabilistic approaches in order to make a relevant prediction. The reliability theory provides interesting features as a decision-making framework for the optimization (serviceability limit state design) of concrete structures.

The Papadakis' and Bakker's carbonation models are studied in this paper through a reliability analysis. The first model predicts the formation of a sharp carbonation front which evolves as a square root of time law. The Bakker's model improves the Papadakis' approach by taking into account the influence of wetting and drying cycles. A performance function is introduced to express the margin between the carbonation depth and the concrete cover. The serviceability limit state is reached when this margin vanishes. The result of the durability assessment is a limit state-based failure probability which is assessed with the Hasofer-Lind reliability index determined using the Rackwitz-Fiessler algorithm.

In a first stage, a sensitivity analysis is performed in order to identify and quantify the most sensitive variables to be considered as probabilistic while some others can be treated as deterministic. In a second stage, a reliability analysis is carried out, as an illustration, to assess the residual service life of a 16-year old reinforced concrete structure. Finally, this study focuses on the use of field data (e.g. a depth of carbonation at a given time) for updating the reliability analysis according to a Bayesian approach.

1 INTRODUCTION

Long-term durability of reinforced concrete (RC) structures has become of major concern in view of the vast amounts of money required to maintain these infrastructures in a serviceable state. Regarding the steel RC-corrosion resulting from chloride ingress and/or atmospheric carbonation, the traditional approach has been to follow deem-to-satisfy rules which set requirements on mix-parameters, thickness of the cover concrete, crack width limitations, etc. However, these requirements are no longer appropriate and adequate, and even stifle the designer who has nowadays numerous possibilities in terms of material's mix-design parameters (use of admixtures like superplasticizers, air-entraining agents, etc., and use of cement blended with fly ashes, slag, etc.). That is why, a need is currently appearing for a performance-based approach [Baroghel-Bouny 2007], in which the rules basically concern the performance to be achieved in terms of concrete properties, the so-called durability indicators (porosity, water permeability, diffusion coefficients, etc.) and ambient exposure conditions (carbon dioxide concentration, external relative humidity, etc.).

Corrosion of the embedded reinforcement steel, resulting from atmospheric carbonation, is a matter of considerable concern which affects the serviceability of the RC-structures during their service life. Most concrete structures are actually exposed to the atmosphere, and thus to the action of carbon dioxide CO_2 which diffuses into the concrete cover, dissolves in the pore water, and reacts with the hydration products, causing a strong reduction of the pH-value from 12.5-13.5 to a level below 9 which makes the corrosion of the reinforcements possible. The simplest, and most effective way of enhancing the service life of RC-structures, is to increase the length of the induction period which is defined as the time required for the steels to be passivated [Tuuti 1982]. To make the prediction of this induction period possible, models are used, ranging from simple to very complex ones. Most of the time, a deterministic approach, where each parameter of the model is characterized by a mean value, is adopted. However, because of the random nature of the physical and chemical properties of the concrete cover, and owing to the uncertainties in the geometry of the structure and in the environmental conditions, it is necessary to resort to a probabilistic approach, in which each parameter is represented by a type of statistical distribution, a mean value, and a standard deviation. The outcome of such a probabilistic approach is a probability that a performance function, which corresponds to the margin between the carbonation depth and the concrete cover, vanishes. This probability value is related to a reliability index β_{HL}.

In this article two simple models of carbonation (the Papadakis and Bakker models) are studied in the framework of a time-dependent reliability approach. A sensitivity analysis is performed in order to identify and quantify the most sensitive variables. In a second stage, a reliability analysis is carried out to assess the service life of a concrete exposed to *in situ* conditions. Finally, this study focuses on the use of field data (e.g. a depth of carbonation at a given time) to update the reliability analysis.

2 CARBONATION MODELLING

2.1 The Papadakis Model

The Papadakis model [Papadakis *et al.* 1991] makes the assumption that carbonation is controlled by a steady-state regime of CO_2-diffusion, meaning that the chemical reactions involved are instantaneous. Under these conditions, it is possible to demonstrate that the carbonation front is sharp and separate a fully carbonated zone from an intact one. The carbonation depth X_C follows a square root of time law (see Eq. 1), involving the external CO_2-concentration C_0, the water liquid saturation S, the porosity ϕ, and the initial $Ca(OH)_2$ content of the material n_i.

$$X_C(t) = \sqrt{\frac{2C_0D}{n_i}}\sqrt{t} \qquad (1)$$

where D is the CO_2-diffusion coefficient which has been adjusted *vs.* ϕ and S [Thiery *et al.* 2007]: $D=D_0\phi^a(1-S)^b$ with a=2.74 and b=4.20.
The Papadakis model is based on two main assumptions:

a- An initially uniform medium: the model does not take into account the so-called skin-effects near the surface layer of the concrete, where wall-effects, sedimentation and segregation (as a result of gravity), permeation and evaporation of free water out of concrete lead to variations in cement-, aggregates- and water content, and so in porosity. Nevertheless, any microstructural changes due to carbonation, such as a decrease in porosity, are included in the model, since ϕ corresponds in Eq. (1) to the porosity of the completely carbonated area.
b- The liquid water saturation S is uniform and steady in time. S is at equilibrium with the external relative humidity RH, regardless the amount of H_2O which is produced by the chemical reactions. The link between S and RH is inferred from the desorption-adsorption isotherms which are experimentally determined by Baroghel-Bouny for a wide range of cement-based materials [Baroghel-Bouny 2007]. A good fit of the experimental desorption-adsorption curves S(HR) is obtained through the van Genuchten's functions (see Eq. 2) where α and β are two parameters which can be adjusted for the desorption and adsorption isotherms. Note that the capillary pressure p_C can also be written with respect to S (see Eq. 3) by taken the Kelvin equation into account (ρ_l is the water density, R is the gas constant, T is the absolute temperature, and M_v is the molar mass of water).

$$S = [1 + (-\alpha \ln HR)^{1/(1-\beta)}]^{-\beta} \quad (2)$$

$$p_C = \frac{\rho_l RT}{M_v}[S^{-1/\beta} - 1]^{1-\beta} \quad (3)$$

The second assumption (b) denotes that the Papadakis model is not able to take into account the variations of the external RH, and thus the wetting-drying cycles ocurring in the cover thickness of the concrete during rain period or dry intervals.

2.2 The Bakker's Model

Drying-wetting cycles have a dominating influence on the carbonation process of RC-structures, since the CO_2-diffusion coefficient in the concrete cover and the reaction rate of the CO_2-dissolution in the pores strongly depend on the moisture content. A minimum amount of water in which CO_2 has to be dissolved is needed for the reaction, while if the relative humidity is too high the liquid water inside the pores inhibits the CO_2-diffusion in the gaseous phase. Generally, it is considered that the carbonation ideally occurs for a relative humidity in the concrete pores between 50% and 70% [Wierig 1984].

At the present time, most of complex numerical models of carbonation are likely to take into account realistic drying-wetting cycles [Thiery *et al.* 2005]. However, there are currently very few simple engineering approaches existing which can tackle this problem. The physically- and chemically-based Bakker's model [Bakker 1993] was among the first ones. It is based on the assumption that the carbonation progress is negligible as long as the concrete is wet. To describe the carbonation progress, the Papadakis theory is used as a first approximation. Interactions between carbonation and drying-wetting cycles are taken into account by considering that the carbonation progress is stopped when the relative humidity in the pores is higher than a limit value HR_{lim}=80%.

During drying, the depth at which RH is equal to 80% follows a square root of time law ($X_d=d\sqrt{t}$). The coefficient d is assessed by a model of moisture transport [Thiery *et al.* 2007] where the porosity, the liquid water permeability (K_l), the capillary curve (desorption regime), and external and initial relative humidity intervene as input data. This model distinguishes the water vapor diffusion under gradients of partial vapor pressure from the liquid water permeation under gradients of capillary pressure. The following relationship illustrates the evolution of d according to small variations of the porosity ϕ, the

liquid water permeability K_l, the van Genuchten's coefficients α and β, and the external relative humidity around their mean value (symbolized by a 0 subscript or exponent):

$$d = d_0 \left(\frac{Kl}{K_l^0}\right)^{0.61} \left(\frac{\phi}{\phi_0}\right)^{-0.61} \left(\frac{\alpha}{\alpha_0}\right)^{-0.61} \left(\frac{\beta}{\beta_0}\right)^{0.95} \left(\frac{HR_{ext}}{HR_{ext}^0}\right)^{0.51} \quad (3)$$

During the drying step, the external RH_{ext} is lower than RH_{lim}, otherwise the carbonation cannot go ahead. Thus, the carbonation depth will in practice not proceed further than the maximum drying depth which can be reached. This drying depth depends not only on the concrete quality, but also on the environmental conditions. During wetting, the kinetic of water absorption (imbibition) is described in the same manner as the drying kinetic by a square root of time law ($X_w=w\sqrt{t}$), except that the capillary curve characterizes a phenomenon of water imbibition. t_w denotes the length of the wetting period and t_d the duration of the drying one. It is generally recognized that the wetting period is much shorter than the drying one. It is even possible to make the assumption that $t_w<<t_d$ (t_w tends towards zero).

The evolution of the carbonation front with time is given by a simple algorithm which depends on:

- The carbonation properties: an effective diffusion coefficient of CO_2 in the carbonated area (with respect to the liquid water saturation and the porosity of the material), the environmental CO_2 concentration C_0 and the initial content of $Ca(OH)_2$ n_i.
- The moisture properties: the kinetics coefficients (d and w), the drying t_d and wetting t_w periods determined by an environmental humidity monitoring, and the external RH_{ext}.

It appears that the carbonation depth predicted with this model deviates from an usual square root of time law (see Eq. 1) since the succession of wetting-drying cycles hinders the progress of carbonation.

2.3 Numrical Models

The Bakker's model is based on simplified approach concerning the modelling of carbonation, drying and wetting. Like the Papadakis model, the Bakker's one takes into account neither the build-up of water during carbonation (release of free water from the hydration products), nor the microstructure evolution caused by carbonation. Furthermore, these two models are based on an instantaneous mechanism of carbonation which is limited, given that it is usually recognized that the carbonation front is not sharp (Thiery *et al*, 2007). More accurate and comprehensive models have been recently elaborated. Most of them are based on numerical solving of the transport equations of CO_2 and moisture together with the chemical reactions of carbonation which are at stake. Saetta *et al.* (1993), Bary & Sellier (2004) and Thiery (2005) have proposed such sophisticated approaches. These models are suitable and efficient as long as the input data are available. Although possible in laboratory within the framework of accelerated carbonation tests, obtaining such properties for existing concrete structures is very difficult. In such conditions, the use of simplified models appears justified, provided that the input data are accompanied by statistical information (mean value, standard deviation, type of statistical distribution).

3 PROBABILISTIC APPROACH

3.1 The performance Function

The probability of corrosion being initiated by carbonation P_f is the propability of the carbonation front exceeding the concrete cover e. It can be expressed as:

$$P_f = \Pr ob(G(\mathbf{X}) < 0) = \int_{G(\mathbf{X})<0} f(\mathbf{X}) d\mathbf{X} \quad (4)$$

where $G(\mathbf{X})=e-X_C$ is the performance function and $f(\mathbf{X})$ is the joint probability function of the random vector $\mathbf{X}$ whose coordinates are the concrete parameters (ϕ, K_l, α, and β), the concrete cover (e), the environmental parameters (HR_{lim}, HR_{ext}, and C_0), and even some model's parameters like a and b (see the definition of the CO_2-diffusion coefficient). The probability of corrosion initiation may be assessed from the Hasofer-Lind reliability index β_{HL}. This is defined in the standard space as the minimum distance from the origin to the failure surface, which is the frontier between the safe set where $G(\mathbf{X})<0$ and the failure set where $G(\mathbf{X})>0$. Here, the Rackwitz-Fiessler is used to calculate β_{HL}.

3.2 A Practical Example: Concrete B25 Exposed to *in Situ* Carbonation Conditions

A low-grade concrete (B25, W/C=0.84, cement CEM I 52,5) has been studied under *in situ* conditions in Melun, an urban exposure site in France [Baroghel-Bouny *et al.* 2004]. Cores have been drilled out from RC structural elements exposed for 4 years to this natural urban environment. Note that RC-elements are not sheltered from rain.

Table 1. Statistical distribution of the input data of the model (concrete, envrionmental, and model properties).

Variable	Units	**Distribution**	**Mean**	**Standard deviation or**
W/C	(-)	-	0,84	-
C	($kg.m^{-3}$)	-	230	-

b (-)	(-)	Normal	4.20	*10 %*

3.3 Concrete Parameters

Table 1 shows the characteristic parameters relating to the concrete B25 adopted in the Papadakis and Bakker's models. Note that some parameters are specific to the Bakker's model. The concrete porosity ϕ has been measured by gammadensitometry on drilled cores extracted from the RC-elements after a 4-year exposure. An average porosity is calculated by integrating the entire profile of porosity over 3 cm depth from the exposed surface. The initial $Ca(OH)_2$ content n_i is assessed by a thermogravimetric analysis (associated with a chemical analysis) carried out on a sample extracted at core, in the intact zone of the drilled specimen. The liquid water permeability K_l (used to assess the drying coefficient d in the Bakker'model) is determined by the Katz-Thompson [Thompson & Katz 1987] theory which involves the pore size distribution measured by mercury-intrusion porosimetry.

The near-surface properties of the concrete are affected over the first 3 cm by wall-effects, cement sedimentation, aggregates segregation, and evaporation of liquid water which hinders the hydration reactions if the curing step is too short and/or not efficient enough. Furthermore, some mix-parameters, like the water-cement ratio, show a random behavior, mainly as a result of the batching variability. As well as measurement inaccuracies, all these uncertainties sources lead to strong variations of the concrete parameters which are used as input data in durability models of carbonation (ϕ, n_i, K_l, α, and β).

In the framework of the Bakker's model, the van Genuchten's parameters α and β are fitted for desorption or adsorption conditions (see Table 1). Due to a lack of information about the type of probability density which should be chosen for these random variables, a normal distribution (matched with a coefficient of variation equal to 10%) is retained. In the framework of the Papadakis model, the wetting-drying cycles are not taken into account. Therefore, the van Genuchten's parameters α and β are considered to follow a uniform distribution whose boundaries are the coefficients which are fitted for adsorption or desorption.

The concrete cover e is a key parameter of the carbonation models which is required to define the performance function G (see equation 4). Its value strongly depends on the batching variability. This geometrical variable is considered as a random lognormal parameter which can be defined from data available in the literature. The coefficient of variation is generally high and can reach 20%-30%.

3.4 Environmental Parameters

The CO_2-concentration is assumed to follow a normal distribution (see Table 1). The average relative humidity data (given by *in situ* measurements) can be approximated as a cosine function (see figure 1) involving maximum and minimum relative humidity values (HR_{min} and HR_{max}). Regarding the Papadakis model, an uniform distribution is chosen for the external relative humidity between the two boundaries values HR_{min} and HR_{max}. Concerning the Bakkers' model, the limit relative humidity HR_{lim}, above which carbonation is stopped, is assumed to follow a normal distribution with a standard deviation of 10%. The external relative humidity RH_{ext}, which is used as input data in the Bakker's model, is the average value over the days whose daily RH is below RH_{lim} (assessed around 65%, see figure 1). RH_{ext} is considered to follow a normal distribution of standard deviation equal to 10%. In the framework of the Bakker's model, the drying and wetting times, t_d and t_w, are assumed to be described by a normal distribution associated with a coefficient of variation around 10%.

3.5 Model Parameters

The CO_2-diffusion coefficient is calculated with two parameters a and b (see Eq. 1) which are considered to follow a normal distribution with a coefficient of variation equal to 10% (see Table 1).

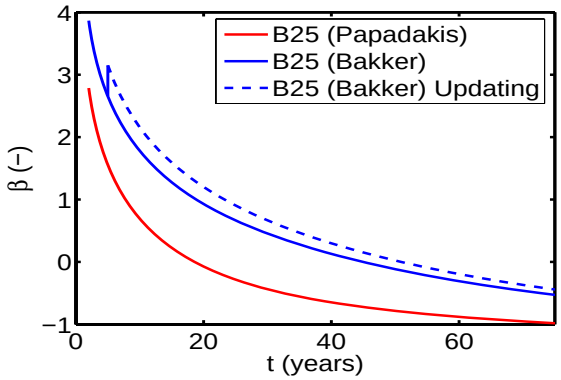

Figure 2. Reliability index *vs*. time for the two proposed models. For the Bakker's model: with and without updating.

4 RESULTS AND DISCUSSIONS

Fig. 2 illustrates the variation of the reliability index *vs.* the exposure time for the two models. Remember that this index is relevant to the occurrence of reinforcing depassivation due to carbonation and the subsequent risk of corrosion initiation. It can be seen that a significant decrease of the reliability arises with time: the starting value of the reliability index is close to 3 (in fact the first point is calculated for two years of exposure), but passes under the threshold value 1.5 recommended by the Eurocode for Serviceability Limit States after 6 years of exposure for the Papadakis model and 12 years for the Bakker's one. Note that the deterministic value is obtained for a reliability index which is 0 (after 18 years of exposure for the Papadakis model and 50 years for the Bakker's one).

The Papadakis model overestimates the carbonation depth (and so underestimates the reliability index) in opposition to the Bakker's model. Besides, the carbonation depth has been measured around 1 cm after a 5-year exposure, whereas the Papadakis model predicts a carbonation depth around 2 cm at the same date. Actually, the Papadakis approach is inappropriate if the external relative humidity varies with time. Concerning this last point, it is especially the case when the concrete is subject to drying-wetting cycles, since the effective diffusion coefficient of CO_2 is slower through the moisture-filled pores of the wetted concrete cover. Therefore, the use of the Papadakis model in the framework of a design strategy would offer a too high level of safety. The carbonation-depth measured after a 5-year exposure is used to revise the prediction given by the Bakkers's model. This updating is based on a Bayesian approach. The updated reliability index is shown in Fig. 2. The updating effect is modest pointing out that the Bakker's approach is rather efficient.

An useful measure for the importance of the uncertainty of the input variables is the normal unit vector $\boldsymbol{\alpha}$ to the limit-state surface at the design point (in the standardized space). When the α_i-coordinate is close to 0, the relative error on the reliability index is low. In practical situations, it is possible to identify if the random variable X_i may be replaced by a fixed value. Fig. 3 shows the α_i-coordinates *vs*. time if the Bakker's model is used. The less influential parameters are the initial $Ca(OH)_2$ content (n_i), the wetting time (t_w), the limit relative humidity (HR_{lim}), the external CO_2-concentration, and the model parameter b.

Fig. 4 illustrates the sensitivities with respect to the mean value for each random variable used in the Papadakis or Bakker's models. It appears that the influence of the concrete cover e, the porosity ϕ, the van Genuchten's parameter β is clear in every case of model. Among the variables which are specific to the Bakker's model, the most sensitive is the liquid water permeability K_l showing thus the importance of the drying-wetting cycles. Fig. 5 reports the sensitivities with respect to the standard deviations. This figure points out that standard deviations of the cover concrete e, the external relative

humidity HR_{ext}, the two van Genuchten's parameters, and the model parameter a need to be assessed with precision, so as to counteract the lack of reliability with respect to the serviceability limit states revealed for the present B25 concrete design.

Durability Limit States of Concrete Structures: Probabilistic Modeling

Dita Matesová [1]
Markéta Chromá [2]
Břetislav Teplý [3]

T 43

ABSTRACT

In the context of performance-based approaches, sustainability and whole life costing, the concrete structures durability issue has recently gained considerable attention. In the present paper a list and explanation of durability limit states (DLS) specialized for concrete structures and a combination of initiation and propagation durability states are introduced. The assessment of such limit states is based on degradation modeling and a probabilistic approach, enabling the assessment of service life and the relevant reliability level.

In this paper the durability limit states specialized for concrete structures are discussed and the review of some available analytical models for reinforced concrete degradation assessment, their randomization and the use of simulation techniques are provided. Some numerical examples using a special software tool are presented.

1 INTRODUCTION

During the last twenty years the concrete structures service life issue has been given considerable attention. This is clearly reflected also in standardization activities: the ISO/WD 13823 and fib-Model Code [2006] which are based on probabilistic approaches and will introduce the design of structures for durability – i.e. a time-dependent limit state approach with service life consideration.

2 DURABILITY LIMIT STATES FOR REINFORCED CONCRETE

When considering the degradation of reinforced concrete structures, the corrosion of reinforcement is the dominant effect. Usually the initiation and propagation periods are assessed. The former is the time from concrete casting to the moment when the reinforcement is no longer passivated. The latter includes the period since corrosion initiation. Generally, the limit state condition may be written as:

$$P_f(t_D) = P\left\{B(t_D) - A(t_D) \le 0\right\} \le P_d \qquad (1)$$

where $\boldsymbol{A}$ is the action effect, $\boldsymbol{B}$ is the barrier at time t_D = design service life and P_d is the design (acceptable, target) probability value. More about the limit states for durability (DLS) see e.g. in Teplý et al. [2008] or in fib-Model Code [2006]. Let us list possible actions and barriers usable for DLS:

Carbonation: $\boldsymbol{B} = a$ is a concrete cover and $\boldsymbol{A} = x_c$ is the depth of carbonation at time t_D.
